Acknowledgments

Firstly we must thank all the many leading scientists and technologists who have contributed so generously to the chapters of this book. It is no small task to produce a comprehensive and dispassionately accurate summary, even of your own research field, and we are most grateful to all of our authors.

John Dakin would like to acknowledge all his family, close friends and colleagues at Southampton University who have been most understanding during the production of this Handbook.

Robert Brown would like to acknowledge the constant support of his wife and close family throughout the preparation of this book.

We both wish to give special thanks to the (UK) Institute of Physics Publishing (IoPP) staff who did so much during the book's development and production period. Gillian Lindsay worked hard with the two of us at the outset some years ago, and Karen Donnison took over in the middle-period and patiently cajoled the editors and authors to deliver on their promises. Lastly we thank Dr. John Navas, who took over the reins in the final stages. He carried the book forward from IoPP to Taylor and Francis in the last few months and enabled the final product to be delivered.

Robert G W Brown
John P Dakin

Introduction

Optoelectronics is a remarkably broad scientific and technological field that supports a multi-billion US-dollar per annum global industry, employing tens of thousands of scientists and engineers. The optoelectronics industry is one of the great global businesses of our time.

In this Handbook, we have aimed to produce a book that is not just a text containing theoretically-sound physics & electronics coverage, nor just a practical engineering handbook, but a text designed to be strong in both these areas. We believe that, with the combined assistance of many world experts, we have succeeded in achieving this very difficult aim. The structure and contents of this Handbook have proved fascinating to assemble, using this input from so many leading practitioners of the science, technology and art of optoelectronics.

Today's optical telecommunications, display and illumination technologies rely heavily on optoelectronic components: laser diodes, light emitting diodes, liquid crystal and plasma screen displays etc. In today's world it is virtually impossible to find a piece of electrical equipment that does not employ optoelectronic devices as a basic necessity – from CD and DVD players to televisions, from automobiles and aircraft to medical diagnostic facilities in hospitals and telephones, from satellites and space-borne missions to underwater exploration systems – the list is almost endless. Optoelectronics is in virtually every home and business office in the developed modern world, in telephones, fax machines, photocopiers, computers and lighting.

'Optoelectronics' is not precisely defined in the literature. In this Handbook we have covered not only optoelectronics as a subject concerning devices and systems that are essentially electronic in nature, yet involve light (such as the laser diode), but we have also covered closely related areas of electro-optics, involving devices that are essentially optical in nature but involve electronics (such as crystal light-modulators).

To provide firm foundations, this Handbook opens with a section covering 'Basic Concepts'. The 'Introduction' is followed immediately by a chapter concerning 'Materials', for it is through the development and application of new materials and their special properties that the whole business of optoelectronic science and technology now advances. Many optoelectronic systems still rely on conventional light sources rather than semiconductor sources, so we cover these in the third chapter, leaving semiconductor matters to a later section. The detection of light is fundamental to many optoelectronic systems, as are optical waveguides, amplifiers and lasers, so we cover these in the remaining chapters of the Basic Concepts section.

The 'Advanced Concepts' section focuses on three areas that will be useful to some of our intended audience, both now, in advanced optics and photometry – and now and increasingly in the future concerning non-linear and short-pulse effects.

'Optoelectronics Devices and Techniques' is a core foundation section for this Handbook, as today's optoelectronics business relies heavily on such knowledge. We have attempted to cover all the main areas of semiconductor optoelectronics devices and materials in the eleven chapters in this section, from light emitting diodes and lasers of great variety to fibers, modulators and amplifiers. Ultra-fast and integrated devices are increasingly important, as are organic electroluminescent devices and photonic bandgap and crystal fibers. Artificially engineered materials provide a rich source of possibility for next generation optoelectronic devices.

At this point the Handbook ‘changes gear’ – and we move from the wealth of devices now available to us – to how they are used in some of the most important optoelectronic systems available today. We start with a section covering ‘Communication’, for this is how the developed world talks and communicates by internet and email today – we are all now heavily dependent on optoelectronics. Central to such optoelectronic systems are transmission, network architecture, switching and multiplex architectures – the focus of our chapters here. In Communication we already have a multi-tens-of-billions-of-dollars-per-annum industry today.

‘Imaging and displays’ is the other industry measured in the tens of billions of dollars per annum range at the present time. We deal here with most if not all of the range of optoelectronic techniques used today from cameras, vacuum and plasma displays to liquid crystal displays and light modulators, from electroluminescent displays and exciting new 3-dimensional display technologies just entering the market place in mobile telephone and laptop computer displays – to the very different application area of scanning and printing.

‘Sensing and Data Processing’ is a growing area of optoelectronics that is becoming increasingly important – from non-invasive patient measurements in hospitals to remote sensing in nuclear power stations and aircraft. At the heart of many of today’s sensing capabilities is the business of optical fiber sensing, so we begin this section of the Handbook there, before delving into remote optical sensing and military systems (at an un-classified level – for here-in lies a problem for this Handbook – that much of the current development and capability in military optoelectronics is classified and un-publishable because of it’s strategic and operational importance). Optical information storage and recovery is already a huge global industry supporting the computer and media industries in particular; optical information processing shows promise but has yet to break into major global utilization. We cover all of these aspects in our chapters here.

‘Industrial Medical and Commercial Applications’ of optoelectronics abound and we cannot possibly do justice to all the myriad inventive schemes and capabilities that have been developed to date. However, we have tried hard to give a broad overview within major classification areas, to give you a flavor of the sheer potential of optoelectronics for application to almost everything that can be measured. We start with the foundation areas of spectroscopy – and increasingly important surveillance, safety and security possibilities. Actuation and control – the link from optoelectronics to mechanical systems is now pervading nearly all modern machines: cars, aircraft, ships, industrial production etc – a very long list is possible here. Solar power is and will continue to be of increasing importance – with potential for urgently needed breakthroughs in photon to electron conversion efficiency. Medical applications of optoelectronics are increasing all the time, with new learned journals and magazines regularly being started in this field.

Finally we come to the art of practical optoelectronic systems – how do you put optoelectronic devices together into reliable and useful systems, and what are the ‘black art’ experiences learned through painful experience and failure? This is what other optoelectronic books never tell you – and we are fortunate to have a chapter that addresses many of the questions we should be thinking about as we design and build systems – but often forget or neglect at our peril.

In years to come, optoelectronics will develop in many new directions. Some of the more likely directions to emerge by 2010 will include optical packet switching, quantum cryptographic communications, three-dimensional and large-area thin-film displays, high-efficiency solar-power generation, widespread bio-medical and bio-photonic disease analyses and treatments and optoelectronic purification processes. Many new devices will be based on quantum dots, photonic crystals and nano-optoelectronic components. A future edition of this Handbook is likely to report on these rapidly changing fields currently pursued in basic research laboratories.

We are confident you will enjoy using this Handbook of Optoelectronics, derive fascination and pleasure in this richly rewarding scientific and technological field, and apply your knowledge in either your research or your business.

Table of Contents

BASIC CONCEPTS *Alan Rogers*

A1.1 An introduction to optoelectronics *Alan Rogers* 1
A1.2 Optical materials *Neil Ross* 21
A1.3 Incandescent, discharge and arc lamp sources *David O Wharmby* 45
A1.4 Detection of optical radiation *Antoni Rogalski and Zbigniew Bielecki* 73
A1.5 Propagation along optical fibres and waveguides *John Love* 119
A1.6 Introduction to lasers and optical amplifiers *William S Wong, Chien-Jen Chen and Yan Sun* 179

ADVANCED CONCEPTS *Alan Rogers and Galina Khitrova*

A2.1 Advanced optics *Alan Rogers* 205
A2.2 Basic concepts in photometry, radiometry and colorimetry *Yoshi Ohno* 287
A2.3 Nonlinear and short pulse effects *Günter Steinmeyer* 307

OPTOELECTRONIC DEVICES AND TECHNIQUES *John P Dakin, Roel Bates and Michel Digonnet*

B1.1 Visible light-emitting diodes *Klaus Streubel* 329
B1.2 Semiconductor lasers *Jens Buus* 385
B2 Optical detectors and receivers *Hidehiro Kume* 413
B3 Optical fibre devices *Suzanne Lacroix and Xavier Daxhelet* 457
B4 Optical modulators *Nadir Dagli* 489
B5 Optical amplifiers *Johan Nilsson, Jesper Lægsgaard and Anders Bjarklev* 533
B6 Ultrafast optoelectronics *Günter Steinmeyer* 565
B7 Integrated optics *Nikolaus Boos and Christian Lerminiaux* 587
B8 Infrared devices and techniques *Antoni Rogalski and Krzysztof Chrzanowski* 653
B9 Organic light emitting devices *Martin Grell* 693
B10 Microstructured optical fibres *Tanya M Monro, Anders Bjarklev and Jesper Lægsgaard* 719
B11 Engineered optical materials *Peter G R Smith* 745

A1.1
An introduction to optoelectronics

Alan Rogers

A1.1.1 Objective

In this chapter, we shall take a quite general look at the nature of photons and electrons (and of their interactions) in order to gain a familiarity with their overall properties, insofar as they bear upon our subject. Clearly it is useful to acquire this 'feel' in general terms before getting immersed in some of the finer detail which, whilst very necessary, does not allow the inter-relationships between the various aspects to remain sharply visible. The intention is that the familiarity acquired by reading this chapter will facilitate an understanding of the other chapters in the book.

Our privileged vantage point for the modern views of light has resulted from a laborious effort by many scientists over many centuries, and a valuable appreciation of some of the subtleties of the subject can be obtained from a study of that effort. A brief summary of the historical development is our starting point.

A1.1.2 Historical sketch

The ancient Greeks speculated on the nature of light from about 500 BC. The practical interest at that time centred, inevitably, on using the sun's light for military purposes; and the speculations, which were of an abstruse philosophical nature, were too far removed from the practicalities for either to have much effect on the other.

The modern scientific method effectively began with Galileo (1564–1642), who raised experimentation to a properly valued position. Prior to his time experimentation was regarded as a distinctly inferior, rather messy activity, definitely not for true gentlemen. (Some reverberations from this period persist, even today!) Newton was born in the year in which Galileo died, and these two men laid the basis for the scientific method which was to serve us well for the following three centuries.

Newton believed that light was corpuscular in nature. He reasoned that only a stream of projectiles, of some kind, could explain satisfactorily the fact that light appeared to travel in straight lines. However, Newton recognized the difficulties in reconciling some experimental data with this view, and attempted to resolve them by ascribing some rather unlikely properties to his corpuscles; he retained this basic corpuscular tenet, however.

Such was Newton's authority, resting as it did on an impressive range of discoveries in other branches of physics and mathematics, that it was not until his death (in 1727) that the views of other men such as Euler, Young and Fresnel began to gain their due prominence. These men believed that light was a wave motion in a 'luminiferous aether', and between them they developed an impressive theory which well explained all the known phenomena of optical interference and diffraction. The wave theory rapidly gained ground during the late 18th and early 19th centuries.

The final blow in favour of the wave theory is usually considered to have been struck by Foucault (1819–1868) who, in 1850, performed an experiment which proved that light travels more slowly in water than in air. This result agreed with the wave theory and contradicted the corpuscular theory.

For the next 50 years the wave theory held sway until, in 1900, Planck (1858–1947) found it mathematically convenient to invoke the idea that light was emitted from a radiating body in discrete packets, or 'quanta', rather than continuously as a wave. Although Planck was at first of the opinion that this was no more than a mathematical trick to explain the experimental relation between emitted intensity and wavelength, Einstein (1879–1955) immediately grasped the fundamental importance of the discovery and used it to explain the photoelectric effect, in which light acts to emit electrons from matter: the explanation was beautifully simple and convincing. It appeared, then, that light really did have some corpuscular properties.

In parallel with these developments, there were other worrying concerns for the wave theory. From early in the 19th century its protagonists had recognized that 'polarization' phenomena, such as those observed in crystals of Iceland spar, could be explained if the light vibrations were transverse to the direction of propagation. Maxwell (1831–1879) had demonstrated brilliantly (in 1864), by means of his famous field equations, that the oscillating quantities were electric and magnetic fields.

However, there arose persistently the problem of the nature of the 'aether' in which these oscillations occurred and, in particular, how astronomical bodies could move through it, apparently without resistance. A famous experiment in 1887, by Michelson and Morley, attempted to measure the velocity of the earth with respect to this aether, and consistently obtained the result that the velocity was zero. This was very puzzling in view of the earth's known revolution around the sun. It thus appeared that the medium in which light waves propagate did not actually exist!

The null result of the aether experiment was incorporated by Einstein into an entirely new view of space and time, in his two theories of relativity: the special theory (1905) and the general theory (1915). Light, which propagates in space and oscillates in time, plays a crucial role in these theories.

Thus physics arrived (ca. 1920) at the position where light appeared to exhibit both particle (quantum) and wave aspects, depending on the physical situation. To compound this duality, it was found (by Davisson and Germer in 1927, after a suggestion by de Broglie in 1924) that electrons, previously thought quite unambiguously to be particles, sometimes exhibited a wave character, producing interference and diffraction patterns in a wave-like way.

The apparent contradiction between the pervasive wave-particle dualities in nature is now recognized to be the result of trying to picture all physical phenomena as occurring within the context of the human scale of things. Photons and electrons appear to behave either as particles or as waves to us only because of the limitations of our modes of thought. We have been conditioned to think in terms of the behaviour of objects such as sticks, stones and waves on water, the understanding of which has been necessary for us to survive, as a species, at our particular level of things.

In fact, the fundamental atomic processes of nature are not describable in these same terms and it is only when we try to force them into our more familiar framework that apparent contradictions such as the wave–particle duality of electrons and photons arise. Electrons and photons are neither waves nor particles but are entities whose true nature is somewhat beyond our conceptual powers. We are very limited by our preference (necessity, almost) for having a mental picture of what is going on.

Present-day physics with its gauge symmetries and field quantizations rarely draws any pictures at all, but that is another story…

A1.1.3 The wave nature of light

In 1864, Clerk Maxwell was able to express the laws of electromagnetism known at that time in a way which demonstrated the symmetrical interdependence of electric and magnetic fields. In order to complete the symmetry he had to add a new idea: that a changing electric field (even in free space) gives rise to a magnetic field. The fact that a changing magnetic field gives rise to an electric field was already well known, as Faraday's law of induction.

Since each of the fields could now give rise to the other, it was clearly conceptually possible for the two fields mutually to sustain each other, and thus to propagate as a wave. Maxwell's equations formalized these ideas and allowed the derivation of a wave equation.

This wave equation permitted free-space solutions which corresponded to electromagnetic waves with a defined velocity; the velocity depended on the known electric and magnetic properties of free space, and thus could be calculated. The result of the calculation was a value so close to the known velocity of light as to make it clear that light could be identified with these waves, and was thus established as an electromagnetic phenomenon.

All the important features of light's behaviour as a wave motion can be deduced from a detailed study of Maxwell's equations. We shall limit ourselves here to a few of the basic properties.

If we take Cartesian axes Ox, Oy, Oz (figure A1.1.1) we can write a simple sinusoidal solution of the free-space equations in the form:

$$\begin{aligned} E_x &= E_0 \ \exp[\mathrm{i}(\omega t - kz)] \\ H_y &= H_0 \ \exp[\mathrm{i}(\omega t - kz)]. \end{aligned} \tag{A1.1.1}$$

These two equations describe a wave propagating in the Oz direction with electric field (E_x) oscillating sinusoidally (with time t and distance z) in the xz plane and the magnetic field (H_y) oscillating in the yz plane. The two fields are orthogonal in direction and have the same phase, as required by the form of Maxwell's equations: only if these conditions obtain can the two fields mutually sustain each other. Note also that the two fields must oscillate at right angles to the direction of propagation, Oz. Electromagnetic waves are transverse waves.

The frequency of the wave described by equation (A1.1.1) is given by:

$$f = \frac{\omega}{2\pi}$$

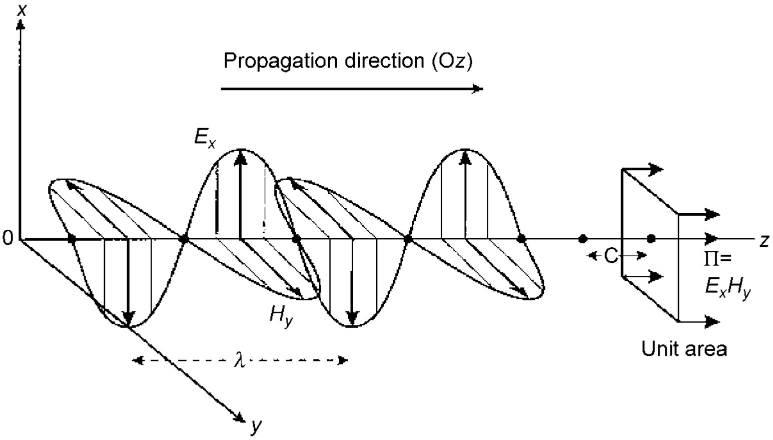

Figure A1.1.1. Sinusoidal electromagnetic wave.

and its wavelength by:

$$\lambda = \frac{2\pi}{k}$$

where ω and k are known as the angular frequency and propagation constant, respectively. Since f intervals of the wave distance λ pass each point on the Oz axis per second, it is clear that the velocity of the wave is given by:

$$c = f\lambda = \frac{\omega}{k}.$$

The free-space wave equation shows that this velocity should be identified as follows:

$$c_0 = \frac{1}{(\varepsilon_0\mu_0)^{1/2}} \tag{A1.1.2}$$

where ε_0 is a parameter known as the electric permittivity, and μ_0 the magnetic permeability, of free space. These two quantities are coupled, independently of equation (A1.1.2), by the fact that both electric and magnetic fields exert mechanical forces, a fact which allows them to be related to a common force parameter, and thus to each other. This 'force-coupling' permits a calculation of the product $\varepsilon_0\mu_0$ which, in turn, provides a value for c_0, using equation (A1.1.2). (Thus Maxwell was able to establish that light in free space consisted of electromagnetic waves.)

We can go further, however. The free-space symmetry of Maxwell's equations is retained for media which are electrically neutral and which do not conduct electric current. These conditions obtain for a general class of materials known as dielectrics; this class contains the vast majority of optical media. In these media the velocity of the waves is given by:

$$c = (\varepsilon\varepsilon_0\mu\mu_0)^{-1/2} \tag{A1.1.3}$$

where ε is known as the relative permittivity (or dielectric constant) and μ the relative permeability of the medium. ε and μ are measures of the enhancement of electric and magnetic effects, respectively, which are generated by the presence of the medium. It is, indeed, convenient to deal with new parameters for the force fields, defined by:

$$\boldsymbol{D} = \varepsilon\varepsilon_0\boldsymbol{E}$$

$$\boldsymbol{B} = \mu\mu_0\boldsymbol{H}$$

where $\boldsymbol{D}$ is known as the electric displacement and $\boldsymbol{B}$ the magnetic induction of the medium. More recently they have come to be called the electric and magnetic flux densities, respectively.

The velocity of light in the medium can (from equation (A1.1.3)) also be written as

$$c = \frac{c_0}{(\varepsilon\mu)^{1/2}} \tag{A1.1.4}$$

where c_0 is the velocity of light in free space, with an experimentally determined value of $2.997925 \times 10^8\,\mathrm{m\,s^{-1}}$. For most optical media of any importance we find that $\mu \approx 1$, $\varepsilon > 1$ (hence the name 'dielectrics'). We have already noted that they are also electrical insulators. For these, then, we may write equation (A1.1.4) in the form:

$$c \approx \frac{c_0}{\varepsilon^{1/2}} \tag{A1.1.5}$$

and note that, with $\varepsilon > 1$, c is smaller than c_0. Now the refractive index, n, of an optical medium is a measure of how much more slowly light travels in the medium compared with free space, and is defined by:

$$n = \frac{c_0}{c}$$

and thus

$$n \approx \varepsilon^{1/2}$$

from equation (A1.1.5).

This is an important relationship because it connects the optical behaviour of the optical medium with its atomic structure. The medium provides an enhancement of the effect of an electric field because that field displaces the atomic electrons from their equilibrium position with respect to the nuclei; this produces an additional field and thus an effective magnification of the original field. The detailed effect on the propagation of the optical wave (which, of course, possesses an electric component) will be considered in chapter A1.2 but we can draw two important conclusions immediately. First, the value of the refractive index possessed by the material is clearly dependent upon the way in which the electromagnetic field of the propagating wave interacts with the atoms and molecules of the medium. Second, since there are known to be resonant frequencies associated with the binding of electrons in atoms, it follows that we expect ε to be frequency dependent. Hence, via equation (A1.1.5), we expect n also to be frequency dependent. The variation of n (and thus of optical wave velocity) with frequency is a phenomenon known as optical dispersion and is very important in optoelectronic systems, not least because all practical optical sources emit a range of different optical frequencies, each with its own value of refractive index.

We turn now to the matters of momentum, energy and power in the light wave. The fact that a light wave carries momentum and energy is evident from a number of its mechanical effects, such as the forced rotation of a conducting vane in a vacuum when one side is exposed to light (figure A1.1.2). A simple wave picture of this effect can be obtained from a consideration of the actions of the electric and magnetic fields of the wave when it strikes a conductor. The electric field will cause a real current to flow

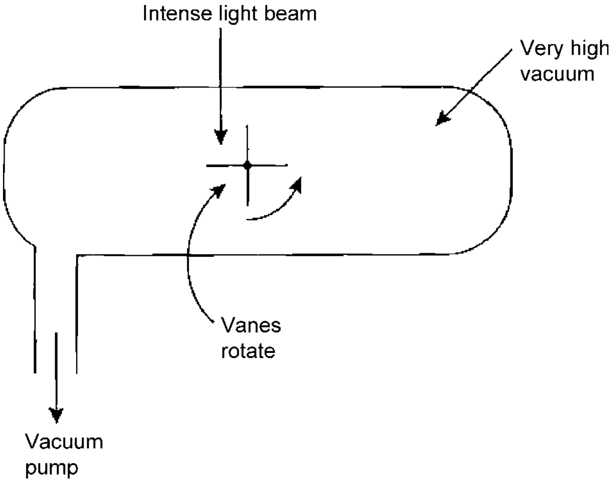

Figure A1.1.2. Force exerted by light falling on a conducting vane.

in the conductor (it acts on the 'free' electric charges in the conductor) in the direction of the field. This current then comes under the influence of the orthogonal magnetic field of the wave. A current-carrying conductor in a magnetic field which lies at right angles to the current flow experiences a force at right angles to both the field and the current (motor principle) in a direction which is given by Fleming's left-hand rule (this direction turns out to be, fortunately, the direction in which the light is travelling!). Hence the effect on the conductor is equivalent to that of energetic particles striking it in the direction of travel of the wave; in other words, it is equivalent to the transport of momentum and energy in that direction.

We can take this description one stage further. The current is proportional to the electric field and the force is proportional to the product of the current and the magnetic field, hence the force is proportional to the product of electric and magnetic field strengths. The flow of energy, that is the rate at which energy is transported across unit area normal to the direction of propagation, is just equal to the vector product of the two quantities;

$$\boldsymbol{\Pi} = \boldsymbol{E} \times \boldsymbol{H}$$

(the vector product of two vectors gives another vector whose amplitude is the product of the amplitudes of the two vectors multiplied by the sine of the angle between their directions (in this case $\sin 90° = 1$) and is in a direction orthogonal to both vectors, and along a line followed by a right-handed screw rotating from the first to the second vector. Vectors often combine in this way so it is convenient to define such a product).

Clearly, if $\boldsymbol{E}$ and $\boldsymbol{H}$ are in phase, as for an electromagnetic wave travelling in free space, then the vector product will always be positive. $\boldsymbol{\Pi}$ is known as the Poynting vector. We also find that, in the case of a propagating wave, $\boldsymbol{E}$ is proportional to $\boldsymbol{H}$, so that the power across unit area normal to the direction of propagation is proportional to the square of the magnitude of either $\boldsymbol{E}$ or $\boldsymbol{H}$. The full quantitative relationships will be developed in later chapters, but we may note here that this means that a measurement of the power across unit area, a quantity known as the intensity of the wave (sometimes the 'irradiance') provides a direct measure of either $\boldsymbol{E}$ or $\boldsymbol{H}$ (figure A1.1.1). This is a valuable inferential exercise since it enables us, via a simple piece of experimentation (i.e. measurement of optical power) to get a handle on the way in which the light will interact with atomic electrons, for example. This is because, within the atom, we are dealing with electric and magnetic fields acting on moving electric charges.

The units of optical intensity, clearly, will be watts metre^{-2}.

A1.1.4 Polarization

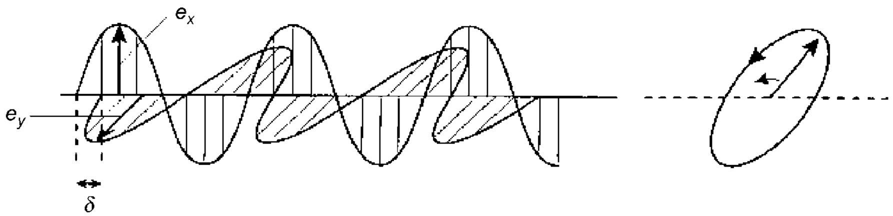
The simple sinusoidal solution of Maxwell's wave equation for $\boldsymbol{E}$ and $\boldsymbol{H}$ given by equation (A1.1.1) is only one of an infinite number of such solutions, with $\boldsymbol{E}$ and $\boldsymbol{H}$ lying in any direction in the xy plane, and with ω taking any value greater than zero.

It is customary to fix attention on the electric field for purposes of general electromagnetic wave behaviour, primarily because the effect of the electric field on the electrical charges within atoms tends to be more direct than that of the magnetic field. But the symmetry which exists between the $\boldsymbol{E}$ and $\boldsymbol{H}$ fields of the electromagnetic wave means that conclusions arrived at for the electric field have close equivalence for the magnetic field. It is simply convenient only to deal with one of them rather than two.

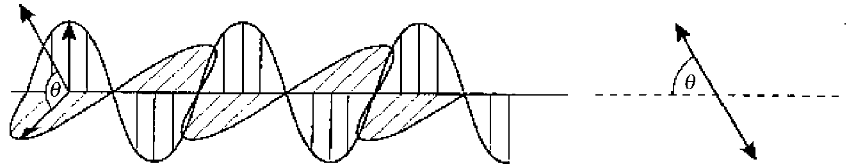
Suppose that we consider two orthogonal electric field components of a propagating wave, with the same frequency but differing phases (figure A1.1.3(*a*)):

$$E_x = e_x \cos(\omega t - kz + \delta_x)$$

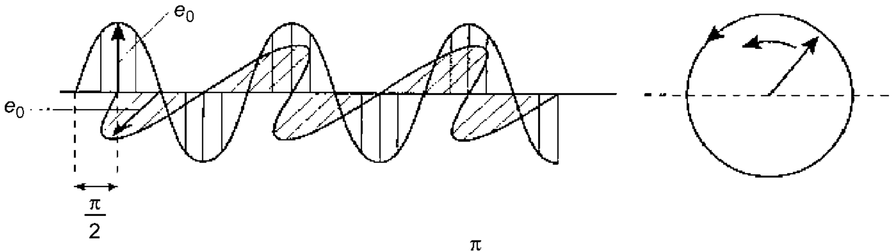
$$E_y = e_y \cos(\omega t - kz + \delta_y).$$



(a) Elliptical polarization: e_x, e_y, $\delta(=\delta_y-\delta_x)$



(b) Linear polarization: e_x, e_y, $\delta=m\pi$



(c) Circular polarization: $e_x=e_y=e_0$, $\delta=(2m+1)\,\frac{\pi}{2}$

Figure A1.1.3. Linear and circular polarization as special cases of elliptical polarization.

From figure A1.1.3 we can see that the resulting electric field will rotate as the wave progresses, with the tip of the resulting vector circumscribing (in general) an ellipse. The same behaviour will be apparent if attention is fixed on one particular value of z and the tip of the vector is now observed as it progresses in time. Such a wave is said to be elliptically polarized. (The word ‘polarized’, being associated, as it is, with the separation of two dissimilar poles, is not especially appropriate. It derives from the attempt to explain crystal-optical effects within the early corpuscular theory by regarding the light corpuscles as rods with dissimilar ends, and it has persisted.) Of notable interest are the special cases where the ellipse degenerates into a straight line or a circle (figure A1.1.3(b) and (c)). These are known as linear and circular polarization states, respectively, and their importance lies not least in the fact that any given elliptical state can be resolved into circular and linear components, which can then be dealt with separately. The light will be linearly polarized, for example, when either e_x or $e_y=0$, or when $\delta_y-\delta_x=m\pi$. It will be circularly polarized only when $e_x=e_y$ and $\delta_y-\delta_x=(2m+1)\pi/2$, where m is a positive or negative integer: circular polarization requires the component waves to have equal amplitude and to be in phase quadrature. A sensible, identifiable polarization state depends crucially on the two components maintaining a constant phase and amplitude relationship. All of these ideas are further developed in chapter A2.1.

The polarization properties of light waves are important for a number of reasons. For example, in crystalline media, which possess directional properties, the propagation of the light will depend upon its polarization state in relation to the crystal axes. This fact can be used either to probe crystal structure or to control the state of the light via the crystal. Furthermore, the polarization state of the light can provide valuable insights into the restrictions imposed on the electrons which gave rise to it.

Wherever there is directionality (i.e. the properties of the medium vary with spatial direction) in the medium in which the light is travelling, the polarization state of the light will interact with it and this is an extremely useful attribute with a number of important applications.

A1.1.5 The electromagnetic spectrum

Hitherto in this chapter we have dealt with optical phenomena in fairly general terms and with symbols rather than numbers. It may help to fix ideas somewhat if some numbers are quoted.

The wave equation allows single-frequency sinusoidal solutions and imposes no limit on the frequency. Furthermore, the equation is still satisfied when many frequency components are present simultaneously. If they are phase-related then the superposition of the many waveforms provides a determinable time function via the well known process of Fourier synthesis. If the relative phases of the components are varying with time, then we have 'incoherent' light; if the spread of frequencies in this latter case exceeds the bandwidth of the optical detector (e.g. the human eye) we sometimes call it 'white' light.

The electromagnetic spectrum is shown in figure A1.1.4. In principle, it ranges from (almost) zero frequency to infinite frequency. In practice, since electro-magnetic wave sources cannot be markedly smaller than the wave-length of the radiation which they emit, the range is from the very low frequency ($\sim 10^3$ Hz) radio waves ($\lambda \sim 300$ km) to the very high frequency ($\sim 10^{20}$ Hz) gamma radiation, where the limit is that of the very high energy needed for their production.

The most energetic processes in the universe are those associated with the collapse of stars and galaxies (supernovae, black holes), and it is these which provide the radiation of the highest observable frequencies.

Visible radiation lies in the range 400–700 nm (1 nm $= 10^{-9}$ m), corresponding to a frequency range of 7.5×10^{14}–4.3×10^{14} Hz. The eye has evolved a sensitivity to this region as a result of the fact that it corresponds to a broad maximum in the spectral intensity distribution of sunlight at the earth's surface: survival of the species is more likely if the sensitivity of the eye lies where there is most light!

The infrared region of the spectrum lies just beyond 700 nm and is usually taken to extend to about 300 000 nm ($\equiv$ 300 μm; we usually switch to micrometres for the infrared wavelengths, in order to keep the number of noughts down).

The ultraviolet region lies below 400 nm and begins at about 3 nm. Clearly, all of these divisions are arbitrary, since the spectrum is continuous.

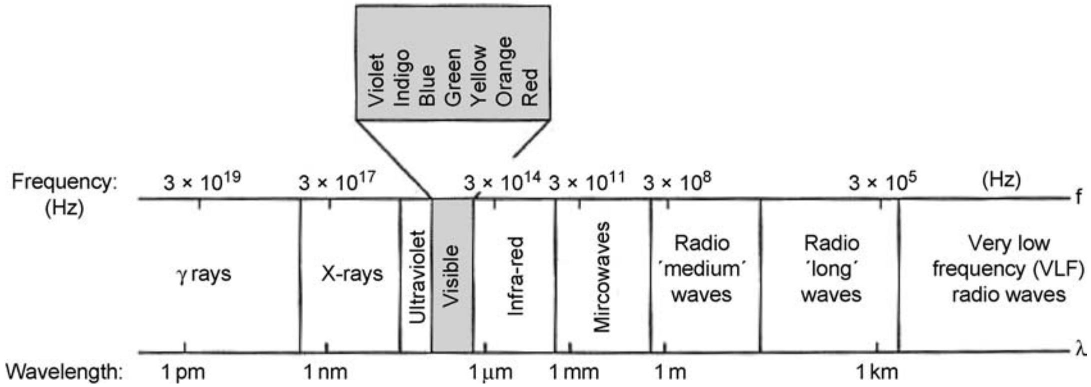


Figure A1.1.4. The electromagnetic spectrum.

It is worth noting that the refractive index of silica (an important optical material) in the visible range is ~ 1.47, so the velocity of light at these wavelengths in this medium is close to $2 \times 10^8\,\mathrm{m\,s^{-1}}$. Correspondingly, at the given optical frequencies, the wavelengths in the medium will be $\sim 30\%$ less than those in air, in accordance with the relation: $\lambda = c/f$. (The frequency will remain constant.)

It is important to be aware of this wavelength change in a material medium, since it has a number of noteworthy consequences which will be explored in chapter A1.2.

A1.1.6 Emission and absorption processes

So far, in our discussions, the wave nature of light has dominated. However, when we come to consider the relationships between light and matter, the corpuscular, or (to use the modern word 'particulate'), nature of light begins to dominate. In classical (i.e. pre-quantum theory) physics, atoms were understood to possess natural resonant frequencies resulting from a conjectured internal elastic structure. These natural resonances were believed to be responsible for the characteristic frequencies emitted by atoms when they were excited to oscillate by external agencies. Conversely, when the atoms were irradiated with electromagnetic waves at these same frequencies, they were able to absorb energy from the waves, as with all naturally resonant systems interacting with sympathetic driving forces. This approach seemed to provide a natural and reasonable explanation of both the emission and absorption spectral characteristics of particular atomic systems.

However, it was soon recognized that there were some difficulties with these ideas. They could not explain why, for example, in a gas discharge, some frequencies were emitted by the gas and yet were not also absorbed by it in its quiescent state; neither could they explain why the energy with which electrons were emitted from a solid by ultraviolet light (in the photoelectric effect) depends not on the quantity of absorbed light energy but only on the light's frequency.

We now understand the reasons for these observations. We know that atoms and molecules can exist only in discrete energy levels. These energy levels can be arranged in order of ascending value: E_0, E_1, $E_2 \cdots E_m$ (where m is an integer) and each such sequence is characteristic of a particular atom or molecule. The highest energy level corresponds to the last below the level at which the atom becomes ionized (i.e. loses an electron).

Fundamental thermodynamics (classical!) requires that under conditions of thermal equilibrium the number, N_i, of atoms having energy E_i is related to the number N_j having energy E_j by the Boltzmann relation:

$$\frac{N_i}{N_j} = \exp\left[-\frac{(E_i - E_j)}{kT}\right]. \tag{A1.1.6}$$

Here k is Boltzmann's constant ($1.38 \times 10^{-23}\,\mathrm{J\,K^{-1}}$) and T is the absolute temperature.

The known physics now states that light of frequency ν_{ij} can be either emitted or absorbed by the system only if they corresponds to a difference between two of the discrete energy levels, in accordance with the relation

$$h\nu_{ij} = E_i - E_j$$

where h is Planck's quantum constant ($6.626 \times 10^{-34}\,\mathrm{J\,s}$). The more detailed interpretation is that when, for example, an atom falls from an energy state E_j to E_i, a 'particle' of light with energy $h\nu_{ij}$ is emitted. This 'quantum' of light is called the photon; we use the symbol ν to denote frequency rather than f (or $\omega/2\pi$) to emphasize that light is now exhibiting its particulate, rather than its wave, character.

Thus, the relationship between light and matter consists of the interaction between atoms (or molecules) and photons. An atom either absorbs/emits a single photon, or it does not. There is no intermediate state.

The classical difficulties to which reference was made earlier are now resolved. First, some lines are emitted from a gas discharge which are not present in the absorption spectrum of the quiescent gas because the energetic conditions in the discharge are able to excite atoms to high energy states from which they can descend to some lower states; if these states are not populated (to any measurable extent) in the cold gas, however, there is no possibility of a corresponding incoming frequency effecting these same transitions and hence being absorbed. Second, for an incoming stream of photons, each one either interacts or does not interact with a single atom. If the photon energy is higher than the ionization energy of the atom then the electron will be ejected. The energy at which it is ejected will be the difference between the photon energy and the ionization energy. Thus, for a given atom, the ejection energy will depend only on the frequency of the photon.

Clearly, in light/matter interactions, it is convenient to think of light as a stream of photons. If a flux of p photons of frequency ν crosses unit area in unit time then the intensity of the light (defined by the Poynting vector) can be written

$$I = ph\nu. \tag{A1.1.7}$$

It is not difficult to construct any given quantity in the photon approach which corresponds to one within the wave approach. However, there does still remain the more philosophical question of reconciling the two approaches from the point of view of intellectual comfort. The best that can be done at present is to regard the wave as a ‘probability’ function, where the wave intensity determines the probability of ‘finding’ a photon in a given volume of space. This is a rather artificial stratagem which does, however, work very well in practice. It does not really provide the intellectual comfort which we seek, but that, as has been mentioned earlier, is a fault of our intellect, not of the light!

Finally, it may be observed that, since both the characteristic set of energy levels and the return pathways from an excited state are peculiar to a particular atom or molecule, it follows that the emission and/or absorption spectra can be used to identify and quantify the presence of species within samples, even at very small partial concentrations. The pathway probabilities can be calculated from quantum principles, and this whole subject is a sophisticated, powerful and sensitive tool for quantitative materials analysis. It is not, however, within the scope of this chapter.

A1.1.7 Photon statistics

The particulate view of light necessitates the representation of a light flux as a stream of photons ‘guided’ by an electromagnetic wave. This immediately raises the question of the arrival statistics of the stream.

To fix ideas let us consider the rate at which photons are arriving at the sensitive surface of a photodetector.

We begin by noting that the emission processes which gave rise to the light in the first place are governed by probabilities, and thus the photons are emitted, and therefore also arrive, randomly. The light intensity is a measurable, constant (for constant conditions) quantity which, as we have noted, is to be associated with the arrival rate p according to equation (A1.1.7), i.e. $I = ph\nu$. It is clear that p refers to the mean arrival rate averaged for the time over which the measurement of I is made. The random arrival times of the individual particles in the stream imply that there will be statistical deviations from this mean, and we must attempt to quantify these if we are to judge the accuracy with which I may be measured.

To do this we begin with the assumption that atoms in excited states emit photons at random when falling spontaneously to lower states. It is not possible to predict with certainty whether any given excited atom will or will not emit a photon in a given, finite time interval. Added to this there is the knowledge that for light of normal, handleable intensities, only a very small fraction of the atoms in the source material will emit photons in sensible detection times. For example, for a He–Ne laser with an output power of 5 mW, only 0.05% of the atoms will emit photons in 1 s.

Thus we have the situation where an atom may randomly either emit or not emit a photon in a given time, and the probability that it will emit is very small: this is the prescription for Poisson statistics, i.e. the binomial distribution for very small event probability (see, for example, Kaplan, 1981).

Poisson statistics is a well-developed topic and we can use its results to solve our photon arrival problem.

Suppose that we have an assemblage of N atoms and that the probability of any one of them emitting a photon of frequency ν in time τ is q, with $q \ll 1$.

Clearly, the most probable number of photons arriving at the detector in time τ will be Nq and this will thus also be the average (or mean) number detected, the average being taken over various intervals of duration τ. But the actual number detected in any given time τ will vary according to Poisson statistics, which state that the probability of detecting r photons in time τ is given by (Kaplan, 1981):

$$P_r = \frac{(Nq)^r}{r!}\exp(-Nq).$$

Hence the probability of receiving no photons in τ is $\exp(-Nq)$, and of receiving two photons is $[(Nq)^2/2!]\exp(-Nq)$ and so on.

Now the mean optical power received by the detector clearly is given by:

$$P_{\mathrm{m}} = \frac{Nqh\nu}{\tau} \tag{A1.1.8}$$

and P_{m} is the normally-measured quantity. Hence equation (A1.1.8) allows us to relate the mean of the distribution to a measurable quantity, i.e.

$$Nq = \frac{P_{\mathrm{m}}\tau}{h\nu} = \frac{P_{\mathrm{m}}}{h\nu B}$$

where B is the detector bandwidth ($B = 1/\tau$). Now we need to quantify the spread of the distribution in order to measure the deviation from the mean, and this is given by the standard deviation which, for the Poisson distribution, is the square root of the mean. Thus the deviation of the arrival rate is

$$D = (Nq)^{1/2} = \left(\frac{P_{\mathrm{m}}}{h\nu B}\right)^{1/2}.$$

This deviation will comprise a ‘noise’ on the measured power level and will thus give rise to a noise power

$$P_{\mathrm{noise}} = \left(\frac{P_{\mathrm{m}}}{h\nu B}\right)^{1/2}\frac{h\nu}{\tau} = (P_{\mathrm{m}}h\nu B)^{1/2}.$$

Thus the signal-to-noise ratio will be given by

$$\mathrm{SNR} = \frac{P_{\mathrm{m}}}{P_{\mathrm{noise}}} = \left(\frac{P_{\mathrm{m}}}{h\nu B}\right)^{1/2}.$$

This is an important result. It tells us what is the fundamental limit on the accuracy with which a given light power can be measured. We note that the accuracy increases as $(P_\mathrm{m}/h\nu)^{1/2}$, and it is thus going to be poor for low rates of photon arrival. This we would expect intuitively, since the 'granular' nature of the process will inevitably be more noticeable when there are fewer photons arriving in any given time. It will also be poor for large optical frequencies, since this means more energy per photon, and thus fewer photons for a given total light energy. Again the 'granular' nature will be more evident. For good SNR, therefore, we need large powers and low frequencies. Radio wave fluxes from nearby transmitters are easy to measure accurately, gamma rays from a distant galaxy are not.

Finally, it should be remembered that the above conclusions only apply strictly when the probability q is very small. For the very intense emissions from powerful lasers ($\sim 10^6\ \mathrm{W\,m^{-2}}$, say) a substantial proportion of the atoms will emit photons in a typical detection time. Such light is sometimes classed as non-Poissonian (or sub-Poissonian) for reasons which will now be clear.

A1.1.8 The behaviour of electrons

Our subject is optoelectronics, and so far we have been concerned almost exclusively with just one half of it: with optics. The importance of our subject derives from the powerful interaction between optics and electronics, so we should now evidently gain the necessary equivalent familiarity with electronics, to balance our view. We shall, therefore, now look at the general behaviour of electrons.

A free electron is a fundamental particle with negative electrical charge (e) equal to 1.602×10^{-19} C and mass (m) equal to 9.11×10^{-31} kg.

All electrical charges exert forces on all other charges and, for any given charge, q, it is convenient to summarize the effect of all other charges by defining the electric field, $\boldsymbol{E}$, via the value of the force $\boldsymbol{F}_\mathrm{E}$ which the field exerts on q:

$$\boldsymbol{F}_\mathrm{E} = q\boldsymbol{E}.$$

A magnetic field exerts no force on a stationary charge. When the charge moves with velocity v with respect to a magnetic field of induction $\boldsymbol{B}$, however, the force on the charge is given by

$$\boldsymbol{F}_\mathrm{B} = q(v \times \boldsymbol{B})$$

where $v \times \boldsymbol{B}$ denotes the vector product of v and $\boldsymbol{B}$, so that the force is orthogonal to both the vectors v and $\boldsymbol{B}$. Of course, a uniformly moving charge comprises an electrical current, so that $v \times \boldsymbol{B}$ also describes the force exerted by a magnetic field on a current-carrying conductor. The two forces are combined in the Lorentz equation:

$$\boldsymbol{F} = q(\boldsymbol{E} + v \times \boldsymbol{B}) \tag{A1.1.9}$$

which also is a full classical description of the behaviour of the electron in free space, and is adequate for the design of many electron beam devices (such as the cathode-ray tube of television sets) where the electron can be regarded as a particle of point mass subject to known electromagnetic forces.

If an electron (or other electrical charge) is accelerating, then it comprises an electric current which is varying with time. Since a constant current is known to give rise to a constant magnetic field, a varying current will give rise to a varying magnetic field, and this, as we have seen, will give rise in turn to an electric field. Thus an accelerating electron can be expected to radiate electromagnetic waves. For example, in a dipole antenna (figure A1.1.5) the electrons are caused to oscillate sinusoidally along a conducting rod. The sinusoidal oscillation comprises accelerated motion, and the antenna radiates radio waves.

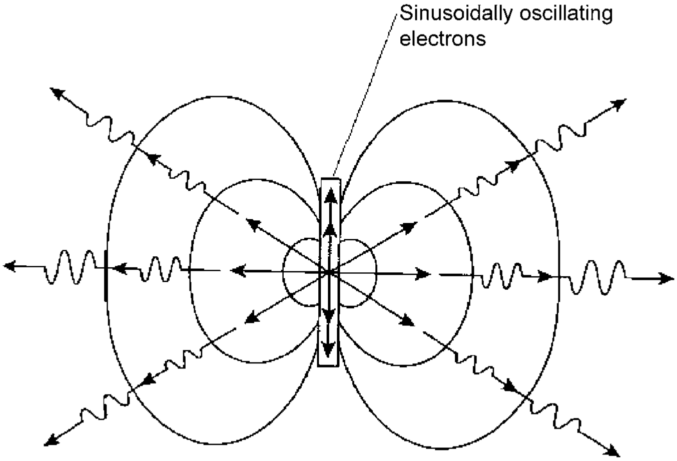

Figure A1.1.5. The radiating dipole.

However, the electron also itself exhibits wave properties. For an electron with momentum p there is an associated wavelength λ given by

$$\lambda = \frac{h}{p}$$

which is known as the de Broglie wavelength, after the Frenchman who, in 1924, suggested that material particles might exhibit wave properties. (The suggestion was confirmed by experiment in 1927.) Here h is, again, the quantum constant.

The significance assigned to the wave associated with the electron is just the same as that associated with the photon: the intensity of the wave (proportional to the square of the amplitude) is a measure of the probability of finding an electron in unit volume of space. The wave is a ‘probability’ wave. The particle/wave duality thus has perfect symmetry for electrons and photons. One of the direct consequences of this duality, for both entities, is the uncertainty principle, which states that it is fundamentally impossible to have exact knowledge of both momentum and position simultaneously, for either the photon or the electron. The uncertainty in knowledge of momentum, Δp, is related to the uncertainty in position, Δx, by the expression:

$$\Delta p \Delta x \approx \frac{h}{2\pi}.$$

There is a corresponding relation between the uncertainty in the energy (ΔE) of a system and the length of time (Δt) over which the energy is measured:

$$\Delta E \Delta t \approx \frac{h}{2\pi}.$$

The interpretation in the wave picture is that the uncertainty in momentum can be related to the uncertainty in wavelength, i.e.

$$p = \frac{h}{\lambda}$$

so that

$$\Delta p = \frac{-h\Delta\lambda}{\lambda^2}$$

and hence

$$\Delta x = \frac{h}{2\pi\Delta p} = \frac{\lambda^2}{2\pi\Delta\lambda}.$$

Hence, the smaller the range of wavelengths associated with a particle, the greater is the uncertainty in its position (Δx). In other words the closer is the particle's associated wave function to a pure sine wave, having constant amplitude and phase over all space, the better is its momentum known: if the momentum is known exactly, the particle might equally well be anywhere in the universe!

The wave properties of the electron have many important consequences in atomic physics. The atomic electrons in their orbits around the nucleus, for example, can only occupy those orbits which allow an exact number of wavelengths to fit into a circumference: again, the escape of electrons from the atomic nucleus in the phenomenon of β-radioactivity is readily explicable in terms of the 'tunnelling' of waves through a potential barrier. But probably the most important consequence of these wave properties, from the point of view of our present discussions, is the effect they have on electron behaviour in solids, for the vast majority of optoelectronics is concerned with the interaction between photons and electrons in solid materials. We shall, therefore, need to look at this a little more closely.

The primary feature which solids possess compared with other states of matter (gas, liquid, plasma) is that the atoms or molecules of which they are composed are sufficiently close together for their electron probability waves to overlap. Indeed, it is just this overlap which provides the interatomic bonding strength necessary to constitute a solid material, with its resistance to deformation.

When two identical atoms, with their characteristic set of energy levels, come close enough for their electronic wave functions (i.e. their waves of probability) to overlap, the result is a new set of energy levels, some lower, some higher than the original values (figure A1.1.6). The reason for this is analogous to what happens in the case of two identical, coupled, mechanical resonant systems, say two identical pendulums, which are allowed to interact by swinging them from a common support rod (figure A1.1.7). If one pendulum is set swinging, it will set the other one in motion, and eventually the second will be swinging with maximum amplitude while the first has become stationary. The process then reverses back to the original condition and this complete cycle recurs with frequency f_B. The system, in fact, possesses

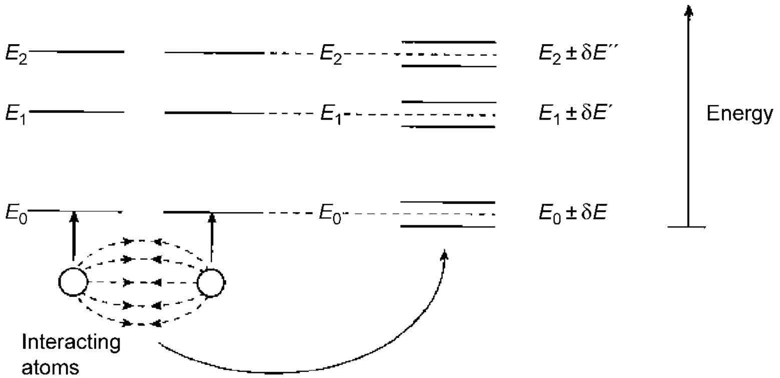

Figure A1.1.6. Splitting of energy levels for two interacting atoms.

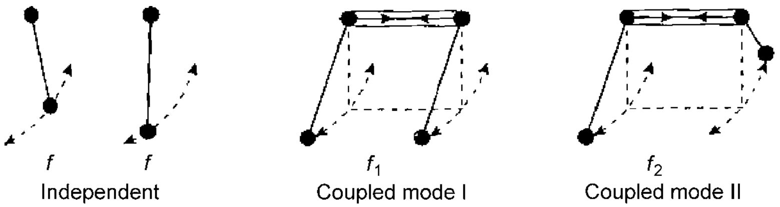

Figure A1.1.7. Interacting pendulums.

two time-independent normal modes: one is where both pendulums are swinging with equal amplitude and are in phase; the other with equal amplitudes in anti-phase. If these two frequencies are f_1 and f_2 we find

$$f_1 - f_2 = f_B$$

and the frequency of each pendulum when independent, f, is related to these by

$$f_1 = f + \frac{1}{2} f_B$$

$$f_2 = f - \frac{1}{2} f_B$$

i.e. the original natural frequency of the system, f, has been replaced under interactive conditions by two frequencies, one higher (f_1) and one lower (f_2) than f.

It is not difficult to extend these ideas to atoms and to understand that when a large number of identical atoms is involved, a particular energy level becomes a band of closely spaced levels. Hence, in a solid, we may expect to find bands separated by energy gaps, rather than discrete levels separated by gaps; and that, indeed, is what is found.

The band structure of solids allows us to understand quite readily the qualitative differences between the different types of solid known as insulators, conductors and semiconductors, and it will be useful to summarize these ideas.

We know from basic atomic physics that electrons in atoms will fill the available energy states in ascending order, since no two electrons may occupy the same state: electrons obey the Pauli exclusion principle. This means that, at the absolute zero of temperature, for N electrons the lowest N energy states will be filled (figure A1.1.8(*a*)). At a temperature above absolute zero the atoms are in thermal motion and some electrons may be excited to higher states, from which they subsequently decay, setting up a dynamic equilibrium in which states above the lowest N have a mean level of electron occupation. The really important point here is that it is only those electrons in the uppermost states which can be excited to higher levels, since it is only for those states that there are empty states within reach (figure A1.1.8(*b*)). This fact has crucial importance in the understanding of solid state behaviour. The electrons are said to have a Fermi–Dirac distribution among the energy levels at any given temperature, rather than the Maxwell–Boltzmann distribution they would have if they were not constrained within the solid, and which is possessed by freely-moving gas molecules, for example.

Consider now the energy band structure shown in figure A1.1.9(*a*). Here the lower band is filled with electrons and there is a large energy gap before the next allowable band, which is empty. The available electrons thus have great difficulty in gaining any energy. If an electric field is applied to this solid it would have very little effect on the electrons, since in order to move in response to the force exerted by the field, they would need to gain energy from it, and this they cannot do, since they cannot

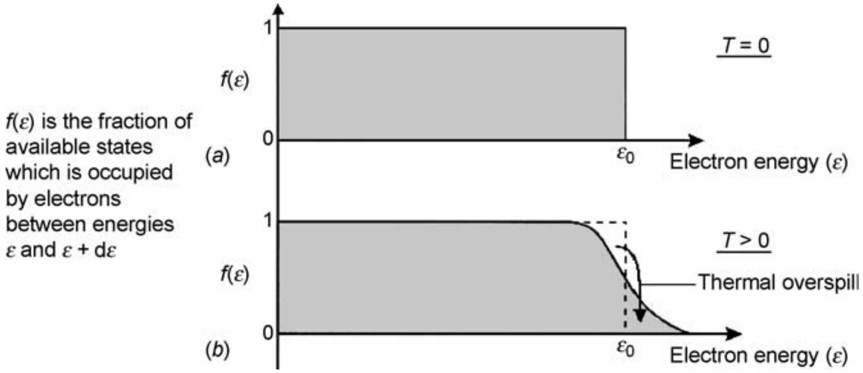

Figure A1.1.8. The Fermi–Dirac distribution for electrons in solids.

jump the gap. Hence the electrons do not move; no current flows in response to an applied voltage; the material is an insulator.

Consider now the situation in figure A1.1.9(*b*). Here the upper band is only half full of electrons. (The electrons in this band will be those in the outer reaches of the atom, and hence will be those responsible for the chemical forces between atoms, i.e. they are valency electrons. Consequently, the highest band to contain any electrons is usually called the valence band.) The situation now is quite different from the previous one. The electrons near the top of the filled levels now have an abundance of unfilled states within easy reach and can readily gain energy from external agencies, such as an applied electric field. Electric currents thus flow easily in response to applied voltages; the material is a metallic conductor.

The third case figure A1.1.9(*c*) looks similar to the first, the only difference being that the gap between the filled valence band and the next higher unoccupied band is now much smaller. As a result, a relatively small number of electrons can be excited into the higher band (known as the conduction band) by thermal collisions and, once there, they can then move freely in response to an applied electric field. Hence there is a low level of conductivity and the material is a semiconductor; more specifically it is an intrinsic semiconductor. It is clear that the conductivity will rise with temperature since more energetic thermal collisions will excite more electrons into the conduction band. This is in contrast to metallic conductors in which the conductivity falls with temperature (owing to greater interference from the more strongly vibrating fixed atoms). There is a further important feature in the behaviour of intrinsic semiconductors. When an electron is excited from the valence band into the conduction band it leaves behind an unfilled state in the valence band. This creates mobility in the valence band, for electrons there

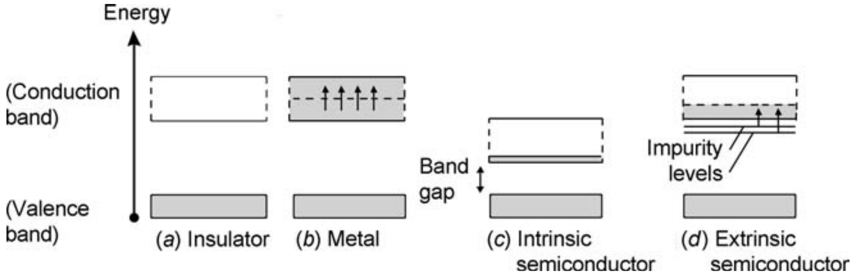

Figure A1.1.9. Energy-level schematic for the three main classes of solid ($T > 0$).

which previously had no chance of gaining energy can now do so by moving into the empty state, or hole, created by the promotion of the first electron. Further, the valence electron which climbs into the hole, itself leaves behind another hole which can be filled in turn. The consequence of all this activity is that the holes appear to drift in the opposite direction to the electrons when an electric field is applied, and thus they are behaving like positive charges. (This is hardly surprising because they are created by the absence of negative charge.) Hence we can view the excitation of the electron to the conduction band as a process whereby an electron/hole pair is created, with each particle contributing to the current which flows in response to an applied voltage.

Finally, we come to another very important kind of semiconductor. It is shown in figure A1.1.9(*d*). Here we note that there are discrete energy levels within the region of energy 'forbidden' to states, the gap between bands. These are due to intruders in the solid, to 'impurities'.

To understand what is going on, consider solid silicon. Silicon atoms are tetravalent (i.e. have a valency of four), and in the solid state they sit comfortably in relation to each other in a symmetrical three-dimensional lattice (figure A1.1.10). Silicon is an intrinsic semiconductor with an energy gap between the filled valence band and the empty (at absolute zero) conduction band of 1.14 eV. (An electron volt is the kinetic energy acquired by an electron in falling through a potential of 1 V, and is equal to 1.6×10^{-9} J.) The Boltzmann factor (equation (A1.1.6)) now allows us to calculate that only about one in 10^{20} electrons can reach the conduction band at room temperature; but since there are of order 10^{24} electrons per cm^3 in the material as a whole, there are enough in the conduction band to allow it to semiconduct.

Suppose now that some phosphorus atoms are injected into the silicon lattice. Phosphorus is a pentavalent (valency of five) atom, so it does not sit comfortably within the tetravalent (valency of four) silicon structure. Indeed, it finds itself with a spare valence electron (it has five as opposed to silicon's four) after having satisfied the lattice requirements. This electron is loosely bound to the phosphorus atom and thus is easily detached from it into one of the conduction band states, requiring little energy for the excitation. Effectively, then, the electron sits in a state close to the conduction band (as shown in figure A1.1.9(*d*)) and, depending on the density of phosphorus atoms (i.e. the 'doping' level), can provide significantly greater conductivity than is the case for pure silicon. Such impurity-doped materials are called extrinsic semiconductors.

As the impurity we chose donated an electron to the conduction band (as a result of having one spare) it is called an n-type semiconductor, since it donates negative charge carriers. Conversely, we could have doped the silicon with a tervalent (valency of three) element, such as boron, in which case it would sit in the lattice in need of an extra electron, since it has only three of its own. The consequence of

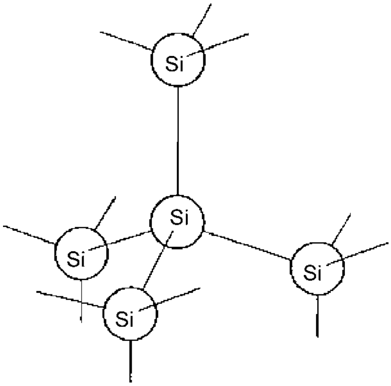

Figure A1.1.10. Structure of silicon lattice.

this will be that a neighbouring silicon valence electron can easily be excited into that vacant state, leaving a positive hole in the valence band as a consequence. This hole now enhances the electrical conductivity, leading to p-type ('positive carrier') semiconductivity. It is now easy to understand why 'pentavalent' elements are said to give rise to 'donor' energy levels and 'tervalent' elements to 'acceptor' levels (in silicon).

There are several reasons why extrinsic semiconductors are so important. The first is that the level of conductivity is under control, via the control of the dopant level. The second is that p-type and n-type materials can be combined with great versatility in a variety of devices having very valuable properties, the most notable of which is the transistor: many thousands of these can now be integrated on to electronic chips.

We are now in a position to understand, in general terms, the ways in which photons can interact with electrons in solids.

Consider again the case of an intrinsic semiconductor, such as silicon, with a band-gap energy E_g. Suppose that a slab of the semiconductor is irradiated with light of frequency ν such that

$$h\nu > E_g.$$

It is clear that the individual photons of the incident light possess sufficient energy to promote electrons from the valence band to the conduction band, leaving behind positive 'holes' in the valence band. If a voltage is now applied to the slab, a current, comprised of moving electrons and holes, will flow in response to the light: we have a *photo*conductor. Moreover, the current will continue to flow for as long as the electron can remain in the conduction band, and that includes each electron which will enter the slab from the cathode whenever one is taken up by the anode. Hence the number of electrons and holes collected by the electrodes per second can far exceed the number of photons entering the slab per second, provided that the lifetime of the carriers is large. In silicon the lifetime is of the order of a few milliseconds (depending on the carrier density) and the electron/photon gain can be as large as 10^4. However, this also means that the response time is poor, and thus photoconductors cannot measure rapid changes in light level (i.e. significant changes in less than a few milliseconds).

Small band-gap materials such as indium antimonide must be used to detect infrared radiation since the corresponding photon energy is relatively small. An obvious difficulty with a narrow band gap is that there will be a greater number of thermally excited carriers, and these will constitute a noise level; hence these infrared detectors usually must be cooled for satisfactory performance, at least down to liquid nitrogen temperatures (i.e. $< 77\,\mathrm{K}$)

In order to increase the speed with which the photoconduction phenomenon can be used to make measurements of light level, we use a device consisting of a combination of n- and p- type semiconductor materials. The two types of material are joined in a 'pn junction' which forms a 'photodiode' (figure A1.1.11). In this case the electron/hole pairs created by the incident photons drift in the electric field across the junction, thus giving rise to a measurable current as before; but each is quickly annihilated at the boundaries of the junction by an abundance of oppositely-charged carriers which combine with them. The reduced recombination time leads to a fast response and, with careful design, responses in times of order tens of picoseconds may be achieved. These pn photodiodes, in addition to being fast, are compact, rugged, cheap and operate at low voltage. They are not generally as sensitive as photoconductive devices, however, since they do not allow 'gain' in the way described for these latter devices (unless used in an 'avalanche' mode, of which more in later chapters).

The pn detection process can also be used in reverse, in which case the device becomes a light emitter. For this action electrons are injected into the pn junction by passing a current through it using, now, 'forward' bias. The electrons combine with holes in the region of transition between p and n materials, and, in doing so, release energy. If conditions are arranged appropriately this energy is in

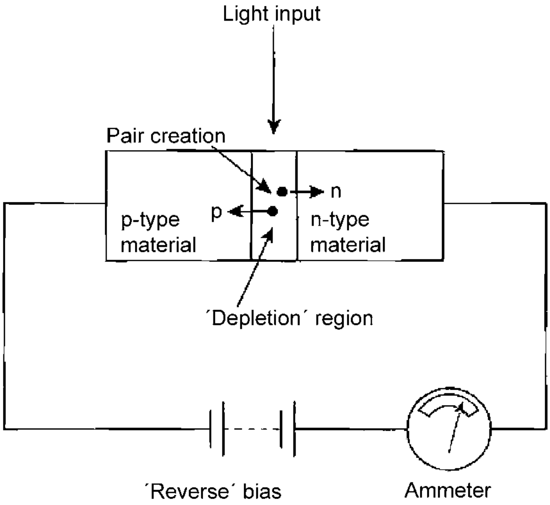

Figure A1.1.11. Schematic view of p–n junction photodiode.

the form of photons and the device becomes an emitter of light—a light-emitting diode (LED). Again this has the advantages of ruggedness, compactness, cheapness and low voltage operation. LEDs already are in widespread use.

A1.1.9 Lasers

Finally, in our general view of optoelectronics, we must have a quick glance at the laser, for that is from where it really all derives.

Our subject began (effectively) with the invention of the laser (in 1960) because laser light is superior in so many ways to nonlaser light. In 'ordinary', so-called 'incoherent', sources of light, each photon is emitted from its atom or molecule largely independently of any other, and thus the parameters which characterize the overall emission suffer large statistical variations and are ill-defined: in the case of the laser, this is not so. The reason is that the individual emission processes are correlated, via a phenomenon known as stimulated emission, where a photon which interacts with an excited atom can cause it to emit another similar photon which then goes on to do the same again, etc. This 'coupling' of the emission processes leads to emitted light which has sharply defined properties such as frequency, phase, polarization state and direction, since these are all correlated by the coupling processes. The sharpness of definition allows us to use the light very much more effectively. We can now control it, impress information upon it and detect it with much greater facility than is the case for its more random counterpart. Add to this facility the intrinsic controllability of electrons via static electric and magnetic fields and we have optoelectronics.

A1.1.10 Summary

Our broad look in this chapter at the subject of optoelectronics has pointed to the most important physical phenomena for a study of the subject and has attempted to indicate the nature of the relationships between them in this context.

Of course, in order to practise the art, we need much more than this. We need to become familiar with quantitative relationships and with a much finer detail of behaviour. These the succeeding chapters will provide.

A1.2

Optical materials

Neil Ross

A1.2.1 Introduction

Optoelectronics is, in essence, concerned with the interactions between light and the electrons within materials through which the light is propagating. This paper reviews the basic solid state physics that is necessary to understand the behaviour of many optoelectronic devices. The emphasis is on the physical models that are used to understand and predict the behaviour of materials. It is assumed that the reader has some knowledge of the basic principles of quantum mechanics, but no attempt will be made to formulate the models in a rigorous mathematical form. Only inorganic materials will be considered in this paper, as polymers and organic materials are considered elsewhere. As the interaction between light and a material is primarily through the electrons, it will be necessary to review the behaviour of electrons in a solid material in some detail, with particular emphasis on semiconductors because of their technological importance.

A1.2.2 Optical properties of some common materials

Before considering the underlying physics of materials for use, it is appropriate to consider the optical properties of some commonly used materials. The two most fundamental of these optical properties are the *transmission window*, i.e. the range of wavelengths over which the material is able to transmit light, and the refractive index.

Refractive index is defined as the ratio of the speed of light in vacuum to its speed in the material. Strictly this is the ratio of the *phase velocities*, rather than the *group velocities*, of the electromagnetic wave but the difference is rarely significant. For most optical materials, which are transparent in the visible region of the spectrum, this ratio has a value that is within the range of about 1.3–1.8. The refractive index of some different types of optical glass for use in the UV, visible and near infrared regions of the spectrum is shown in figure A1.2.1. Much higher values are often found for materials transmitting in the infrared. For example, zinc selenide has a refractive index of about 2.4, silicon about 3.4 and germanium 4.0. Refractive index is important because it determines the reflection and refraction at the boundaries between materials. This makes it possible to produce familiar components, e.g. lenses, and also guided wave devices, e.g. optical fibres.

For some materials (usually crystalline), the refractive index depends on the polarization of the light and on the direction of propagation. Such materials are said to show *birefringence*. Examples of birefringent materials are quartz (SiO_2) and calcite ($CaCO_3$). The maximum difference in refractive index between the two orthogonal linear polarizations is quite small in quartz (0.009), but quite large in calcite (0.17). Isotropic materials, such as most glasses and some crystals, do not normally show

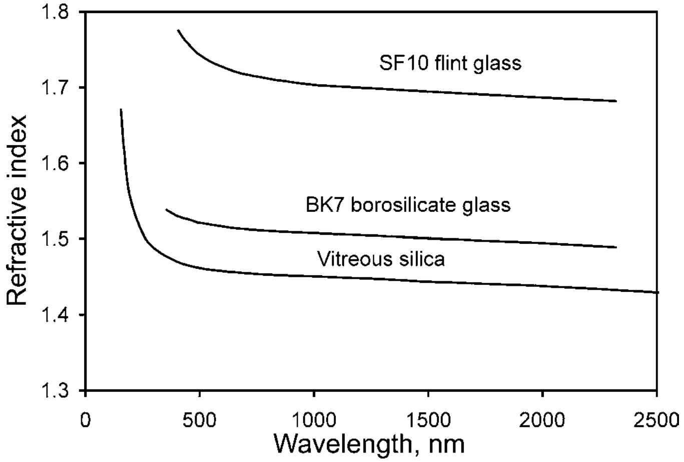

Figure A1.2.1. The refractive index of some optical glasses.

birefringence. However, when an isotropic material is subjected to mechanical strain or to an electric field, which introduces some anisotropy, birefringence may be induced.

The attenuation of light as it travels through a medium is due to *scattering* and *absorption*. Scattering arises from inhomogeneities, possibly on an atomic or molecular scale, and microscopic voids or inclusions in the material. Light is scattered in all directions, rather like the beam of a vehicle headlight in fog. This process leads to an attenuation of the light beam, as the light diffuses out in all directions. Scattering is not usually a limiting factor for many applications of optical materials, because the materials have been chosen for their clarity and optical homogeneity. The limiting factor on transmission is usually absorption. However, for optical fibres, where very high purity, low absorption glasses are used, it is the residual scattering from the microscopic fluctuations in the refractive index that ultimately limits the transmission. These fluctuations in refractive index arise from the thermal density fluctuations that occur in the molten glass. As the glass solidifies, these fluctuations become frozen in.

The other loss mechanism is that the light may be absorbed by the material. Generally, the region of good optical transparency is bounded at the short wavelength end by strong electronic absorption as electrons within the material are excited to higher energy states. At the long wavelength end, it is generally the excitation of molecular vibrations or *phonons* (vibrational or elastic waves) that provides the limit to the region of optical transparency.

Figure A1.2.2 shows the transmission of various optical materials in the visible and infrared parts of the spectrum. The transmission curves show values of the external transmission. That is, the measured transmission includes not only the losses within the material, but also the reflection losses at the two faces of the sample. Often, some of the absorption may be due to impurities in the material. This is the case for the absorption spectrum of UV-grade vitreous silica shown in figure A1.2.2. The strong absorption lines at around 1400, 2300 and 2800 nm are due to hydroxyl (OH) radicals (water). This is a consequence of the method of fabrication of the glass and alternative methods of production lead to much lower absorption in this region, at the cost of increased absorption in the ultra violet. The OH radicals conveniently act to reduce the absorption at short wavelengths by interacting with absorbing *colour centres*, which can otherwise occur in the silica glass. The colour centres are sites where there are nonbridging (i.e. missing) Si–O bonds and they introduce extra electronic states which lead to additional absorption. Hydroxyl (OH) groups may become attached at these sites, reducing the UV absorption.

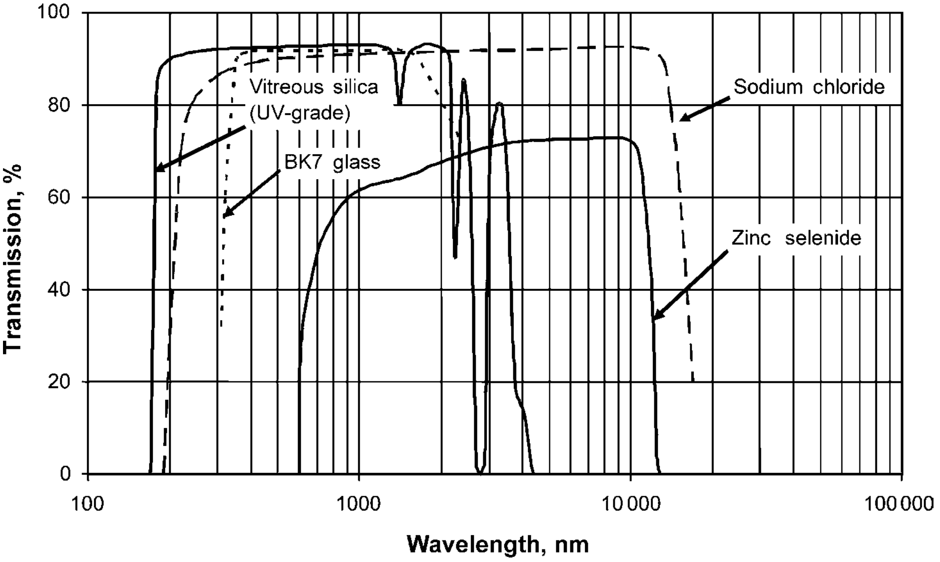

Figure A1.2.2. The external transmission of various optical materials for a 10 mm path length.

A1.2.3 Crystalline and amorphous materials

While glasses are widely used for passive optical components (e.g. lenses, windows and optical fibres), crystalline materials are generally used for many active electro-optic components (light sources, detectors, modulators, etc). Crystalline materials are also the simplest and the best-understood materials. The essential feature of a crystal is that the atoms and molecules are arranged in a periodic pattern. An abstract concept of a periodic structure, the *lattice*, is used to describe the location of the molecules within the crystal [1, chapter 1]. At each so-called *lattice point*, the atoms surrounding the point form the same pattern with the same orientation. Associated with each lattice point is a fixed volume, the *primitive cell*. There are many possible choices for the shape of the primitive cell, but in each case the volume is the same. The group of atoms associated with each lattice point is the *basis*. Together the lattice and the basis define the structure of the crystal. Of particular significance is that they determine its symmetry properties with respect to refraction and reflection of light. These properties are of interest when considering the polarization and nonlinear properties of optical materials.

To illustrate the concept of the lattice and the basis, consider the diamond structure, which is a structure characteristic not only of diamond but also of the elemental semiconductors silicon and germanium. This structure has a face centred cubic structure with lattice points lying at the corners of a cube and also at the centres of the six faces (figure A1.2.3(*a*)). The basis is an atom at a lattice point (0, 0, 0) and a second atom at a point (1/4, 1/4, 1/4), where the units are that of the lattice spacing (figure A1.2.3(*b*)). These combine to give the diamond structure (figure A1.2.3(*c*)), where each atom is bonded to four nearest neighbours. The solid lines indicate the bonds.

The lattice of an ideal single crystal extends throughout the crystal. In practice, defects, which disrupt the regular pattern, are often found in the structure. These defects will, in general, change the physical properties of the material. For electronic or electro-optic devices, it is usually necessary to minimize or eliminate such defects. While some materials, e.g. common salt, are easily identified as crystals, because of the regular shape in which they form, some, e.g. most metals, are not. This is generally because, in the latter, the bulk material is polycrystalline and made up of many small

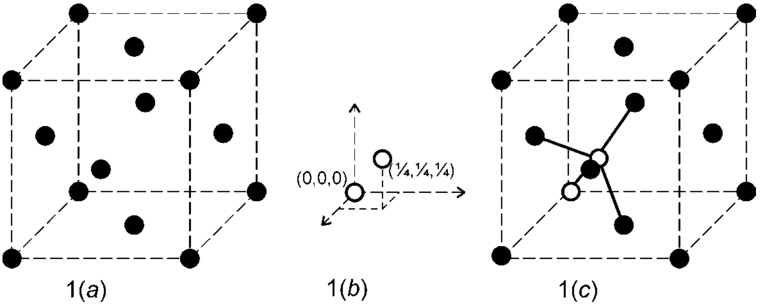

Figure A1.2.3. Diamond crystalline structure: (*a*) face centred cubic lattice; (*b*) basis; (*c*) full structure.

crystallites with varying orientations. These crystallites are not readily visible but can be seen by suitable treatment of the surface, e.g. chemical etching.

Amorphous materials differ from crystals, in that there is no long-range order [1, chapter 17]. Around each atom there may be some semblance of order, in that its nearest neighbours are approximately in the same pattern for all atoms, but this order rapidly decreases as the distance increases. Examples of amorphous materials would be soot, or of more relevance to electro-optics, amorphous silicon. Some of these are soft materials with little mechanical strength. Glasses are also amorphous materials, which may be considered to be composed of one large macromolecule, with strong bonding between atoms, but no long or medium range order or periodicity. They are of considerable importance in optics. Glasses are essentially super-cooled liquids. They have no well-defined melting point, but they progressively soften and become less viscous over a range of temperature. Although there is no long-range order, there is some degree of structure at short distances.

A1.2.4 Atomic bonding

In a crystalline material, strong forces bond the atoms together. This force is primarily due to the interaction of the outer electrons of the atoms (valence electrons). The number of valence electrons determines the chemical properties and the position in the periodic table. Several types of bond are commonly identified.

A1.2.4.1 Ionic bonds

In ionic crystals, two dissimilar atoms are bonded by charge transferred from one atom to the other, leaving a positive ion and a negative ion, with a consequent electrical force bonding the atoms together. A typical example would be common salt, NaCl.

A1.2.4.2 Covalent bonds

In this case, the bonding occurs with electrons being shared among adjacent atoms. A typical example would be silicon. Such bonds are strong, and generally have a well-defined direction, which will determine the structure of the unit cell.

A1.2.4.3 Metallic bonds

In the case of metals, electrons are also shared among atoms, but unlike covalent bonds, the electrons involved are free to move through the whole crystal, giving high electrical and thermal conductivity and,

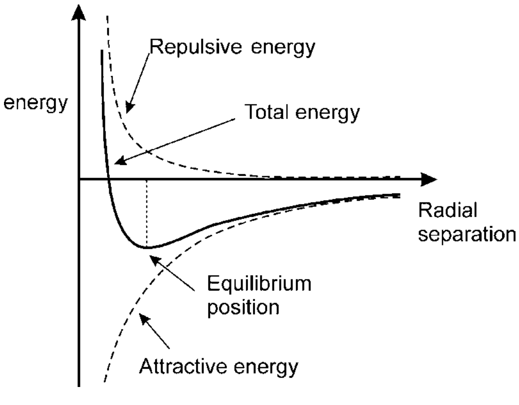

Figure A1.2.4. The binding energy between two atoms.

generally, very low optical transmission. Because of the high conductivity, the reflectivity for light and longer wavelength electro-magnetic waves is usually high.

A1.2.4.4 Van der Waals bonds

These are much weaker bonds arising from a dipole interaction among the atoms. This type of bonding may be important in organic materials.

The attractive forces pull the atoms together, but as they approach more closely, a repulsive force arises due to the interaction of the inner core electrons. Thus, as two isolated atoms are brought together, the potential energy will fall to a minimum and then rise again (figure A1.2.4). The equilibrium separation will be at the location of the minimum. For small displacements from the minimum, the potential energy curve will be approximately quadratic with displacement. Thus, if the atoms are displaced, they will oscillate with simple harmonic motion. This vibrational mode of oscillation generally occurs at frequencies corresponding to the infrared region of the spectrum and may determine the infrared properties of a material.

A1.2.5 The free electron model for metals

A good place to start when looking at the electrons in solid state materials is with metals. While metals are not generally thought of as optical materials, starting the discussion here enables some of the key theoretical concepts to be introduced in a relatively simple way.

In a metal, the valence electrons are free to move through the body of the material. This permits the use of a simple model, which is to treat the electrons as a ‘gas’ of free particles. This provides a good starting point for considering the electronic properties of solid materials, and introduces some of the essential concepts.

The properties of this electron gas are analysed by assuming that the electrons are completely free (no potential energy) up to the boundaries of the material, when the potential becomes infinite [1–5]. Using this ‘electron in a box’ model, the energy states are found by solving the Schrödinger wave equation. Of course, there is no net electric charge. It is assumed that the positive charge of the ionized atoms is uniformly distributed through the whole ‘box’. The model also ignores the interaction among the electrons, and the consequent collective effects. This is a rather odd assumption given the long-range Coulomb forces. Hook and Hall [3, chapter 13], discuss the reasons why this simplified model works.

Inside the box, the electrons can be analysed as simple plane waves, with the walls of the box imposing boundary conditions that require the wave function to be zero outside the box. This requires standing wave solutions. The permitted solutions are characterized by their *wavevector*, $\boldsymbol{k}$, which has a magnitude, k, of $2\pi/\lambda$ where λ is the *de Broglie wavelength* of the electron. Usually k is called the *wavenumber*, although this term is also frequently used for the inverse of the wavelength. The direction of $\boldsymbol{k}$ is the direction in which the electron is moving. Details of the analysis can be found in any good text on solid state physics [1–4].

From this model, it is possible to calculate the *density of states*, $N(E)$:

$$N(E) = \frac{V}{\pi^2 \hbar^3}(2m^3 E)^{1/2} \tag{A1.2.1}$$

where $N(E)\mathrm{d}E$ is the number of states with energy between E and $E + \mathrm{d}E$ for a volume V of the metal.

For a metal at very low temperature, the states will fill up from the bottom. The Pauli exclusion principle requires that each state can be occupied by only one electron. The maximum energy is therefore found by integrating $N(E)$ from zero to E_F and equating this number of states to the number of electrons. The *Fermi energy*, E_F, is given by

$$E_\mathrm{F} = \frac{\hbar^2}{2m}(3\pi^2 n_\mathrm{e})^{2/3} \tag{A1.2.2}$$

where n_e is the number of electrons per unit volume. The value of k corresponding to the Fermi energy forms a spherical surface in three-dimensional k-space. This is the *Fermi surface.*

To give some idea of the magnitude of the Fermi energy, consider potassium, a simple metal for which the free electron theory works well. A mole of potassium has a volume of $4.54 \times 10^{-5}\,\mathrm{m}^2$ and contains 6.0×10^{23} atoms, each atom contributes one electron, so $n_\mathrm{e} = 1.32 \times 10^{28}$ electrons m^{-3}. Substituting this into equation (A1.2.2) gives the Fermi energy as 2.04 eV.

At finite temperatures, electrons will be excited to energies somewhat higher than the Fermi energy and unfilled states will be left at lower energies. The Fermi–Dirac distribution function, $f(E)$, governs the probability that any particular state is occupied by an electron:

$$f(E) = \frac{1}{\mathrm{e}^{(E-\mu)/k_\mathrm{B}T} + 1} \tag{A1.2.3}$$

where k_B is Boltzmann's constant, T the absolute temperature and μ the *chemical potential*. At absolute zero temperature, μ is equal to E_F. At finite temperatures, the value will vary, but only slowly. Provided $k_\mathrm{B}T$ is much less than E_F, μ and E_F may be assumed equal. In figure A1.2.5, $f(E)$ is plotted for a chemical potential of 2 eV, at temperatures of 0, 300 and 600 K. In practice, the transition from 1 to 0 is usually quite sharp since the thermal energy kT is usually much less than μ. The chemical potential is also commonly referred to as the *Fermi level*.

The number of electrons with energies lying between E and $E + \mathrm{d}E$ is given by

$$n(E) = N(E)f(E)\,\mathrm{d}E. \tag{A1.2.4}$$

The energy of the electrons may also be related to their momentum, or wavenumber. Classically, the energy of an electron is given by

$$E = \frac{p^2}{2m}$$

where E is the electron energy, p the electron momentum and m the electron mass. The quantum mechanical equivalent is obtained by replacing p with $\hbar k$. This gives the relationship between energy, E,

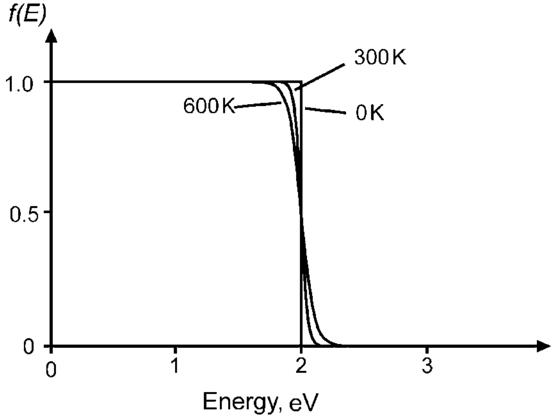

Figure A1.2.5. The Fermi distribution function at three temperatures.

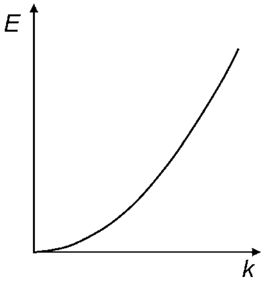

Figure A1.2.6. The parabolic variation of electron energy with k for the free electron model.

and the electron wavenumber, k, for free electrons:

$$E = \frac{\hbar^2 k^2}{2m}. \tag{A1.2.5}$$

Diagrams plotting E against k are useful for understanding band structure, particularly in semiconductors. The E–k diagram for free electrons (figure A1.2.6) is the simplest example.

At zero temperature, with no electric field, the electrons will lie within the Fermi surface in k-space. At finite temperatures, the edge of this sphere will not be distinct but the distribution will still be spherically symmetric. When an electric field is applied to the metal, the electrons will acquire a drift velocity in a direction determined by the field. The net effect is that the whole distribution of electrons in k-space will be shifted slightly, while still maintaining its spherical symmetry. This shift corresponds to a small increase in momentum in the direction of motion and a small increase in total energy.

A1.2.6 Electrons in a periodic lattice

The free electron model has neglected the presence of the atoms associated with the crystal lattice. These atoms will provide a potential that will attract electrons at a large distance from the core of the atom and repel electrons that move so close as to interact with the tightly bound electrons of the atom's core. A one-dimensional representation of the potential along a line through a series of atoms is illustrated in

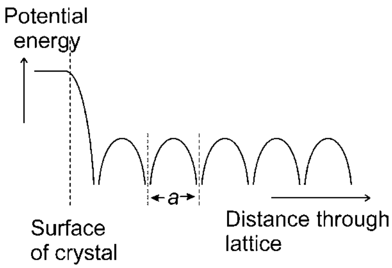

Figure A1.2.7. A representation of the periodic potential experienced by an electron due to the attraction of atomic nuclei.

figure A1.2.7. The most significant feature of the potential is the periodic attractive potential due to the charged atomic cores, separated by a distance a. If the electrons have a de Broglie wavelength equal to the distance between atoms, then strong reflections may be expected. The solution of the Schrödinger wave equation is clearly more complex with this modulated potential.

The *nearly free electron model* provides insight into the behaviour of electrons in a periodic potential [1–5]. Assuming that the interaction of the electrons with the periodic potential is weak, the electrons behave essentially as free electrons, unless their wavelength is close to the separation of the atoms, when travelling electron waves will interact coherently with the periodic potential and will be reflected. For a one-dimensional model of a crystal, with a line of atoms separated by a distance a, this reflection will occur when the electron wavenumber is given by

$$k = n\pi/a \tag{A1.2.6}$$

where n is an integer. The variation of energy with k would be expected to follow that for free electrons (equation (A1.2.5)), except in the region of k given by equation (A1.2.6). This simple model is able to predict that the electrons may only have energy within certain bands, separated by energy gaps.

In order to investigate the band structure, it is necessary to postulate a form for the potential energy and to solve the Schrödinger equation. One such model is the *Kronig–Penney model* [5]. This assumes a simple rectangular model for the potential along the one-dimensional line of atoms (figure A1.2.8). The Schrödinger equation is solved, assuming that the rectangular potential reduces to a series of delta functions (b tends to zero, keeping bV_0 constant). Solutions of the wave equation are not possible for all values of the energy E. Discontinuities in the E–k diagram occur at $k = n\pi/a$, where n is an integer. Away from these values of k, the solution is approximately parabolic, as for the free electron model. This is illustrated in figure A1.2.9(a). As k approaches $k = n\pi/a$, the gradient of the E–k curve approaches zero.

Usually the E–k diagram is modified by mapping all the bands to lie within the range of k between $-\pi/a$ to $+\pi/a$ (referred to as the *first Brillouin zone*), and usually only the positive values of k are

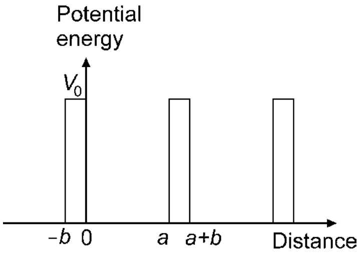

Figure A1.2.8. The periodic potential used in the Kronig–Penney model.

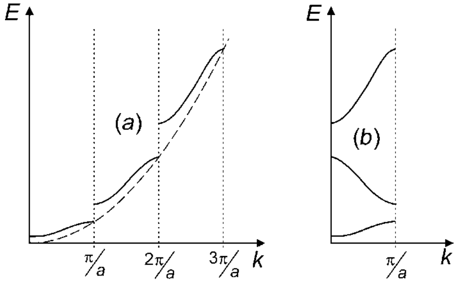

Figure A1.2.9. (*a*) Sketch of the *E–k* diagram obtained using the Kronig–Penney model and (*b*) the same data mapped using the reduced zone scheme.

included, since the negative values give a mirror image. This mapping is referred to as the *reduced zone scheme* [1] and is illustrated in figure A1.2.9(*b*). The mapping is mathematically valid because of the periodicity in k-space of the electron wave functions.

The one-dimensional, nearly free electron model demonstrates that the periodicity of a crystal results in electrons being confined to bands separated by energy gaps. It also enables the dynamics of the electron to be analysed. The free electron equations may be used, provided that the electron mass is replaced by an effective mass. This effective mass takes account of the interaction between the electrons and the lattice (see, for example [3, chapter 4]. The effective mass of an electron is given by

$$m^* = \hbar^2 \left(\frac{\mathrm{d}^2 E}{\mathrm{d}k^2}\right)^{-1}. \tag{A1.2.7}$$

Thus, the effective mass of an electron depends on the curvature of the band and hence will take positive values, in the lower part of a band, negative values in the upper part of the band and will become infinite at some intermediate point.

Another important result from the one-dimensional model is the total number of states in a band. It may be shown [4] that, for a line of atoms of density N_a atoms per unit length and length L, the total number of states is $2N_aL$. Hence, at low temperature and filling up the bands from the lowest energy, all the bands will be full if the atoms have an even number of electrons, and if the number of electrons is odd, the final band will be half full.

Extending the model to three dimensions clearly increases its complexity, but the same general features exist. Obviously, the periodicity will vary with direction through the crystal. The wavenumber must be replaced by the wavevector and the value of $\boldsymbol{k}$ at which the discontinuities occur will now be surfaces in three dimensions. The E–k diagram is still useful, but of course it must now be a plot of E against the wavevector in a particular direction. Frequently, E will be plotted against two different wavevector directions on one diagram, one direction for the positive axis and the other for the negative axis. For real materials, the band structure is much more complex than for the simple one-dimensional model. One particular feature is that, unlike the bands predicted by the simple model, the bands do not necessarily align. The maximum of one band does not necessarily occur at the same k value as the minimum of the next. The significance of this will become apparent shortly.

A1.2.7 Metals, insulators and semiconductors

Conduction of electricity is only possible if there are electrons in a band, having vacant states. A simple way to see this is to recall that, for free electrons, the effect of applying an electric field was to shift

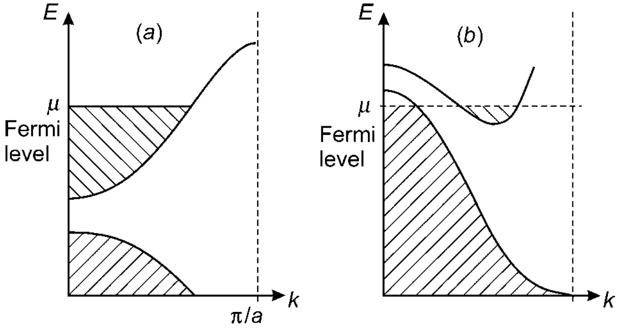

Figure A1.2.10. Schematic showing partially filled bands in a metal: (*a*) a simple metal with partially filled conduction band; (*b*) metal with overlapping bands.

the whole electron distribution slightly to reflect the change in electron momentum when an electric current flows. For a full band, this process is not possible, the distribution of electrons within the band is fixed. A full band cannot contribute to conduction.

A metal must have free electrons; it must therefore have an unfilled band (or bands). For the one-dimensional model discussed earlier, this implies that the number of electrons must be odd, in which case the highest energy band will be only half full. Such a metal will be well described by the free electron model. This simple model works well for the alkali metals, sodium and potassium, which have odd number of electrons. Many metals, however, e.g. magnesium or lead, have an even number of electrons and the simple one-dimensional theory does not work. This is because there is overlap between bands, hence filling up the available energy states from the lowest available states gives two partially filled bands. These two scenarios are illustrated schematically in figures A1.2.10(*a*) and (*b*).

There is a significant difference between the two cases. For the simple metal, the electrons in the conduction band behave very much as predicted by the free electron model, however, in the case of overlapping bands, one band is nearly full and the other nearly empty. Near the Fermi surface, the curvature of the E–k curve for the almost full band will be negative. Hence, the effective mass given by equation (A1.2.7) will also be negative. Rather than considering the effective mass to be negative, it is conventional to introduce the concept of *holes*. In essence, in an almost full band, an electron with an effective negative mass behaves like a positively charged particle with positive effective mass [1, chapter 8, or, 3, chapter 5]. A more physical way to view a hole is that it is the absence of an electron from an atom, leaving a positively charged core, hence the name. The hole is able to move through the lattice as electrons move in the opposite direction, conserving charge. The hole carries positive charge and behaves like a positively charged particle. While these two models for a hole are very different, they are equivalent. In materials where there are two bands contributing to conduction, one almost full and one with only a few of its available states occupied, conduction will effectively be bipolar, with both electrons and holes contributing to the conduction.

If, at low temperature, the electrons exactly fill a number of bands, and there is an energy gap before the next band, then conduction will not be possible and the material is an insulator. At nonzero temperature, the Fermi distribution function (equation (A1.2.3)) will still apply and the probability of electrons in the next band will be nonzero. If the energy gap is large, the number in this higher band will be very small and the material is an insulator. If, however, the energy gap is not so large (~1 eV), then there will be significant excitation at room temperature, and the material will be a semiconductor. The distinction between an insulator and a semiconductor is therefore not clearly defined in this model. However, diamond with a band gap of 5.4 eV would usually be considered an insulator, while silicon with a band gap of 1.17 eV would be a semiconductor. The full band(s) (at low temperature) below the energy gap are referred to as the *valence* band(s), while the band above the energy gap is the *conduction* band.

A1.2.8 Carriers, conduction and doping in semiconductors

In a semiconductor, the Fermi level, or chemical potential, lies within the energy gap. For a pure (intrinsic) semiconductor, the location of the Fermi level is determined by the need to balance the population of electrons in the conduction band with the holes in the valence band. Taking the zero of energy as the top of the valence band, μ is given by [3, chapter 5]

$$\mu = \frac{1}{2}E_G + \frac{3}{4}k_BT\ln\left(\frac{m_h}{m_e}\right) \tag{A1.2.8}$$

where E_G is the energy gap and m_e and m_h the effective electron and hole masses at the bottom of the conduction band and the top of the valence band, respectively. This will generally be close to the centre of the gap, as the second term is small. The density of electrons in the conduction band, n, and holes in the valence band, p, are related by the equation

$$np = n_i^2 = 4\left(\frac{k_BT}{2\pi\hbar^2}\right)^3 (m_h m_e)^{3/2} \exp\left(\frac{E_G}{k_BT}\right). \tag{A1.2.9}$$

In an intrinsic semiconductor $n = p = n_i$.

When an electric field is applied, both the electrons and holes will drift under the influence of the applied field. The drift velocity depends on the strength of the applied field, the carrier density and the rate at which the carriers lose energy to the atoms in the lattice. Generally, it is assumed that the current density $\boldsymbol{j}$ is proportional to the carrier density and to the applied field $\boldsymbol{E}$ (Ohm's law is obeyed). Then the total current density is given by

$$\boldsymbol{j} = (ne\mu_e + pe\mu_h)\boldsymbol{E} \tag{A1.2.10}$$

where μ_e and μ_h are the electron and hole mobilities, respectively, and e the electronic charge. Generally, the electron mobility will be greater than the hole mobility. For silicon, at room temperature, the electron and hole mobilities are about $\mu_e = 1500\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$ and $\mu_h = 450\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$. These values may be significantly reduced by impurities in the silicon.

In semiconductors, as in some metals, conduction is due to both the motion of electrons and holes. However, in semiconductors, adding low concentrations of certain impurity atoms (doping) may be used to control both the conductivity and the dominant carriers. In an elemental semiconductor with valency 4, such as silicon or germanium, adding pentavalent impurities such as phosphorous or arsenic will greatly increase the concentration of free electrons giving ‘n type’ material. The impurity atoms can fit into the lattice reasonably well, but the extra electron is not required for the covalent bonding and is only weakly bonded to the *donor* atom. At room temperature, many of these donor atoms are thermally ionized, releasing their electrons into the conduction band where they are free to move. In a similar way, adding trivalent atoms such as boron or aluminium will provide *acceptor* sites, where an electron may be removed from the valence band and trapped. The hole created in the valence band is free to move and will contribute to electrical conduction. Material with this type of doping is ‘p type’. If the electrons or holes from the ionized impurities dominate conduction, the semiconductor is said to be *extrinsic*. If the dominant mechanism by which the electrons and holes are produced is direct thermal excitation of

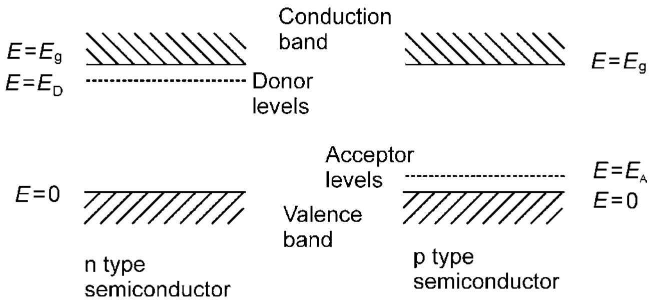

Figure A1.2.11. The location of the donor and acceptor levels within the band gap of a semiconductor.

carriers from the valence to conduction band, then the semiconductor is said to be *intrinsic*. The latter usually exhibits a low conductivity for most semiconductors at room temperature. However, the conductivity of an intrinsic semiconductor increases rapidly with rising temperature.

From the point of view of the energy, the donors or acceptors introduce extra energy levels within the energy gap (figure A1.2.11). The donor or acceptor levels at E_D or E_A lie close to the conduction or valence bands, respectively, and, when ionized, will either donate an electron to the conduction band or accept an electron from the valence band (leaving a hole). Taking the energy of the top of the valence band as zero, and the energy gap as E_g, then the energies E_A and $E_g - E_D$ are typically of order 0.05 eV for the dopants used in silicon.

Equation (A1.2.9) will still hold for an extrinsic semiconductor. Thus, if we consider an n type material, increasing the concentration of donors will increase the number of majority carriers (electrons) and decrease the concentration of minority carriers (holes). For p type materials, the holes will be the majority carriers.

As the temperature is increased from absolute zero, a number of changes occur in a doped semiconductor. At very low temperature, the impurity atoms are not ionized, the carrier concentrations are very small and the Fermi level lies mid-way between E_D and E_G for an n doped material. For a p doped material, the Fermi level will lie at an energy level of $E_A/2$. At very low temperature, the material behaves as an insulator. As the temperature rises, the donors or acceptors are ionized and the majority carrier density increases until all the impurities are ionized (extrinsic region). At the same time, the Fermi level decreases for n doped material, and increases for p doped material. Increasing the temperature still further, direct thermal ionization across the energy gap becomes significant and the semiconductor moves into intrinsic conduction, with the Fermi level moving towards its intrinsic value (equation A1.2.8). These changes are illustrated schematically in figure A1.2.12 for an n doped material.

A1.2.9 The interaction between light and materials

A1.2.9.1 Refraction

Classical electromagnetic theory gives the interaction between a light wave and a medium in terms of the dielectric constant, ε_r, and the conductivity, σ. The solution of Maxwell's equations, for a plane wave of angular frequency ω travelling in the $+z$ direction is of the form [6, chapter 8]

$$E_x = E_{x0} \exp[\mathrm{j}\omega(t - nz/c)] \tag{A1.2.11}$$

Figure A1.2.12. A schematic representation of the variation of majority carrier density and Fermi Level in an n type semiconductor.

where E_x is the electric field, n is the (complex) refractive index that is given by:

$$n = n' - jn'' = \sqrt{\mu_r\varepsilon_r - j\left(\frac{\sigma\mu_r}{\omega\varepsilon_0}\right)}. \tag{A1.2.12}$$

In equation (A1.2.12), μ_r is the relative permeability (generally very close to 1 for nonferromagnetic materials), ε_r the dielectric constant, σ the conductivity and ε_0 the permittivity of free space.

Substituting a complex index of refraction into equation (A1.2.11) gives:

$$E_x(\omega) = E_{x0}\exp(-\omega n'' z/c)\exp(j\omega(t - n'z/c))$$

from which it can be seen that the absorption coefficient, α is given by:

$$\alpha = \omega n''/c. \tag{A1.2.13}$$

In a highly conducting material such as a metal, where there are plenty of free electrons, the second term in equation (A1.2.12) will be dominant and n will be of the form

$$n = n' - jn'' = \sqrt{\left(\frac{\sigma\mu_r}{2\omega\varepsilon_0}\right)}(1 - j). \tag{A1.2.14}$$

The absorption coefficient is therefore given by

$$\alpha = \frac{\omega n''}{c} = \left(\frac{\sigma\mu_r\mu_0\omega}{2}\right)^{1/2} = \delta^{-1} \tag{A1.2.15}$$

where c has been replaced by $(\varepsilon_0\mu_0)^{-1/2}$ and δ is the *skin depth*. The skin depth is a measure of the penetration of the field into a conductor. For aluminium, with a resistivity of $6.65 \times 10^{-8}\ \Omega\,\mathrm{m}^{-1}$, the skin depth at a wavelength of 500 nm (green light) is about 3.3 nm, corresponding to an attenuation coefficient $3 \times 10^8\ \mathrm{m}^{-1}$.

For a metal, the conductivity term generally dominates the absorption and the term in ε_r can be neglected. For an insulating material, the conductivity term may be neglected, but not ε_r. The dielectric constant, ε_r, is a measure of the induced polarization of the material by the applied field. The polarization may be due to either the physical alignment of polar molecules, which generally only occurs at frequencies much below optical frequencies, or it may be due to dipole moments in the atoms or molecules induced by the applied field. In dense materials, the local field at a particular molecule or atom is distorted by the adjacent, induced dipoles. Taking account of this distortion (the *Lorentz field*), the Clausius–Mossotti equation may be deduced:

$$\frac{\varepsilon_\mathrm{r} - 1}{\varepsilon_\mathrm{r} + 2} = \frac{1}{3\varepsilon_0} \sum \alpha_i \tag{A1.2.16}$$

where α_i is the polarizability of the i^{th} atom or molecule [3, chapter 9]. The α_i here must not be confused with the absorption coefficient. This relation applies to isotropic materials and needs to be treated with caution. The formula works well for gases but less well for solid state materials where the interaction between the molecular dipoles is stronger.

The simplest model for the polarizability of the atoms is to treat them as classical harmonic oscillators, comprising an electron bound to a fixed atomic core. Using this model α_i will in general be complex. Close to resonance, the imaginary part of α_i, and hence ε_r, will be significant, corresponding to stronger absorption. Well away from the resonance, the polarization will be real and given by

$$\alpha_i = \frac{e^2}{m(\omega_0^2 - \omega^2)}. \tag{A1.2.17}$$

The dc polarizability of each atom is given by $e^2/(m\omega_0^2)$. Combining equations (A1.2.16) and (A1.2.17), and replacing ε_r by the square of the refractive index, the refractive index may be calculated as a function of normalized angular frequency ω/ω_0. The results are plotted in figure A1.2.13, where it has been assumed that the low frequency refractive index is 1.5

The simple model using classical harmonic oscillators clearly has weaknesses. A damping or loss term should be included to avoid the infinity at $\omega = \omega_0$, that can never occur in real materials. Treating the atoms as quantum mechanical oscillators modifies equation (A1.2.17), by introducing a constant, the oscillator strength, f_i. Also, it is not appropriate to treat all the oscillators as having a single resonant frequency. In solid materials, there are usually at least two regions of the frequency spectrum in which such resonances occur. In the infrared, vibrational modes of the lattice (phonons) lead to absorption and dispersion, while at shorter wavelengths, electronic or inter band transitions lead to a further region of strong absorption with associated dispersion.

For visually transparent optical materials, the strong electronic absorption lines occur in the ultraviolet part of the spectrum and, using the simple model, a slowly rising refractive index would be expected over the range of frequencies at which the material is transparent. The refractive index of vitreous silica is shown in figure A1.2.14, as a function of optical frequency. The data shown covers a range of frequencies that correspond to a wavelength range from 2325 to 213.9 nm. As expected from the basic theory, the refractive index rises as the frequency approaches the range in which the silica starts to absorb strongly by electronic transitions. The more rapid fall at the low frequency end of the spectrum occurs as the frequency approaches the near infrared absorption arising from the excitation of vibrational states. In this case, approaching the absorption from the high frequency side, a dip in refractive index would be expected from figure A1.2.13, as is observed in practice.

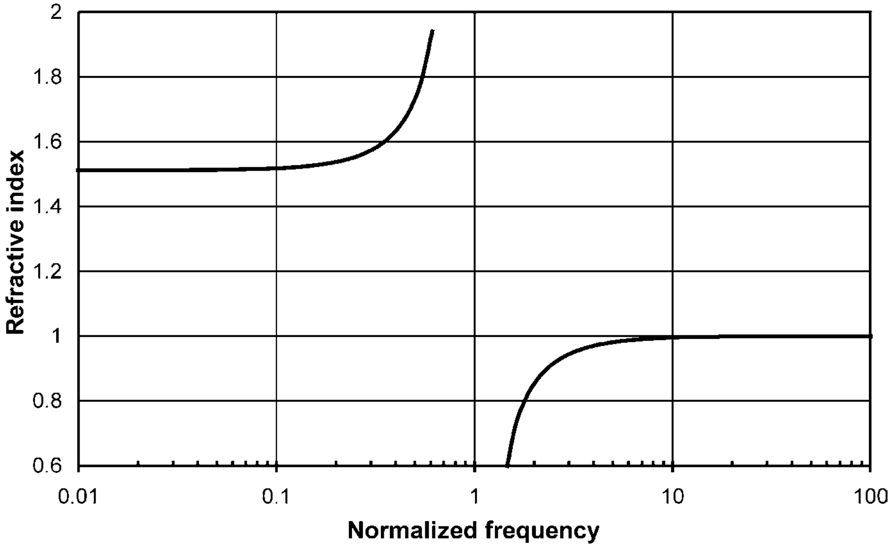

Figure A1.2.13. The refractive index close to resonance as predicted by equations (A1.2.16) and (A1.2.17), with the dc refractive index adjusted to give a refractive index of 1.5 at low frequency.

A1.2.9.2 Absorption and emission

For isolated atoms, light is absorbed when an electron in an atom is excited from one energy state to a higher state (figure A1.2.15(*a*)). Not all transitions are possible as there are selection rules, arising from the need to conserve angular momentum and spin. The interactions only occur if the photon energy matches the difference between the two well-defined states, and the line width is generally narrow. When atoms bond to form larger molecules many additional states are introduced, due to both vibration of the

bonds between atoms, and to rotation of the molecules. In the condensed state (liquid or solid state), the atoms interact strongly with both near and more distant neighbours and the electronic energy levels of the atoms are spread out into bands and hence the absorption spectrum of liquid and solid state materials generally consists of broad bands, although they may have well-defined edges as discussed later. Absorption also occurs when the optical field excites quantized vibrational waves (phonons), which leads to absorption in the infrared part of the spectrum.

An atom in an excited state may emit a photon as it relaxes to a lower energy state. This emission may occur spontaneously (figure A1.2.15(*b*)) or may be stimulated by another photon of the same energy (figure A1.2.15(*c*)). This process of stimulated emission creates a photon that has the same direction and effective phase as the wave function of the incident photon. Stimulated emission and absorption oppose each other, and the net result is that light may be absorbed or amplified, depending on the relative populations of the atoms in the upper and lower states. For a material close to thermodynamic equilibrium, the population of the lower state will exceed that of the upper state and the material will absorb light. In an optical amplifier, or in a laser that includes an optically amplifying region, the upper state is selectively excited and a *population inversion* occurs, with the population of the upper state exceeding that of a lower state. This provides optical gain.

A1.2.9.3 Fluorescence

Fluorescence is the process by which radiation is absorbed at one wavelength and then re-emitted at another, longer wavelength. Frequently, the excited state generated by the absorption relaxes rapidly by nonradiative processes to a somewhat lower energy state with a longer lifetime, before radiating and relaxing to a lower energy state (possibly the ground state). If the lifetime of the excited state of the radiative transition is long, then the fluorescence may continue for a significant period (microseconds to milliseconds) after the exciting radiation has been cut off. Many materials show fluorescence, some with high efficiency.

A1.2.9.4 Scattering

The final interaction to be considered here is scattering. In this case, the material does not absorb the light, but the incident radiation is scattered into all directions. The simplest form of scattering does not involve any interchange of energy and hence, is called *elastic scattering*. Elastic scattering will occur from any small variations in refractive index of the medium. For example, the scattering of light from a clear transparent glass is usually from tiny regions of the glass, where the refractive index differs from its mean value. These refractive index fluctuations arise from statistical density fluctuations, which occur in the liquid phase and then are frozen in as the glass solidifies. These regions of higher or lower refractive index are much smaller than the wavelength of light. Scattering from particles or regions of varying optical density that have dimensions much less than the wavelength of light ($< \lambda/10$) is called *Rayleigh* scattering. Rayleigh scattering occurs in all materials and in all phases, gas, liquid or solid. The strength of the scattering depends inversely on the fourth power of the wavelength of the light (λ^{-4}). Thus, visible or UV light is scattered much more strongly than infrared.

Raman scattering is, by contrast, an inelastic process in which energy is exchanged with the scattering material. This energy is in the form of molecular vibrations, or optical phonons in the quantum explanation of the effect. The wavelength shift depends on the vibrational energy of the molecule, or the phonon energy. The photon may lose energy (creating a phonon) as it is scattered, decreasing its frequency and increasing its wavelength (figure A1.2.16(*a*)). The decrease in the frequency (usually expressed in wavenumbers) is called the Stokes shift. Alternatively, a photon may gain energy by absorbing energy from a phonon or vibrating molecule (figure A1.2.16(*b*)), giving a shift to a higher frequency (anti-Stokes shift). Raman scattering is normally a weak process, generally several orders of magnitude weaker than Rayleigh scattering, but it is useful as a chemical diagnostic technique. The effect is used in some opto-electronic devices, but in most cases here it is stimulated Raman scattering that is used. Stimulated Raman scattering occurs at high optical intensities, such as may occur in optical fibres, even at moderate power levels. The spontaneous Raman effect may be enhanced if there is an excited state close to resonance with the exciting photon.

The third scattering mechanism is *Brillouin* scattering. This is an inelastic process similar to Raman scattering, except the energy states with which the exchange occurs are lower energy acoustic-mode phonons (sound waves). In a simplified classical description, it can be thought of as light scattered from moving regions of acoustic-wave induced compression and rarefaction, which behave like a diffraction grating. The movement of this ‘grating’ at the acoustic velocity induces a Doppler shift in the scattered light. The frequency shift is much smaller than for Raman scattering and again the effect is generally weak. It should, however, be noted that, as with Raman scattering, in a high optical field, with a long interaction length, the mechanism may lead to a nonlinear effect that results in strong stimulated scattering. This can occur at quite modest power levels (a few milliwatts) if a high coherence laser is launched into a long length of low-loss optical fibre.

The typical spectrum of scattered light from a glass, at moderate frequency resolution, is as shown in figure A1.2.17. The central peak at the excitation wavelength is strong and primarily due to the Rayleigh scattering, but also includes unresolved Brillouin scattering. The frequency shift for the Brillouin scattering is only about 10 GHz, and hence can only be resolved by high-resolution spectroscopic techniques. The relative magnitude of the Stokes and anti-Stokes bands depends on the number of thermally excited phonons, and hence the temperature.

A1.2.10 The absorption and emission of light by semiconductors

A1.2.10.1 Absorption and photo-conductivity

In the previous discussion on semiconductors, only thermal excitation of electrons between the valence and conduction bands has been considered. Electrons may also be excited by the absorption of electromagnetic radiation. For materials with an energy gap, photons may only excite electrons across the gap if the photon energy exceeds the energy band gap.

$$\hbar\omega \geqslant E_g$$

where ω is the optical angular frequency. There is a very small possibility of multi-photon absorption, but this will be neglected.

When a photon is absorbed, the usual conservation laws (energy, momentum and spin) must all be satisfied. Thus, for a simple transition in which a photon is absorbed and an electron excited, the change in the energy of the electron will be $\Delta E = \hbar\omega$ and the change in the wavevector (momentum) of the electron will be equal to the wavevector of the photon. The wavevector of the photon will, in general, be very small compared with the wavevectors of the electrons. Hence, a simple absorption results in a very small change in $\boldsymbol{k}$. To illustrate this, consider typical values. The lattice spacing for a typical crystal, a, is of order 10^{-10} m, so the wavevector at the limit of the first Brillouin zone has a magnitude (π/a) of 3.1×10^{10}. The wavevector for a photon of wavelength 1 μm (i.e. an energy close to the band gap of silicon) has a magnitude of only 6.3×10^6. It follows that the absorption or emission of a photon will transfer an insignificant amount of momentum to, or from the electrons. To preserve momentum, therefore, the transition is therefore essentially vertical on the E–k diagram.

For a direct gap semiconductor (such as GaAs), the maximum of the valence band lies directly below the minimum of the conduction band (figure A1.2.18(*a*)). In this case, once the photon energy exceeds the band gap, the absorption in the semiconductor will rise rapidly. For an indirect gap semiconductor (such as Si or Ge), there is a significant change of k between the maximum of the valence band and the minimum of the conduction band (figure A1.2.18(*b*)). Transitions between these two points can only occur if a third 'particle' is available to enable momentum (k) to be conserved. This particle is a phonon, a quantized, vibrational excitation of the crystal lattice [1 chapter 8, 4, chapter 8]. The phonon

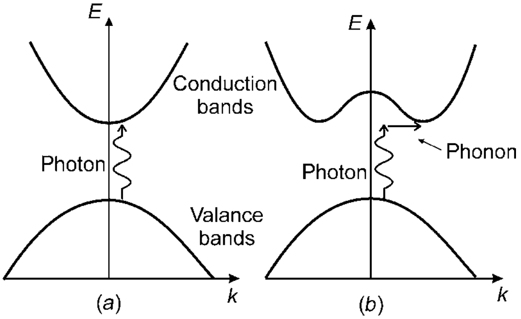

Figure A1.2.18. Diagram illustrating absorption in (*a*) a direct band gap semiconductor and (*b*) an indirect band gap semiconductor.

may be created in the interaction and carry off the momentum and some of the energy or the interaction may be with an existing photon. However, the energy associated with the phonon will be much less than the energy of the photon for the same k value, so most of the energy is transferred to the electron. This *three-body* interaction is much less probable than the simple interaction, where there is no change of electron momentum. Direct band gap semiconductors have an absorption that rises very rapidly near the band edge (photon energy corresponding to the band gap). By contrast, indirect gap semiconductors show a slow rise in absorption until the energy reaches a value that permits direct transitions (figure A1.2.19).

The balance of the excitation rate and the decay rate will determine the steady-state carrier density produced by the radiation and may be written as

$$n_{\mathrm{e}} = n_{\mathrm{h}} = R\tau$$

where τ is the carrier lifetime and R the excitation rate, which will depend on the intensity of the light and the absorption coefficient of the material. The induced carriers will, in turn, lead to increased

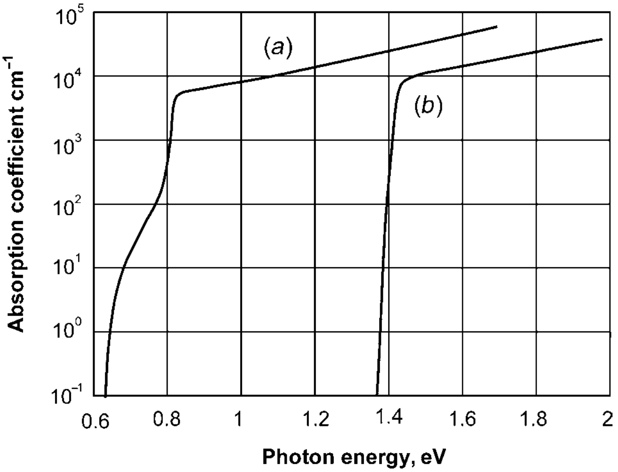

Figure A1.2.19. The absorption of (*a*) germanium and (*b*) gallium arsenide close to the band edge (data taken from [8, 9]).

conductivity (photo-conductivity), which will build up or decay in a time determined by the carrier lifetime.

A1.2.10.2 Emission

If a semiconductor is able to absorb light, exciting electrons from valence band to conduction band, then it will also be possible for light to be emitted by the radiative decay from the conduction band to the valence band. Quantum mechanics shows that the two processes are closely linked. The excited electrons will generally relax very quickly to the bottom of the conduction band, and in the same way, the available holes will float to the top of the valence band. As with absorption, emission of radiation requires that k is conserved, and a high probability of radiative decay requires a simple two-body interaction, hence the electron cannot change its k value. The electrons rapidly decay to the bottom of the conduction band by nonradiative processes, and similarly, the holes rise to the top of the valence band. Hence, in an indirect band gap semiconductor light emission will require the interaction with a phonon of suitable k value. This three-body interaction is, again, of low probability, and recombination is more likely to occur by nonradiative processes. This implies that only direct gap semiconductors can be efficient emitters of light. Obviously, electrons must be excited to the conduction band in order that the semiconductor may emit light. This excitation may be optical, in which case the emission is fluorescence, or it may be due to the injection of minority carriers across a p–n junction.

A1.2.11 Polycrystalline and amorphous semiconductors

In the earlier discussion, it has been assumed that the material is in the form of a perfect crystal. However, as mentioned earlier, crystals usually contain *point defects* and *dislocations*. These are disruptions to the regular lattice and may take a variety of forms [1–3]. Point defects occur when an atom is missing or displaced from its position within the lattice, they may also arise from impurity atoms (as in the deliberate doping of semiconductors). Dislocations are due to imperfections in the lattice which are not localized at a point but extend through the crystal. A simple example is the edge dislocation, when part of a row or plane of atoms is missing, creating stress around the dislocation and leaving *dangling bonds* (figure A1.2.20(*a*)). Dislocations and defects may diffuse through the crystal, especially at elevated temperature. They will modify the band structure introducing extra energy states,

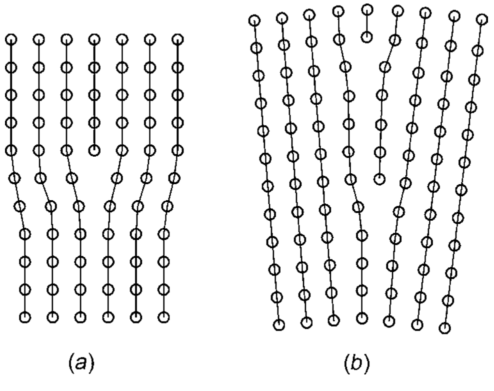

Figure A1.2.20. (*a*) Schematic diagram illustrating an edge dislocation (in cross-section) and (*b*) a small angle grain boundary.

which may trap carriers. Semiconductor devices are usually made from materials, which are as free as possible from dislocations and defects (other than deliberate doping).

In a polycrystalline material, the lattice does not extend unbroken throughout the whole sample, but there are many crystallites or crystal grains with their lattices orientated at different angles. Bonds exist across the grain boundaries, but obviously there is a complex loss of order. For small angles between the lattices at a grain boundary, the boundary may be made up of a row or plane of edge dislocations [1, chapter 20]. This is illustrated schematically for two dimensions in figure A1.2.20(*b*). Grain boundaries will introduce many surface states, which will generally seriously impair the performance of electronic devices. There are, however, cases where the impaired performance may be balanced by a greater need for reduced cost. An example of this is the polycrystalline solar cell, where the lower cost of producing a large area polycrystalline device, as opposed to a large area single crystal cell, makes the reduced performance economically acceptable.

Amorphous semiconductors may be formed as thin films by evaporation or sputtering. Such films have some short-range order due to the directionality of the bonds between atoms, but possess no long-range order. Amorphous semiconductor films differ from polycrystalline films, in that order is maintained over a much shorter distance. Because of the disorder, there will be many dangling bonds, which result in many extra states within the energy gap. For amorphous silicon, it has proved possible to neutralize the effect of the unpaired electrons, by depositing the amorphous silicon in an atmosphere of hydrogen. The hydrogen attaches to the dangling bonds and results in a material, which may be doped p or n type and which can be used to fabricate p–n junctions for solar cells. Although amorphous silicon is relatively cheap to produce, it performs much less well than crystalline silicon.

A1.2.12 Glasses

Glasses are a particular type of amorphous material and are particularly important for optics. They are generally produced from the liquid state by cooling the material. Unlike crystalline materials that have a well-defined melting point, the transition between solid and liquid occurs smoothly over a range of temperatures (the glass transition). They are in essence *super-cooled liquids*, where a large macromolecule is formed as the liquid cools. While most commercially important glasses are very stable over long periods of time, some less stable glasses may revert to a crystalline state more quickly, particularly if held at high temperature or if they are cooled slowly from the molten state. Glasses, unlike crystals, have no long-range order, but because of the preferred directions of the bonds between the constituent atoms, there is an element of short-range order, over a few atomic separations. A consequence of the lack of long-range structure is that there will be density fluctuations that are frozen in as the glass solidifies.

The most common glasses are based on silica (SiO_2) with additions of sodium and calcium oxide (and other metallic oxides) to reduce the temperature at which a glass is formed. Glasses of this type have been produced since prehistoric times and the Romans had a well-developed glass technology. Glasses with special properties are produced by varying the composition. Adding lead oxide increases the refractive index to produce *flint* glass (or lead crystal glass), while the replacement of some of the sodium oxide with boric oxide produces a glass with low thermal expansion (borosilicate glass, e.g. Pyrex). The addition of transition metal oxides, semiconductors or other materials leads to coloured glasses which are frequently used as optical filters. Also, by adding materials such as neodymium or erbium, glasses may be produced which are able to operate as lasers or optical amplifiers.

This ability to control the optical and mechanical properties of glasses accounts for their importance. The development of optical fibres for communications in the 1980s led to the development of new glasses with very low optical attenuation. Such glasses are generally based predominantly on silica, with germania (GeO_2) and B_2O_3 dopants to control the refractive index. In order to achieve

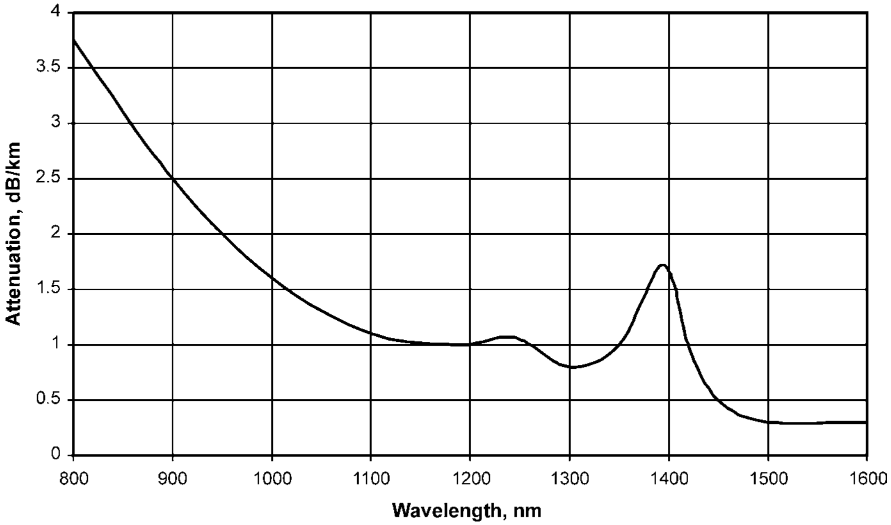

Figure A1.2.21. The attenuation spectrum of a typical silica-based optical fibre.

the very low attenuation required, it is necessary to ensure very high purity, particularly avoiding transition metals. For this reason, the glass is generally fabricated by a vapour phase reaction to generate the basic material, which is usually formed in a molten or finely divided state. The molten glass is then cooled to form the fibre preform rod, which is drawn into a fibre. Using these methods, the attenuation is reduced to a level limited by the scattering from the residual density fluctuations in the glass and the absorption due to the silica. The loss in an optical fibre decreases rapidly with increasing wavelength as the scattering becomes less, until it rises again due to the long wavelength absorption of the glass. Figure A1.2.21 shows an attenuation spectrum for a typical silica-based fibre. The absorption peak around 1400 nm arises from residual hydroxyl radicals in the glass. The success in producing very low loss optical fibres is largely a result of improved fabrication methods, reducing the concentration of these radicals.

While the common forms of glass are all based on oxides, there has recently been much interest in infrared transmitting glasses, for example, chalcogenide glasses that are oxygen free. These glasses are based on the chalcogen group of elements: sulphur, selenium and tellurium, combined with arsenic, antimony or germanium and/or halide elements. Chalcogenide glasses are of interest because of their transparency at longer wavelengths than oxide-based glasses, their semiconducting properties and their optical nonlinearity. In addition, their low phonon energy helps prevent nonradiative decay in infrared optical fibre amplifiers. They are, however, much less robust than conventional glasses softening at much lower temperature (less than 200°C) and showing poor chemical durability.

A1.2.13 Anisotropy and nonlinear optical properties of crystals

A1.2.13.1 Anisotropy

In discussing the refractive index of materials, it was tacitly assumed that the polarizability of a material is a scalar quantity. This must be true for unstrained isotropic materials, such as glasses but is not generally true for crystals. Simple cubic crystals, e.g. sodium chloride, are isotropic, but crystals with more complex crystal structures, e.g. quartz, are not. The relationship between the electric displacement vector, $\boldsymbol{D}$ and the electric field $\boldsymbol{E}$ must be expressed in the more general form:

$$\boldsymbol{D} = \varepsilon_0 \boldsymbol{\varepsilon}_\mathrm{r} \cdot \boldsymbol{E} = \varepsilon_0 \begin{pmatrix} \varepsilon_{xx} & \varepsilon_{xy} & \varepsilon_{xz} \\ \varepsilon_{yx} & \varepsilon_{yy} & \varepsilon_{yz} \\ \varepsilon_{zx} & \varepsilon_{zy} & \varepsilon_{zz} \end{pmatrix} \cdot \boldsymbol{E}. \tag{A1.2.18}$$

It may be shown that the dielectric constant matrix, ε_r, is symmetric and that by suitable choice of major axes, the *principle dielectric axes*, ε_r becomes diagonal. Note that, unless the direction of the electric field, $\boldsymbol{E}$, lies along one of these principle axes the direction of the displacement vector, $\boldsymbol{D}$, and that of the electric field are not in general parallel. The solution of Maxwell's equations for electromagnetic waves in an anistropic medium shows that the propagation depends on the direction and on the polarization state of the wave. For a given direction of propagation, there are generally two normal modes with orthogonal linear polarization, which propagate with different phase velocities. If the wave launched into the crystal is a mixture of the two normal modes, the polarization state will constantly change through a range of elliptical states as the wave propagates.

A1.2.13.2 Electro-optic and nonlinear processes

In discussing the effect of refraction, it was also tacitly assumed that the induced polarization is proportional to the instantaneous electric field. However, for some materials, the interaction between the material and the electric field may be more complex. In the *linear electro-optic* or *Pockels effect*, the interaction is manifest as a change of refractive index with applied electric field. Whether a material shows the linear electro-optic effect or not is determined by the symmetry properties of the crystal. An isotropic material or a crystal with inversion symmetry cannot show the linear effect [10, chapter 6], although it may show the, quadratic, *Kerr effect*. Thus, electro-optic crystals are those having lower symmetry, e.g. quartz or potassium dihydrogen phosphate (KDP). This electro-optic effect finds a use in optical modulators, where electric fields are applied to such a crystal to modulate the polarization or optical phase delay. (A subsequent polarizer or interferometric mixer can convert polarization or phase change to intensity changes.)

If the optical intensity is large, the nonlinearity between the polarization and the applied field may also manifest itself in terms of harmonic generation or optical mixing. The polarization is generally thought of in terms of a power series expansion

$$P = \varepsilon_0 \chi_1 E + \varepsilon_0 \chi_2 E^2 + \varepsilon_0 \chi_3 E^3 + \cdots \tag{A1.2.19}$$

where χ_1 is the linear susceptibility and χ_2 and χ_3 the second- and third-order nonlinear susceptibilities, respectively. The wave equation for propagation of light in a nonlinear medium may be written in the form [10]

$$\nabla^2 \boldsymbol{E} - \mu_0 \mu_\mathrm{r} \varepsilon_0 \varepsilon_\mathrm{r} \frac{\partial^2 \boldsymbol{E}}{\partial t^2} = \mu_0 \mu_\mathrm{r} \frac{\partial^2 \boldsymbol{P}_\mathrm{NL}}{\partial t^2} \tag{A1.2.20}$$

where $\boldsymbol{P}_\mathrm{NL}$ contains all the nonlinear polarization terms. The second-order term $\chi_2 E^2$ acts as a driving term, which will contain components at twice the frequency of the electric field of the original wave, leading to the generation of light at a frequency twice that of the initial wave. The second-order component also leads to optical mixing. The third-order term leads to other nonlinear phenomena such as intensity-dependent refractive effects. Nonlinear effects are generally weak, and require high optical intensity and/or a long interaction length.

Many optical devices take advantage of these electro-optic and nonlinear optical effects. For example, the Pockels effect may be used to create an optical phase modulator, or in combination with polarizers, to produce an optical amplitude modulator. Nonlinear optical effects, although usually weak, have long been used to change the wavelength of lasers by frequency doubling or optical mixing. The high optical intensity and long interaction length that is possible in optical fibres have extended the range of nonlinear effects that may be used, without the need for very large optical power.

A1.2.14 Summary

This paper has attempted to provide a brief introduction to the electronic and optical behaviour of some of the materials used. Many of the subjects raised will be taken up again in later chapters and treated in greater depth, notably chapters A1.7 and A2.1. Clearly this is a very extensive field and due to lack of space in this introduction, many issues have been omitted or only treated superficially. One significant area of omission is that of organic and polymeric materials. These materials are becoming increasingly important in a number of areas of optoelectronics, particularly in display technology, which is the basis of a later chapter.

A1.3
Incandescent, discharge and arc lamp sources

David O Wharmby

A1.3.1 Overview of sources

There is a very wide range of incandescent and discharge lamps. The majority of these are sold as general lighting sources, but many are suited to optoelectronic applications. The major lamp companies, and numerous speciality lamp manufacturers also make lamps for applications other than general illumination. Examples of these applications are: projection, video, film, photographic, architectural, entertainment and other special effects, fibre optic illumination including numerous medical and industrial applications, photobiological processes, photochemical processing, microlithography, solar simulation, suntanning, disinfection, ozone generation, office automation, scientific applications, heating etc.

LED sources are covered in detail in chapter B1.1. Section A1.3.10 of this chapter makes some brief comments on the applications in which LEDs are competing with conventional lamps.

This chapter will concentrate on principles and will be illustrated by a number of examples. These principles should make it possible to understand the wealth of information in manufacturer's web sites and catalogues. A selected list of manufacturers is given in appendix.

There are a number of useful books about light sources. The book by Elenbaas [12] is an excellent overview of the science of light sources, whilst for discharge lamps the book by Waymouth [21] contains clear and detailed explanations of many discharge phenomena. Coaton and Marsden [9] give a comprehensive introduction recent enough to cover many modern developments; their appendix 1 gives a useful generic table of lamp data for nearly every commercial source used for illumination. Zukauskas *et al* [24] give an up to date review of the use of LEDs in lighting.

A1.3.2 Light production

Most optical radiation is the result of accelerating electrons and causing them to make *inelastic* collisions with atoms, ions, molecules or the lattice structure of solids. In the UV, visible and near IR, the photons are the result of *electronic* transitions between energy levels of these materials.

There are exceptions; in synchrotron radiation and related processes emission is from accelerated electrons.

As particle densities increase in the source, the spectral features broaden out until, in incandescent sources the spectrum is continuous. Discharge sources generally emit spectral lines of atoms and molecules that are broadened to an extent depending on the pressure. Lamps of various types therefore emit a wide range of spectral features ranging from narrow atomic lines to a full continuum. The types of spectra are often critical for optical applications [5] (see appendix—Oriel Instruments for a selection of spectra).

In incandescent lamps, the radiation is from the surface of a hot material. In discharge lamps, conduction is the result of ionization of the gas; any light emission is a volume process. The task of the lamp designer is to ensure that this ionization is also accompanied by copious radiation of the correct quality for the application.

A1.3.3 Radiation fundamentals

A1.3.3.1 Full radiator radiation and limits on emission

Both in incandescent and discharge lamps, electron motion is randomized. In all cases of practical interest, the drift velocity of the electrons in the applied electric field is much less than the mean velocity. An electron energy distribution function is established that can usually be characterized by an electron temperature T_e. The distribution function may be far from Maxwellian when particle densities are low, or under transient conditions. It is the electrons in the high-energy tail of the distribution that excite the atoms, with subsequent emission of radiation.

The spectral radiance $L_e(\lambda,T)$ of the full radiator or black body is given by Planck's equation (chapter A2.2, where radiometric and photometric quantities are also defined). The spectral radiance is plotted in figure A1.3.1 for temperatures typical of those found in incandescent and discharge lamps. Convenient units for spectral radiance are W m^{-2} sr^{-1} nm^{-1}, obtained by multiplying the value of c_1 in chapter A2.2 by 10^{-9}.

For incandescent or high-pressure (HP) discharge sources the electron temperature T_e is close in value to the temperature T of the solid or vapour, but for low-pressure (LP) discharges in which collisions between electrons and heavy particles are comparatively rare, T_e may be very much higher than the gas temperature. The Planck equation therefore forms a fundamental limit to the radiance that may be obtained from any source in which the electron motion is randomized. This sets a fundamental limit on the spectral distribution, the energy efficiency and the radiance of the source.

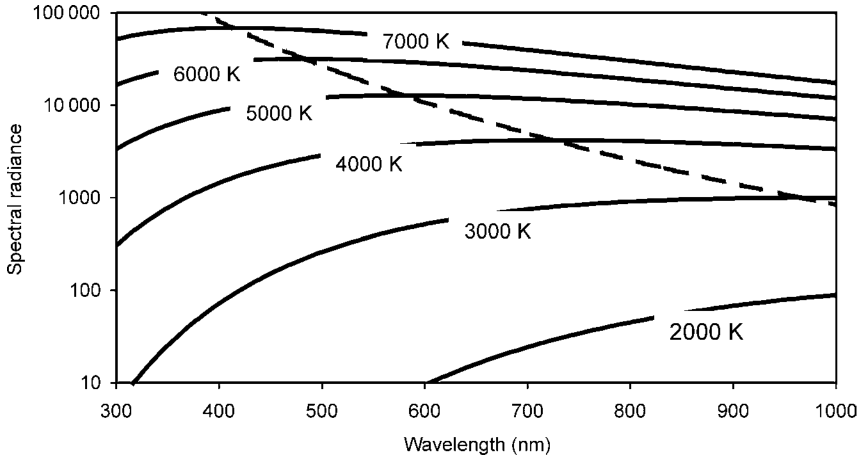

Figure A1.3.1. Spectral radiance of a full radiator (W m^{-2} sr^{-1} nm^{-1}). The broken line is Wien's displacement law showing the shift in peak radiance to shorter wavelengths as the temperature increases.

A1.3.3.2 Absorption and emittance

For radiation falling on a surface

$$a(\lambda, T, \theta) + t(\lambda, T, \theta) + r(\lambda, T, \theta) = 1 \tag{A1.3.1}$$

where the fractions $a(\lambda,T,\theta)$, $t(\lambda,T,\theta)$ and $r(\lambda,T,\theta)$ are known as absorbance, transmittance and reflectance, respectively. In general, they depend on the wavelength, temperature and angle θ between a ray and the normal to the surface.

The spectral emittance $\varepsilon(\lambda,T,\theta)$ is the ratio of the thermal emission from the surface to that of a full radiator (black body) at the same temperature, wavelength and angle. This quantity is also known as spectral emittance. Derived from very general thermodynamic arguments, Kirchhoff's law [13] states that

$$\varepsilon(\lambda, T, \theta) = a(\lambda, T, \theta). \tag{A1.3.2}$$

For a perfect absorber, $a(\lambda, T, \theta) = 1$. Therefore, the spectral emittance of a full radiator is unity; a good approximation can be made by forming a cavity from an absorbing material.

All real materials have $\varepsilon(\lambda, T, \theta) < 1$. The best characterized material is tungsten (figure A1.3.2) [12]. *Selective emittance* is characteristic of most materials; in metals the emittance tails off at long wavelengths, whereas refractory oxides usually have a region of high emittance in the IR.

A1.3.3.3 Étendue

For all optical systems geometry determines how much of the radiation generated by the source can be used by the optical system. This behaviour depends on a very general concept called étendue $\mathcal{E}$, also known as geometric extent [3, 13, 20].

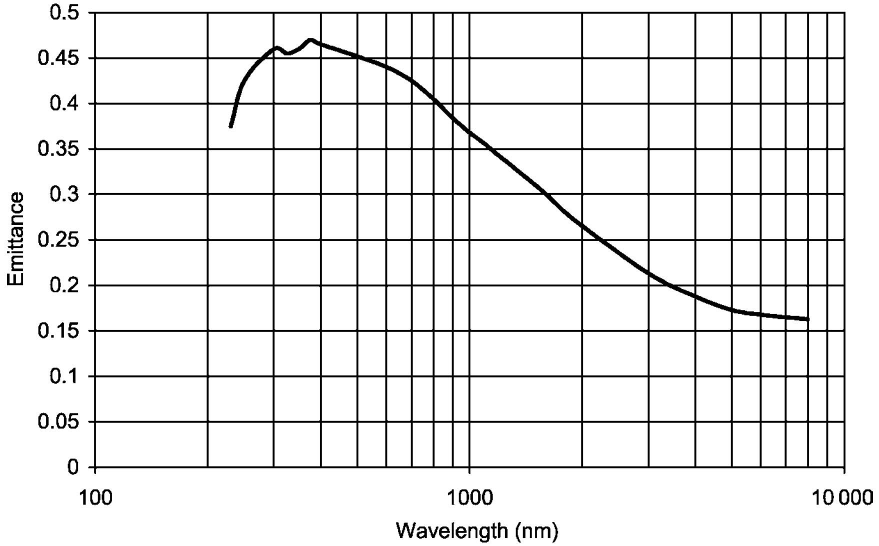

Figure A1.3.2. Spectral emittance of tungsten at 2800 K at normal incidence (after [12]).

A definition of étendue is

$$\mathcal{E} = \iint \cos\theta \, \mathrm{d}A \, \mathrm{d}\Omega \quad (\mathrm{m}^2\,\mathrm{sr}) \tag{A1.3.3}$$

where $\cos\theta\,\mathrm{d}A$ is the projected area of the source under consideration, and $\mathrm{d}\Omega$ is the solid angle into which it is radiating. Notice that the units are geometric, with no mention of amounts of radiation. A more general form is used when refractive indices are > 1 [13]. Energy conservation requires that étendue is conserved in a lossless optical system; if there are losses caused by aberrations, scattering, or diffraction, étendue increases through the system. The étendue of a bundle of rays passing through an optical system either stays the same (ideal) or increases, but never decreases.

A simple example demonstrates some of the issues. Imagine projecting an image of the sun onto a surface. The diameter of the sun is about 1.4×10^9 m with an area $A_\mathrm{S} \approx 1.5 \times 10^{18}\,\mathrm{m}^2$. Our distance from the sun is about 1.5×10^{11} m. Suppose the lens has a focal length of $f = 100$ mm and a diameter of 10 mm so that its area $A_\mathrm{L} \approx 8 \times 10^{-5}\,\mathrm{m}^2$. The solid angle Ω_0 subtended by the lens at the sun is therefore about 3.5×10^{-27} sr. In this simple geometry the étendue $\mathcal{E} = A_\mathrm{S}\Omega_0 \approx 5.4 \times 10^{-9}\,\mathrm{m}^2\,\mathrm{sr}$. The image is brought to a focus at a distance f in a converging beam of solid angle $\Omega_\mathrm{L} = A_\mathrm{L}/f^2 = 8 \times 10^{-3}$ sr. Assuming a perfect optical system so that étendue is conserved, the image area is therefore $A_\mathrm{I} = \mathcal{E}/\Omega_\mathrm{L} \approx 7 \times 10^{-7}\,\mathrm{m}^2$, giving an image diameter of about 0.5 mm.

If we want to focus the sun onto a smaller spot, a lens of the same area needs to have a shorter focal length. Aberrations in a nonideal lens then cause some of the light to fall outside the area predicted above, increasing étendue. Scattering and diffraction are also losses that increase étendue. In general, the integration in equation (A1.3.3) has to be done numerically, e.g. by using an optical design code.

Étendue is also the quantity that determines how the power Φ (W) in the beam is related to the radiance L ($\mathrm{W\,m^{-2}\,sr^{-1}}$), as inspection of the units will confirm:

$$\Phi = L\mathcal{E}t \quad (\mathrm{W}) \tag{A1.3.4}$$

t is the transmittance of the lens (and related optics). Conservation of étendue and of energy means that radiance can never be increased by an optical system.

In a projector, there is always some component that has the smallest (limiting) étendue. Often this will be the film or light gate with its associated projection lens. If the étendue of the source is greater than this, some light will miss the light gate and be wasted. On the other hand, if the étendue of the light gate is much larger than that of the source then the gate will not be fully illuminated. The aim must therefore be to reduce the étendue of the source as far as possible, since it is usually much greater than the limiting étendue. This will minimize the amount of light that misses the light gate. Suppose that a projector lamp has a source of area A_S that radiates in all directions so that the solid angle is 4π and the source étendue is $\mathcal{E}_\mathrm{S} = 4\pi A_\mathrm{S}$. The limiting étendue $\mathcal{E}_\mathrm{L}$ of the system will be usually be that of the light gate. In order that $\mathcal{E}_\mathrm{S}$ does not greatly exceed $\mathcal{E}_\mathrm{L}$, with consequent wastage of light, the area of the source must be very small because the source solid angle is so large. Major advances in projector lamps have been to use HP arcs with an arc gap as small as 1 mm (see section A1.3.7.4) and an effective area in the region of $0.1\,\mathrm{mm}^2$.

The étendue concept is very general. It applies to any illumination system from fibre optics to street lanterns. For example, one of the benefits of LEDs is that their low étendue allows efficient use of the relatively low radiated fluxes; this is a reason why LED headlights for cars are a possibility.

A1.3.3.4 Use of light in systems

The luminous flux in lumens (lm) [9, chapter 1]

$$\Phi_\mathrm{v} = 683 \int_{380}^{780} \Phi_{\mathrm{e}\lambda} V(\lambda)\,\mathrm{d}\lambda \tag{A1.3.5}$$

where $\Phi_{e\lambda}$ is the spectral radiant flux in W nm^{-1} and $V(\lambda)$ is the spectral luminous efficiency for photopic vision (chapter A2.2). The factor 683 (lm W^{-1}) converts power to luminous flux. It is also useful to define the *luminous efficiency of radiation*

$$K = \Phi_v / \Phi_e. \tag{A1.3.6}$$

The (luminous) efficacy of a source is

$$\eta_v = \Phi_v / P_{in} \ \ (\mathrm{lm\,W^{-1}}). \tag{A1.3.7}$$

For many commercial lamps, the input power P_{in} is defined as the power into terminals of the lamp, whereas self-contained sources (such as compact fluorescent lamps), or lamps sold as a system (such as some electrodeless lamps) P_{in} is taken to be the power coming from the electricity supply P_{wall}. The latter power is greater because it contains the losses in the lamp circuit; users should be aware of this possibility for confusion.

Many lighting systems are driven and controlled by electronics and this trend will be maintained in the future. Figure A1.3.3 shows a schematic view of a complete lighting system. To generate light that eventually reaches the eye, every system includes most or all the steps shown. In order to work in terms

P_{eff}

Figure A1.3.3. Schematic diagram of lighting system. The efficiency at each conversion is shown. Power from the wall P_{wall} is converted to dc power P_{dc}, which is used by the lamp circuit to input P_{cir} to the lamp. The broad arrows represent various aspects of the radiation from the lamp. The lamp converts P_{cir} to radiation P_{rad}; a convenient measurement and integration range is 200–2500 nm, which encompasses most of the radiation emitted. A fraction of this P_{VR} is in the visible region. This is then converted into visible power by weighting with the eye sensitivity curve to give power P_{vis}; the luminous flux is $683 \times P_{vis}$. That power is transmitted/reflected by an imperfect optical system onto a surface that reflects light into the eye. All powers P here are in watts and the spectral powers $P(\lambda)$ are in W nm^{-1}.

of power so that we can calculate efficiencies, the quantity in figure A1.3.3 $P_{\mathrm{vis}} = \Phi_{\mathrm{v}}/683$. For each stage in there is a loss and the system efficiency is then

$$\eta_{\mathrm{sys}} = \eta_{\mathrm{dc}} \times \eta_{\mathrm{cir}} \times \eta_{\mathrm{rad}} \times \eta_{\mathrm{VR}} \times \eta_{\mathrm{vis}} \times \eta_{\mathrm{eff}} \tag{A1.3.8}$$

The various terms are defined in figure A1.3.3. Each stage in this chain of light production needs to be examined to discover how system efficiency can be improved. Notice that equation (A1.3.8) applies equally well to a street lamp, a projector, a self-ballasted lamp, a fibre-optic illuminator and, if the conversion from mains to ac is omitted, to battery operated lighting system.

A1.3.3.5 Colour properties and colour temperature of sources

Definitions of quantities mentioned below related to colour are given in chapter A2.2. A comprehensive discussion of colour in lighting is also given by Coaton and Marsden [9, chapter 3].

An important colour property of any source is *colour appearance* or *chromaticity* (specified by the chromaticity coordinates). The colour appearance of any source can be matched by mixture of three sources of different colour appearance (for example, by red, green and blue sources, or by three spectral sources). The space of all possible colours is bounded by the spectral colours. For general illumination and for some opto-electronic applications such as projection, the preferred colour of sources is ‘white’; the chromaticity of these sources is then close to that of a black body having a colour temperature (see below) in the range from about 2800 (yellowish white) to about 8500 K (bluish white). Other sources, such as those used for signalling, usually have more saturated colours (that is colours such as red, green, amber etc.) that are close to the spectral colours). The specifications for these sources are closely controlled [7].

Colour temperature is defined only for those sources having a colour appearance close to that of a black body. The quantity most often used is the *correlated colour temperature* (CCT) [15,19], defined in chapter A2.2. A few examples help to set a scale. The glowing embers of a fire have a CCT in the region of 1000 K whilst a candle flame has a CCT of about 2000 K. Incandescent lamps, depending on type, have CCTs between 2400 and 3400 K. The CCT of the sun is about 6000 K. Discharge lamps for general illumination mostly have CCTs between 3000 and 6500 K. Xenon arcs and flash lamps have CCTs in excess of 6000 K.

Sources of a given chromaticity (that is, having the same colour appearance) may have very different spectral distributions. A commonly observable example (at least in Europe) is that the colour of an amber traffic signal and of the commonly used orange low-pressure sodium street lights are almost identical; the sodium lamp emits only at about 589 nm whereas the traffic signal is a filtered tungsten lamp that emits over a broad spectral range from the yellow through to the red. The value of K (equation (A1.3.6)) for light from the LP sodium lamp also greatly exceeds that for the traffic signal.

Not surprisingly a surface illuminated by these two sources appears to have very different colours. The *colour rendering* capability of a light source is an important measure. For general task illumination colours need to appear ‘natural’; this means that surfaces such as skin, fabric, building materials, etc should not appear distorted when compared with their appearance under natural light or incandescent light, which both have continuous spectra. Along with high efficacy or high luminance, this is a major requirement for commercial light sources. The measure of colour rendering used is the CIE General Colour Rendering Index (CRI) or R_{a} (see chapter A2.2) [6, 23]. R_{a} is computed from the colour shifts shown by a series of coloured surfaces when illuminated by the test illuminant as compared to their colour when illuminated by natural and Planckian reference illuminants.

The better the colour rendering, the lower the efficacy of the lamp. One might think that since the sources that give ‘perfect’ colour rendering have continuous spectra, then high quality lamps should too, and this is usually the case. However, simultaneous optimization of K and R_{a} at constant colour temperature has shown a surprising result; both quantities are maximized if the light is emitted in narrow bands at 450, 540 and 610 nm. This feature of human vision, confirmed by experiment, has been exploited in the *triphosphor* fluorescent lamps that are now standard in all new installations. The lamps use narrow band phosphors that emit close to the critical wavelength. Similar techniques are now being used to optimize white light LEDs (Zukauskas *et al* [24] give a useful review of optimization.)

The CIE CRI is defined so that tungsten and daylight sources have $R_a = 100$. For general lighting in commercial premises requiring high-quality illumination, restaurants and homes, R_a should be 80 or higher. Good quality sources for interior lighting such as triphosphor fluorescent lamps and HP ceramic metal halide (CMH) lamps have $R_a \geq 80$. Lower cost halophosphate fluorescent lamps have R_a around 50–60, as do HP mercury lamps with phosphor coatings. High-pressure sodium (HPS) lamps used for street lighting have R_a around 25.

Human vision is extremely sensitive to small differences in colour [23] particularly in peripheral vision. This has proved to be a major challenge for lamp manufacturers, especially where lamps are used in large installations such as offices and stores. Not only should the initial spread in colour be very small, but also the colour shift during life must be very small otherwise when lamps are replaced it will be very obvious. Amongst the lamps for high-quality illumination triphosphor fluorescent and CMH are pre-eminent in this respect; such colour differences as they have, are barely noticeable.

A1.3.3.6 Radiation from atoms and molecules in extended sources

In a discharge lamp, each elementary volume of plasma emits optical radiation. In a volume source an atom or molecule with an upper state of energy E_u (J) can make a transition to a lower state E_l (J) with a transition probability of A_{ul} (s^{-1}). The emitted wavelength λ (m) is then given by

$$\frac{hc}{\lambda} = E_u - E_l \ \ (\mathrm{J}) \tag{A1.3.9}$$

where h is Planck's constant in J s^{-1} and c is the velocity of light in m s^{-1}.

Since the emission is isotropic, the *emission coefficient* $\varepsilon_\lambda(x)$ from a volume element at position x containing N_u atoms or molecules in the excited state is

$$\varepsilon_\lambda(x) = \frac{10^{-9}}{4\pi} N_u(x) A_{ul} \frac{hc}{\lambda} P(\lambda) \ \ (\mathrm{W\,m^{-3}\,sr^{-1}\,nm^{-1}}). \tag{A1.3.10}$$

$P(\lambda)$ is the line shape function having an area normalized to unity. Do not confuse the emission coefficient ε_λ [18] with the spectral emittance $\varepsilon(\lambda,T,\theta)$ of a surface, which is a dimensionless quantity.

Suppose, we view a nonuniform extended source of depth D. The spectral radiance along a line of sight for a spectral line at wavelength λ is

$$L(\lambda) = 10^{-9} \int_0^D \varepsilon_\lambda(x)\mathrm{d}x \ \ (\mathrm{W\,m^{-2}\,sr^{-1}\,nm^{-1}}). \tag{A1.3.11}$$

This is only an approximation. When absorption is present the radiance does not depend linearly on atom density and is given by the radiation transport equation [18]. Examples of this important phenomenon are described in sections A1.3.6.1 and A1.3.7.1.

A1.3.4 Incandescent lamps

A1.3.4.1 Emission

Tungsten is the pre-eminent material for the manufacture of incandescent lamps. It has a melting point of 3680 K and it can be drawn into the fine wire necessary for making lamps. In normal household bulbs

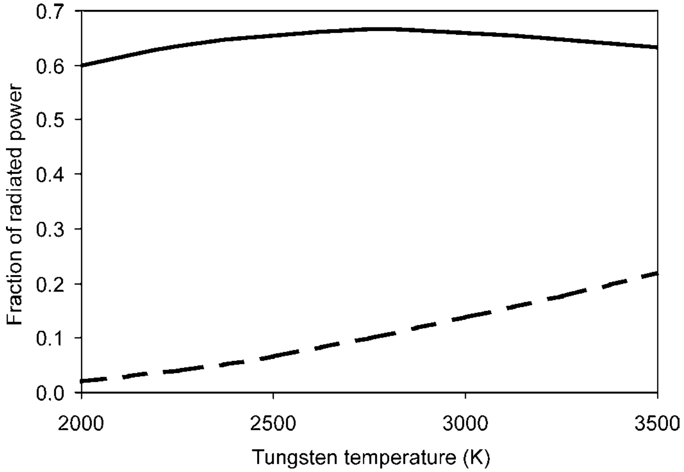

Figure A1.3.4. Calculation of fractions of power emitted from a typical coiled tungsten filament as a function of temperature. The dashed line is the fraction of power radiated at <750 nm (mostly visible but with a very small fraction of UV radiation). The full line is the IR fraction between 750 and 2000 nm. The remaining fraction is at wavelengths >2000 nm (after [1]).

the filament is operated at a temperature in the region of 2800 K, depending on the type. The comparatively low temperature is chosen to limit evaporation and give an acceptable life. This section will concentrate on the higher temperature tungsten–halogen lamps that have many optical applications.

A substantial fraction of radiation from a tungsten filament is emitted between 750 nm and the glass or silica cut-off in the IR. Figure A1.3.4 shows that the fraction of power radiated in the region 750–2000 nm is approximately independent of the tungsten temperature, whilst the visible fraction (<750 nm) doubles for an increase of 500 K in temperature.

A1.3.4.2 Tungsten–halogen lamps

Use of a halogen chemical transport cycle [8] allows tungsten filaments to be operated at higher temperatures than in the standard household bulb. For lamps of similar wattage and life the filament can be operated 100 K higher in a halogen lamp compared with a conventional lamp [1].

The halogen—usually a fraction of a μmol cm^{-3} of iodine or bromine—is added to the lamp before it is sealed. During operation of the lamp the halogen reacts with evaporated tungsten in the cooler regions. The tungsten halide thus produced is a vapour that is transported by diffusion and convection to hotter regions, where it dissociates depositing tungsten and releasing halogen for further clean-up. The dissociation mainly takes place at a region of the filament lead. The net effect of the cycle is therefore to transport the tungsten from the wall to regions of the lamp that do not affect light output.

Because the lamp walls remain clean, the bulb can be made very small and strong. High pressures of inert gas of high molecular weight suppress evaporation. With smaller, stronger bulbs containing high pressures of Kr, or even Xe, the tungsten may be operated at temperatures of up to about 3500 K.

The higher the filament temperature the greater the rate of evaporation and the shorter the life of the lamp. Filaments operating at a colour temperature of 3400 K (filament temperature ≈3330 K) will have a life of a few tens of hours. Life is also strongly dependent on operating voltage; manufacturers' data should be consulted for information.

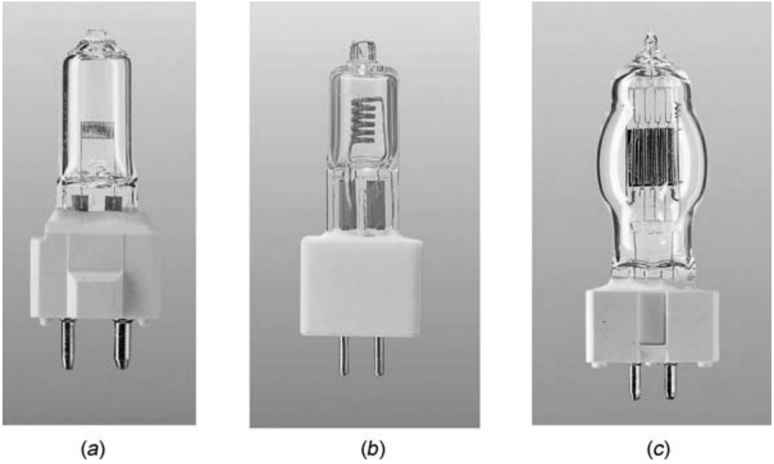
Tungsten–halogen lamps have the advantage over all other sources of having excellent stability. For best stability, lamps should be operated from a dc constant current supply with current controlled to 1 part in 10^4—this is the technique used for operating calibration lamps. The current should be set to ensure that the voltage rating of the lamp is not exceeded. When lamp stability is at premium (as for example in standards of spectral irradiance) optical equipment suppliers select particularly stable lamps (appendix—Oriel Instruments, Ealing).

A1.3.4.3 Varieties of tungsten–halogen lamps

The development of tungsten–halogen lamps has resulted in thousands of new products being introduced. For optical applications the most important consideration is often the ability to focus the light into a tight beam. This is affected by: the size of the filament, the tightness and evenness of winding of the coil, whether the coil is a flat or cylindrical, whether the coil is concentric with the bulb axis or normal to it, the quality and thickness of the bulb wall, and the type of glass used (hard glass can have better optical quality than fused silica). Examples are shown in figure A1.3.5. High colour temperature versions with powers in the range 25–1000 W or even greater are available. In some cases, these are made from silica that is doped to prevent emission of short wave UV. Consult manufacturers' web sites for 'special' lamps designed for particular optical applications.

A1.3.4.4 Lamps with integral reflectors

There is a wide range of tungsten–halogen lamps built into small reflectors. The reflectors may be aluminized, or have a dichroic (interference filter) coating allowing some IR radiation to escape from the rear of the reflector; this means that the beam is comparatively cool. They may also be fitted with cover glasses that reduce the already small amount of short wave UV that is emitted by fused silica tungsten–halogen lamps. Reflector diameters vary from 50 down to 35 mm. Versions are made with beam



(a) (b) (c)

Figure A1.3.5. Examples of tungsten–halogen lamps (not to scale). All are mounted in a ceramic base that is pre-focused to allow accurate replacement. (*a*) and (*b*) operate from low voltage at a CCT of 3000 K or more and in some cases as high as 3500 K. Lamp (*a*) has a flat filament especially suitable for projection. Lamp (*b*) has an axial filament suitable for use in reflectors for video applications. Lamp (*c*) is a mains voltage lamp for use in overhead projectors; available in ratings up to 900 W and CCT is 3200 K (Philips photographs).

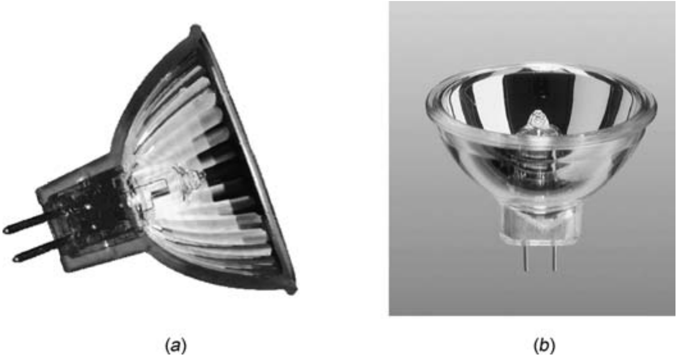


Figure A1.3.6. Examples of low voltage tungsten–halogen lamps in integral pre-focused reflectors. In (*a*) the reflectance of the coating has been reduced to show the positioning of the axial filament in the reflector (Osram). Assembly (*b*) has been specially designed for fibre optic illumination (Philips). Lamps for specific optical purposes are also available from most manufacturers.

divergences from a few degrees up to 40°. Typically wattages vary from 12 to 75 W with a colour temperature of about 3000 K.

These reflector lamps are used in large numbers for all sorts of commercial displays and accent lighting and therefore they are relatively inexpensive. In addition, all the major lamp manufacturers make special versions that are used in a number of optical applications such as overhead projection, microfilm and fibre optic illuminators. Figure A1.3.6 shows examples.

A1.3.4.5 Lamps with IR reflectors

Over 90% of the radiation from tungsten–halogen lamps is in the IR region and so is wasted. Many attempts have been made to return some of this radiation to the filament where it can be absorbed. Commercial success was eventually achieved by using multi-layer interference filters deposited by LP CVD [1]. Less input power is needed to maintain the tungsten coil at the design temperature. The main benefit therefore is a saving in power for a given light output. The beam is cooler since there is less IR radiation emitted although optical quality is degraded slightly by the coating. The main benefit is an improvement of up to 40% in the efficiency of generation of visible light.

A1.3.4.6 IR sources

Incandescent lamps using either tungsten or carbon emitters make use of the IR radiation in industrial heating processes (appendix—Heraeus). The main benefit is a heat source that can be controlled precisely and has a much shorter response time than a conventional oven.

The Nernst source is an example of a ceramic emitter electrically heated to 2000 K, used as an IR illuminator in spectrophotometers. This makes use of selective emittance in the IR. More recent versions of similar devices are given in manufacturers' data (see appendix—Oriel Instruments). There are also low heat capacity carbon emitters that can be modulated at low frequencies (appendix—Hereaus).

A1.3.5 Discharge lamps with electrodes

One way is to group discharge lamps into LP (low-pressure) and HP (high-pressure) types. In LP discharges, the electrons make relatively few collisions per second with the gas atoms and so electron temperature ⩾ gas temperature. In HP discharges, relatively frequent collisions between electrons and gas atoms ensure that both temperatures are approximately equal. The same physical processes occur in LP and HP discharges. Section A1.3.5.1 is concerned with the common features of both types. The electrode regions are described in section A1.3.5.2. Later sections describe their unique features.

Another way to group discharges is by the manner of coupling to the power supply. Most discharges have electrodes in which the cathode is hot; electrons are released into the plasma by thermionic emission. The term *arc* is not uniquely defined, but it is often taken to mean a discharge in which the cathode emits thermionically—examples are all HP discharge lamps and hot cathode fluorescent lamps. In *cold cathode* lamps, the electrodes emit as a result of ion bombardment of the cathode surface. Other discharges (section A1.3.9) are operated at high frequency using induction or microwave sources. Dielectric barrier discharges (DBDs) are transient and self-limiting with little or no emission of electrons from the cathode (section A1.3.9.2).

A1.3.5.1 Stable discharge operation of discharges with electrodes

To start a discharge, a high voltage must be applied to make the gas conducting, and (an electron) current from an external circuit must be passed from cathode to anode through the conducting gas. A by-product of causing the gas to conduct is the production of radiation. To demonstrate the main effects we will consider dc discharges although the majority of commercial lamps operate on ac (section A1.3.8.3).

We will illustrate the main features of a dc discharge using the LP mercury rare-gas discharge of the type used in fluorescent lamps as an example (figure A1.3.7). Other lamps including HP lamps have similar features, but the regions around the electrodes have dimensions that are usually too small to see. The bulk of discharge in figure A1.3.7—the positive column (PC)—is a plasma, so there are equal number of electrons and ions per unit volume. Some discharges such as neon indicators or deuterium lamps used for producing UV are so small that the PC does not exist.

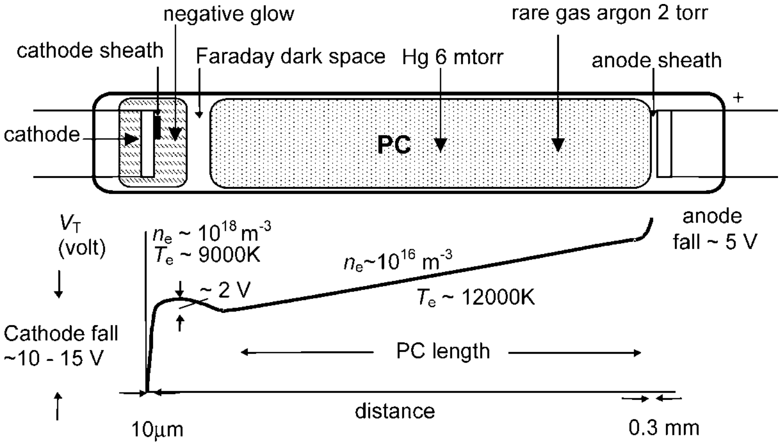

Figure A1.3.7. Structure of a dc discharge. This schematic diagram shows features visible in a typical fluorescent lamp discharge, but they are also present in other discharges. The upper picture shows the positive column (PC), which may be any length, together with the anode and cathode regions in which dimensions are dependent on vapour and pressure. The lower diagram shows the voltage drop V_T along the lamp. The cathode fall field adjusts so that sufficient electrons are extracted to maintain a stable current. Typical electron densities n_e and electron temperatures T_e are shown for the fluorescent lamp case.

In the PC, electrons form a near Maxwellian distribution of energies. Once the discharge has been established, the applied electric field causes the electrons to drift towards the anode and the ions to drift towards the cathode; because their mobility is much greater than that of the ions and the current is carried mainly by the electrons. Therefore, current density is approximately

$$j = n_e|e|\mu_e E \ \ (\mathrm{A\,m^{-2}}) \tag{A1.3.12}$$

where E is the electric field, μ_e the electron mobility, $|e|$ the electron charge and n_e the electron density.

The PC can be any length as long as sufficient open-circuit voltage is available from the supply (think of commercial display signs). A condition for stable operation is that the rate of loss of electrons by recombination with ions must be equal to the rate of gain caused by ionization. In LP discharges, most of the recombination occurs after the carriers have diffused to the wall; in HP discharges, particle densities are high enough for volume recombination to dominate.

The electric field in the column adjusts itself so that electrons are accelerated to a mean energy in the region of 0.5–1.5 eV corresponding to an electron temperature of about T_e of 6000–18000 K. The electron energy distribution then contains enough high-energy electrons to ionize atoms, replacing the electrons lost by recombination. Figure A1.3.7 shows that the electric field in the PC is constant, so in a given gas, the longer the lamp the higher the voltage.

A1.3.5.2 Electrode regions

Adjacent to the anode the voltage usually increases (figure A1.3.7). This is a result of a space charge sheath. If there was no sheath then the anode would only collect the random current. Normally the anode area is too small; to collect the current required it charges positively to attract electrons.

The cathode is more complex [21, chapter 4]. The conditions at the cathode surface have to adjust themselves so that each electron that leaves the cathode initiates events that cause the emission of at least one more electron from the cathode, otherwise the discharge will not be self-sustaining. Electrons emitted thermionically (hot cathode case) or by ion bombardment (cold cathode case) are accelerated in the high field of the cathode fall (CF) region. A beam of electrons from the CF region penetrates the cathode edge of the negative glow (NG) causing the production of positive ions that are accelerated through the cathode sheath. A fraction of these (~0.1) knocks further electrons out of the cathode. The process is entirely self-regulating; if the work function increases, the CF increases and the resulting extra ion bombardment heats the cathode surface to higher temperatures, producing more thermionic emission.

The velocities of electrons leaving the CF are strongly directed toward the anode. This beam is gradually randomized in the direction in the NG region. By the end of the NG they have lost enough energy for the excitation of atomic levels to decrease. This region of comparatively little light is known as Faraday dark space (FDS). At this point, electron motion has been randomized giving a near Maxwellian distribution. Finally as the electrons start to gain energy from the field again, excitation increases and this marks the start of the PC. The NG and FDS therefore serve to change the highly anisotropic electron distribution function coming from the CF into the random distribution in the PC.

In hot cathode lamps, the CF is usually a little greater than the ionization potential of the most easily ionized species (see figure A1.3.7). In cold cathode lamps, the CF is much larger because electrons must be extracted by secondary processes such as ion bombardment. Cold CF voltages are typically in the region of 100–200 V. The CF in cold cathode lamp can be reduced by using hollow cathodes [22].

A1.3.6 Types of LP discharges

By far the most important type is the LP mercury rare-gas discharge used in fluorescent lamps and in UV sources for photochemical and photobiological purposes (section A1.3.6.1). Other LP discharges not described here are LP sodium, used for street lighting of very high luminous efficiency, deuterium lamps used as UV illuminators and LP hollow cathode spectral sources for chemical analysis. There are also a wide variety of LP laser discharges.

A1.3.6.1 Low-pressure mercury rare-gas discharges

LP mercury lamps contain a rare gas, usually argon, krypton or neon or mixtures of these, at a pressure of a few hundred pascal (a few torr). Mercury is added as a small drop of liquid weighing a few milligrams, which collects at the coolest place in the lamp. At typical wall temperatures, the mercury evaporates from the liquid drop at the pressure of about 0.8 Pa (0.6 mTorr). Despite the relatively low number density of the mercury atoms they dominate the properties of the discharge. The fluorescent lamp discharge is a highly efficient emitter of UV in the mercury resonance lines at 254 and 185 nm (>70%).

Phosphors are used to convert UV to visible radiation [9, chapter 7]. Lamp phosphors are ionic materials doped with activators that absorb at short wavelengths and then re-emit at longer wavelengths. The energy deficit in this *Stokes*' shift is converted into lattice vibrations. In fluorescent lamps used in lighting the conversion loss is typically 50%. There is a very large range of phosphors [9, chapter 7], and fluorescent lamps giving white light of many different CCTs and other colour properties are available. Particularly important are the ionic rare-earth based phosphors as these emit at the wavelengths that combine high efficacy and colour rendering index (R_a—section A1.3.3.5). The principle ones are noted in table A1.3.1; notice how close the peaks are to the 450, 540 and 610 nm wavelengths that optimize colour rendering and efficacy.

The notation in table A1.3.1 is the chemical composition of host lattice:activator. The activator is an ion added deliberately at relatively small concentrations to absorb UV and emit visible light. In some cases, the host lattice has this same function. Quantum efficiencies are close to unity.

One very important benefit of rare-earth phosphors is their resistance to degradation by mercury discharges at high power leadings. It is this property that made possible the development of compact fluorescent lamps. The disadvantage is the high cost of rare-earth phosphors compared with the halophosphates that they have largely replaced. The complexity of the materials in table A1.3.1 is such that phosphor research is still largely empirical, so the existence of each of these phosphors represent many man-years of painstaking research.

Table A1.3.1. Phosphors commonly used in fluorescent lamps.

Name	Formula	Wavelength of peak output (nm)
YEO	$Y_2O_3{:}Eu^{3+}$	611
CAT	$Ce_{0.65}Tb_{0.35}MgAl_{11}O_{19}$	543
LAP	$LaPO_4{:}Ce^{3+},Tb^{3+}$	544
CBT	$GdMgB_5O_{10}{:}Eu^{2+}$	545
BAM	$BaMg_2Al_{16}O_{27}{:}Eu^{2+}$	450
Halophosphate	$Ca_5(PO_4)_3(F,Cl){:}Sb^{3+},Mn^{2+}$	broad bands

The mercury vapour pressure is a dominant factor in controlling the amount of radiation emitted and the efficiency with which it is generated. When a mercury atom is excited near the centre of lamp, the emitted photon is at exactly the correct energy to be absorbed by a ground state atom nearby. The photon is absorbed and reabsorbed many times before it finally reaches the wall in a random walk. When the mercury pressure is high, there are so many steps in the random walk that the chance of losing the excitation energy nonradiatively in a collision increases. When the mercury vapour pressure is low the initial excitation energy can escape in a small number of steps, but then the fraction of collisions that lead to excited mercury atoms is low. (The related process in HP lamps is described in section A1.3.7.1.)

This means there is a mercury vapour pressure at which the efficiency of generation of UV radiation is at a maximum. This optimum pressure is achieved by having a small amount of liquid mercury present at about 42 °C. When using fluorescent lamps it is important to arrange for the fixture or unit holding the lamps to operate so that the mercury pressure is close to optimum. Lamps are designed to run close to optimum in commercial lighting fixtures. For other uses, such as backlighting some cooling may be necessary. Some types of multi-limb compact fluorescent lamps are designed for operation in hot fixtures. In these, the mercury is dosed as a solid amalgam containing, for example, bismuth and indium. The vapour pressure of mercury above the amalgam is less than that above free mercury, but the use of an amalgam also substantially increases the ambient temperature range over which the mercury pressure is close to optimum [2].

A1.3.6.2 Applications of LP mercury discharges

The fluorescent lamp discharge lends itself to many different formats [9, chapter 7]. The most familiar are the long thin lamps used in ceiling lighting in nearly all commercial and industrial premises. There are also a wide variety of compact fluorescent (CFL) designed as a high efficiency replacement for incandescent lighting.

Other than illumination, important applications for fluorescent lamps are in office equipment (copiers, fax machines, etc) and in the backlighting of displays. Cold cathode fluorescent lamps have a number of benefits: they can be small in diameter allowing screens to be very thin; at the low powers needed they are efficient enough for the purpose; lives are long; they can be switched frequently; and low cost, efficient power supplies are readily incorporated in the end product. Hot cathode fluorescent lamps produce more light and can be used to backlight displays that are used in high ambient light levels such as ATM machines. Short wave radiation from hot cathode mercury rare-gas discharges is used in photochemical or photobiological processes; or it can be converted using a phosphor to UVA (as in 'black light' sources) that show up fluorescence in materials.

A1.3.7 HP discharges

There are many variants of HP discharges. Most of them are used for street lighting and interior illumination of stores and offices and other commercial premises, in which high luminous flux, high efficacy, good colour quality and long life are at a premium. Lamps exist in *single-ended* (both connections at one end) and *double-ended* (one connection at each end) configurations to suit different applications. Many other types of HP discharges are used in which light must be projected and high brightness is needed. Some of the properties of HP discharges are described below. The two main classes of lamp are those that use volatile or gaseous elements, and those that use metal halides to introduce radiating species into the vapour.

A1.3.7.1 General features of HP discharge lamps

We will illustrate the operation of HP discharges by using the HPS (high-pressure sodium) lamp as an example. An HPS lamp has electrodes inserted into a narrow arc tube made from translucent alumina, resistant to attack from sodium. As with many HP lamps the arc tube is contained within a glass outer bulb. These lamps are used as highly-efficient (120 lm/lamp watt) long-lived ($>$20000 h) street lights that give a pleasant golden light with CCT = 2000 K, albeit with rather poor colour rendering properties ($R_a = 25$).

The dimensions of the tube are typically 7 mm internal diameter with 70 mm length between the electrode tips for 400 W rating, with dimensions decreasing for lower wattage lamps. They contain a small pressure of rare-gas and a few milligram of sodium metal. On applying a voltage the rare gas breaks down. The resulting discharge heats and evaporates sodium until its pressure is about 1.4×10^4 Pa (100 Torr). A radial temperature profile develops in which the centre temperature is about 4000 K and the wall temperature is about 1500 K. Most of the length of the discharge is a positive column uniform along the axial direction. Sodium lamps usually also contain about 10^5 Pa (760 Torr) of mercury vapour. This reduces thermal conduction and increases axis temperature, thus increasing spectral radiance.

The positive column is approximately in local thermodynamic equilibrium (LTE) [18]. This means that the properties are dependent on the local temperature in the plasma. The electron density is given by a version of the law of mass action called the Saha equation [10]

$$\frac{n_e n_i}{n_a} = S(T) \quad (\mathrm{m}^{-3}) \tag{A1.3.13}$$

where n_e and n_i are the electron and ion densities, n_a is the density of atoms (number per m^3) and

$$S(T) = 4.83 \times 10^{21}\,(U_i/U_a)\,T^{3/2}\exp(-E_i/kT) \quad (\mathrm{m}^{-3}) \tag{A1.3.14}$$

where the U factors are partition functions for the ion and atom. $S(T)$ depends strongly on temperature through the exponential factor, where E_i (J) is the ionization potential (including corrections for high electron density) and k is Boltzmann's constant. Since the hot gas is a plasma $n_e = n_i$. The atom density n_a in an elementary volume at temperature T is given by the gas law so $n_a = P/kT$ where P is the gas pressure. Table A1.3.2 shows values of n_e in sodium vapour at various temperatures. Since the current density is proportional to n_e it is clear that the current flow is mainly in the high temperature region.

The population n_u of an energy level of an atom (labeled u) is given by another LTE formula:

$$n_u = \frac{g_u}{g} n_0 \exp\left(\frac{-E_u}{kT}\right) \quad (\mathrm{m}^{-3}) \tag{A1.3.15}$$

where n_0 is the density of atoms in the ground state, E_u is the energy (J) of the upper state of the atom, whilst g_0 and g_u are the statistical weights of ground and upper states, respectively. The number of atoms excited to the upper state depends exponentially on temperature. Because of the exponential *Boltzmann factor* in equation (A1.3.15), the fraction of atoms in the excited state u is very small even at the highest temperatures. Only in the hottest parts of the discharge are significant numbers of atoms excited; the resulting 'corded' appearance is a characteristic feature of an LTE arc. When a HP discharge operates horizontally convection bows the bright part upwards—the origin of the term arc. The importance of equations (A1.3.13) and (A1.3.15) is shown in table A1.3.2.

Self-absorption dominates the spectrum of many HP discharge lamps and is especially dominant in HP sodium discharges. As figure A1.3.8 shows there is no significant radiation at 589 nm, the wavelength at which sodium radiates at low pressures. In an HPS lamp, the sodium pressure is so high that photons

Table A1.3.2. Shows how the plasma temperature affects the number density (m^{-3}) of excited states and ions. Electron density is equal to ion density. There are two excited states at about 2.1 eV giving rise to the characteristic orange sodium D radiation. The ionization potential is 5.14 eV before correction is made for lowering of the value at high electron densities. The arc operates so that the electron density is sufficient to carry the current and the plasma temperature adjusts to make this so. For steady state sodium arcs this sets the maximum plasma temperature to about 4000 K. Calculated using equations (A1.3.13) and (A1.3.15).

	Plasma temperature (K)			
	2000	3000	4000	5000
Number density of sodium atoms	4.8×10^{23}	3.2×10^{23}	2.4×10^{23}	1.9×10^{23}
Fraction of sodium atoms excited to the states radiating at 589 nm	1.5×10^{-5}	8.8×10^{-4}	6.4×10^{-3}	2.3×10^{-2}
Fraction of sodium atoms that are ionized	7.3×10^{-6}	1.9×10^{-3}	3.5×10^{-2}	2.2×10^{-1}

from excited sodium atoms can only travel about 10^{-7} m at the line centre before being absorbed by a ground state atom. However, there is a chance that very close collisions with other sodium atoms can perturb the radiating atom sufficiently so that it radiates at wavelengths far from the line centre at 589 nm. The hot plasma can therefore be considered as storing excitation energy until the energy can escape from an atom having strongly perturbed energy levels. The higher the pressure, the further from the line centre the wavelength has to be, before the light can escape (figure A1.3.8). This behaviour is called self-reversal and it has a dominating effect on the operation of many HP discharges [9, section 5.6.3]. The cover of the book by de Groot and van Vliet [10] shows beautiful colour photographs of the self-reversal of the sodium D lines at different pressures.

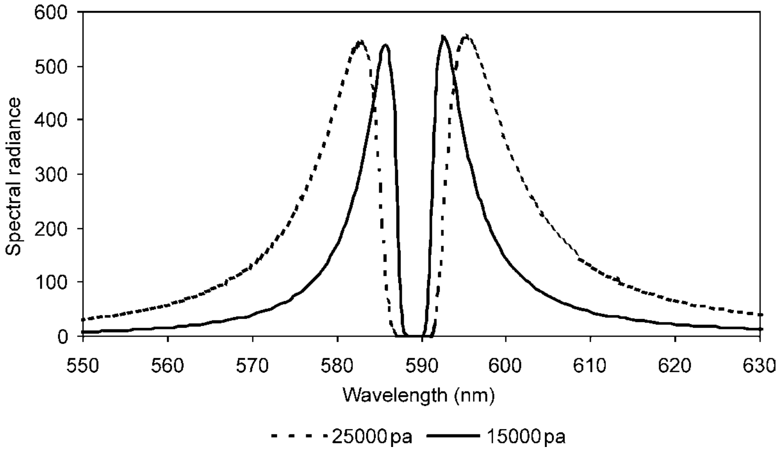

Figure A1.3.8. The formation of self-reversed lines in high-pressure sodium lamps at two sodium pressures. The calculation has been done for a parabolic radial temperature profile for a centre temperature of 4000 K and a wall temperature of 1500 K. Comparison with figure A1.3.1 shows that the peak radiance is substantially lower than that for a black body at the maximum temperature.

A1.3.7.2 HP metal halide lamps

There are very few elements that have well-placed spectral lines *and* sufficiently high vapour pressures to be operated as HP discharges, the most important being mercury, sodium, sulphur, and the permanent gases (of which Xe is by far the most important).

There are perhaps 50 elements that have metal halides that are sufficiently volatile to be used in HP lamps. The principal ones are as follows:

- Na, I, In, Tl, Ga halides in which the metals have relatively few strong atomic lines
- Sc, Fe, Dy (and other rare earth) halides in which the metals have many relatively weak visible lines so close together that the spectrum appears continuous at moderate resolution.
- Sn, Pb and similar halides that form relatively stable monohalide molecules that emit a spectrum that appears continuous at low resolution.

The halide is usually the iodide, which has the least reactive chemistry.

Metal halide lamps are extensively used as efficient white light sources of good colour quality for general illumination; all major lamp manufacturers make them (appendix). Because the spectrum can be tailored to use, metal halide lamps are used extensively for production of UV for photo-polymerization processes, such as ink drying or glue curing (appendix—Heraeus). These lamps are installed as part of large production processes in the printing and packaging industries. The speed of curing is often the bottleneck in the processes, so with suitable UV sources productivity can be increased. HP mercury lamps are also used for similar processes. Other uses of metal halide lamps include special versions for medical conditions such as psoriasis (appendix—Osram).

A1.3.7.3 Operating principles of metal halide lamps

Many metal halide lamps contain thallium iodide (TlI). TlI is considered as a simple case to illustrate how the light is produced in metal halide discharges. Figure A1.3.9 shows a schematic diagram of a HP TlI discharge. When the lamp is made, a few milligram of solid TlI and a rare gas for starting are added. Usually enough mercury is added to give a partial pressure of about 10^6 Pa (10 bar) to reduce thermal conduction and to adjust operating voltage (section A1.3.7.1). When the lamp is operated, the rare gas discharge heats up the Hg and TlI causing them to evaporate. In higher temperature regions, the TlI dissociates into Tl and I atoms. At higher temperatures still the Tl is excited and emits intense green light of high efficiency that can be useful for underwater illumination. Finally, near the axis the Tl is ionized producing the electrons needed to carry the current. This progressive evaporation, dissociation, excitation and ionization occurs in all metal halide discharges.

With mixtures of halides the ratio of salts has to be chosen with due consideration to the chemistry of the liquids and vapours. For example, one of the first types of metal halide lamp used mixtures of indium, thallium and sodium iodides that emit blue, green and orange self-reversed spectral lines. Altering the proportions of these can provide white light discharges of different colour temperatures and quite good efficacy (luminous efficiency). However, their colour rendition is rather poor.

Metal halide arc tubes are generally shorter than HPS lamps (for which the length to diameter ratio is more constrained by requirements of optimization) and may even be close to spherical in shape. This has an effect on étendue and may make fixtures using these lamps more efficient at using the light.

There has been extensive research and development over the last 40 years that has produced mixed metal halide lamps with much improved colour performance and efficacy. The halides used, their vapour

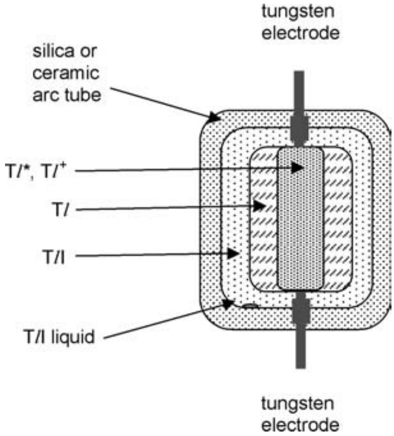

Figure A1.3.9. The principle of operation of a metal halide discharge. In this example solid thallium iodide (T*l*I) is dosed into the lamp along with a rare-gas. The discharge starts in the rare gas, melting and then vaporizing the T*l*I. In the steady state the current is provided by ionising T*l* atoms. For this to happen the temperature on axis needs to be above 5000 K. At this temperature T*l* atoms radiate strongly with their characteristic green line at 535 nm. The boundaries between the various regions are not sharp as shown schematically here, but blend into each other as the temperature increases from the wall to the axis. In a practical lamp, mercury vapour is also introduced at several bars to reduce thermal conduction losses.

pressures and their relative proportions all have a strong influence on the initial colour properties and efficacy.

It is important that these properties stay constant through lives of 10 000 h or more. Reactions between the various components and the tube walls occur at different rates; all metal halide lamps show some colour shift during life. Detailed R&D has improved the colour stability of metal halide lamps in silica arc tubes so that it is acceptable in critical applications such as the lighting of stores and offices. A recent major improvement has been in the use of translucent alumina ceramic arc tubes for containing Na, Dy, Tl, HgI metal halide arcs. Metal halide reactions with the envelope are much slower than with silica and this has provided a further major improvement in initial colour uniformity and colour stability through life.

Most metal halide lamps are used for illumination where the transparency of the arc tube is not an issue, but the scattering by the arc tube is a major disadvantage for projection. For projector and automotive head lamps, silica arc tubes are universally used. Because the axis temperature of metal halides is usually around 5500 K, the radiance of the gas close to the axis can be very high (see figure A1.3.1).

A1.3.7.4 Applications of HP discharge lamps

Table A1.3.3 gives information about HP lamps used for general illumination. It is intended to show the range of types available with some idea of the best characteristics to be expected. All types exist in more than one power rating, but the rating given is a fairly typical one for the indicated application and type. Generally efficacy increases as power rating increases [9, appendix 1].

Table A1.3.3. Indicative characteristics of HP discharge lamps used for general lighting.

Lamp type	Application example	Power (W)	Initial (lm W^{-1})	Life (10^3 h)	CCT (K)	R_a
HPS	Road lighting	400	125	30	2000	25
High CRI	Prestige town lighting	400	100	24	2200	60
HP mercury vapour + phosphor	Road lighting	400	60	24	3500	55
Metal halide	Prestige outdoor, stores	400	90	24	4000	70
CMH	Commercial interiors	100	90	12.5	3000	85

Most of the lamps that are in the table are arcs with positive columns of length of several centimetres that are stabilized by the tube wall. The CMH lamp is a short arc lamp in which the arc is mainly stabilized by the electrodes.

Manufacturers' web sites give many examples of applications other than for illumination. All the major lamps manufacturers make a variety of metal-halide and xenon short arc lamps for projection and related uses (appendix). In short arc lamps (length $<$ few millimetres) there are usually regions close to the electrodes that have particularly high arc temperature. This region of high arc temperature forms because the electrodes cool the arc, and the field close to the electrodes has to increase to maintain conduction; moreover the current density normally increases as the arc contracts toward the cathode hot spot. The combined increase in current density and field means that the power per unit volume of arc is greatest just adjacent to the electrode. Although this generally leads to a reduction of efficacy there may be an increase in luminance. Figure A1.3.10 shows examples of lamps that are used for a variety of projection and entertainment applications and other more specialized applications such as solar simulators.

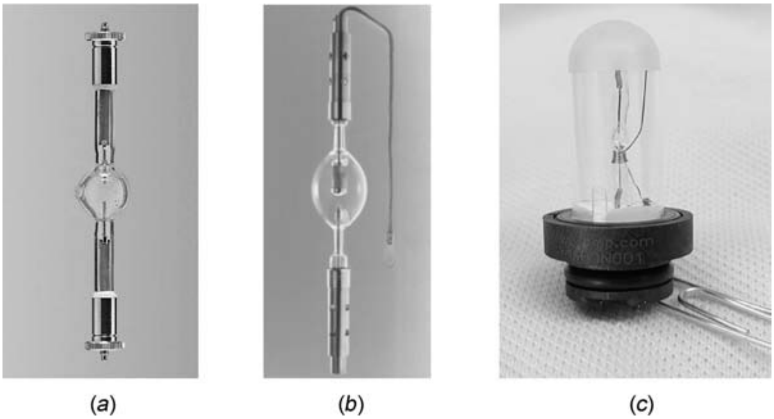

Figure A1.3.10. The large range of powers possible with HP discharges is shown. Not to scale. (*a*) An example of a metal halide lamp for entertainment applications with a CCT of about 6000 K, available in ratings between 575 and 12000 W (Philips). (*b*) An example of a high pressure xenon lamp operated from dc with a CCT of 6000 K, available in ratings between 450 and 12000 W (Osram). (*c*) A 10 W metal halide lamp operating with CCT around 6000 K and ratings between 10 W (Welch-Allyn).

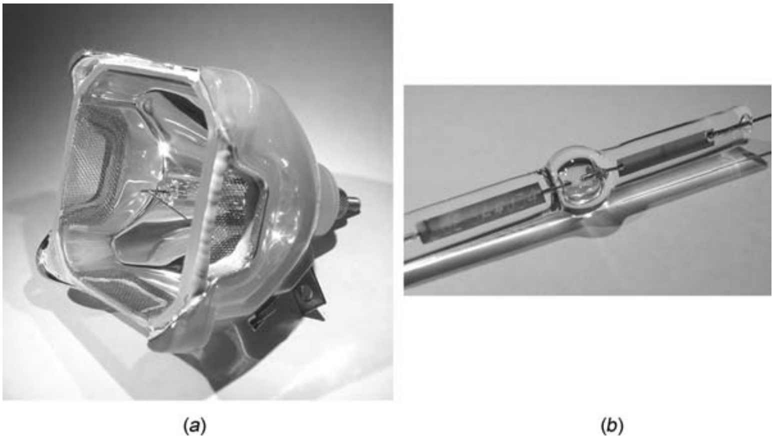

(a) (b)

Figure A1.3.11. (*a*) A pre-focused projection unit designed for LCD projectors. The reflector is carefully designed to keep étendue of the pre-focused unit as low as possible and has a dichroic filter to reduce the amount of IR in the beam. (*b*) The arc tube used in the reflector. It operates at 130 W and a CCT of about 6200 K with a mercury pressure of more than 150 bar. The arc gap of about 1.2 mm with consequently low étendue. (Philips, Osram, GE Lighting.)

Short arc metal-halide lamps can readily be integrated into pre-focused parabolic or elliptical reflectors (appendix—Welch Allyn, Ushio and others). Various beam divergences are available to suit different applications. A relatively recent development is shown in figure A1.3.11 (appendix—Philips, Osram and GE Lighting). This very high-pressure (1.5×10^7 Pa or 150 bar) has extremely high luminance because of its extremely high arc temperature. The reason for the high arc temperature is that 130 W are dissipated in an arc of length hardly more than a millimetre. Spectral lines show extreme broadening and there is an intense continuum giving good colour rendition. With an arc gap of only 1.2 mm the étendue is very small. The lamps are designed to be operated in a pre-focused reflector and the whole assembly used in data or video projectors.

A1.3.8 Electrical characteristics of discharges

A1.3.8.1 Breakdown and starting in discharge lamps

The gas in the lamp must be converted from an excellent insulator into a good conductor with a resistance that can be as low as a few ohms. Figure A1.3.12 shows the voltage across the lamp as a function of current over a very wide range of currents. After breakdown, the current increases rapidly until finally it stabilizes at the value needed to satisfy the circuit equations. In order to start the lamp, the circuit must be able to provide a voltage in excess of the highest lamp voltage in this diagram.

In order to achieve breakdown some source of electrons is necessary. If not provided by other means, they result from ionization by cosmic rays or natural radioactivity in the materials of the lamp. In other cases reliable breakdown is aided by the addition of small amounts of radioactive materials such as Kr^{85}, or by photoemission from surfaces caused by a small external source of UV. In hot cathode fluorescent lamps the electrodes can be heated before the voltage is applied: at low temperatures the field-enhanced thermionic emission provides enough electrons [21]. In HP lamps, a third trigger electrode is often included adjacent to the main electrode. When the voltage is applied across this small gap, breakdown is

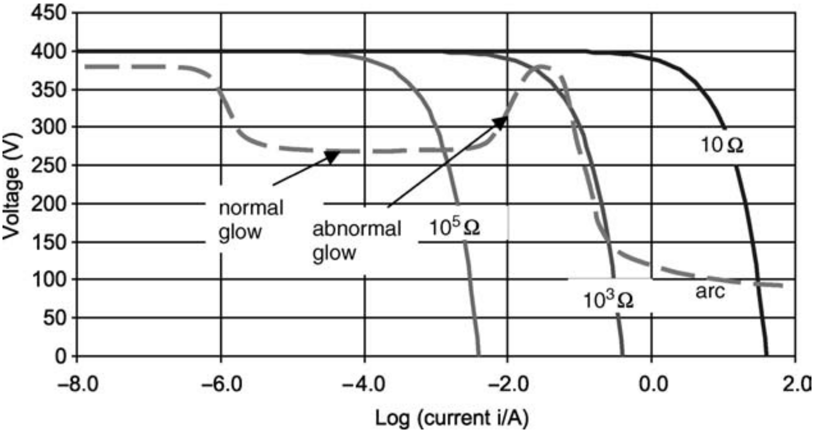

Figure A1.3.12. Discharge voltage as a function of current (dashed line) over a wide range of currents. The well-known discharge regions are shown. The voltage in the arc region is small because of the low cathode fall resulting from hot cathode operation. The load lines for various values of series resistance are shown with intersections in the normal glow, abnormal glow and arc regions. The intersection in the abnormal glow region may not be stable.

assured; this gap then provides initial electrons for the main gap. A general rule is that the fewer the initial electrons the higher the starting voltage needs to be, and the longer the time lag before breakdown.

The majority of lamps operate with hot cathodes that emit thermionically. Once breakdown has been achieved the transition from abnormal glow to arc in figure A1.3.12 must be achieved quickly and cleanly. Staying too long in the region of cold cathode operation, in which the electrons released by ion bombardment can be very damaging and shortens lamp life, sometimes dramatically.

There are various schemes for starting fluorescent lamps [21] in which the electrodes are tungsten coils coated with electron emission mix. One of the most common is to use a starter switch in parallel with the lamp. The starter switch is wired so that when closed, current limited by the ballast is passed through both electrodes. Initially the starter switch is closed. This preheating process raises the temperature of the electrode to about 1000 K before the starter switch opens. On opening the switch the open circuit voltage plus the self-induced voltage across the inductance is applied across the lamp, causing breakdown. The main purpose of preheat ensures that thermionic emission occurs very soon after breakdown. The switch is usually a relatively inexpensive bi-metallic type. The tolerances on starter switch operation are closely constrained according to the lamp type. Increasingly fluorescent lamps are operated from electronic ballasts. It is a relatively simple matter to include a precision electronic preheat circuit to enhance the lamp life. At the low cost end, preheat is not included; after breakdown the electrode is heated rapidly by ion bombardent until it reaches thermionic emitting temperatures. Up to this time secondary emission dominates but the ion bombardment heats the cathode; these so-called instant start lamps generally have shorter life than lamps that are preheated.

For HP lamps, preheating is not an option. Starting from cold when the pressure is around 10^4 Pa (0.1 bar), breakdown voltages in the region of some kilovolts are needed. After an HP lamp has stabilized the pressure may be many atmospheres; on turning off it will require some tens of kV to restart immediately. Various types of pulse ignitor are used. The speed of transition from the glow to the arc is sensitive to many factors related to electrode design, lamp fill, processing quality and the open circuit voltage available. Ballast and lamp designers work together to ensure that the glow to arc transition in figure A1.3.12 occurs rapidly and cleanly to ensure long life.

A1.3.8.2 Steady state electrical characteristics

For an *ohmic* conductor the number of carriers is independent of current, so changing the voltage simply changes the mean drift velocity of the carriers. As long as the temperature remains constant the current is proportional to voltage—Ohm's law. If the temperature increases the carrier mobility decreases and the resistance increases. This is what happens in tungsten lamps in which the hot resistance can be 15 or more times higher than the cold resistance.

Discharges show strongly *nonohmic* behaviour (figure A1.3.12). A discharge is a current-controlled device; and the voltage between the terminals sets itself to maintain this current. An additional impedance called a *ballast* is necessary to control the current. In response to increasing current hot cathode discharges respond by decreasing the voltage across their terminals. This is the so-called negative, or falling V–I characteristic. The rate of decrease of voltage with current is usually quite small. This corresponds to the arc region on the right hand end of figure A1.3.12 where the lamp voltage is comparatively low.

Figure A1.3.12 shows what happens to voltage as the current is increased over many orders of magnitude. Increasing from low values of current the voltage decreases to a plateau region in which a glow is visible on the cathode. On increasing the current, the glow increases in area whilst the voltage remains constant, implying that the current density at the surface of the cathode is constant. This is called the *normal glow* regime. As the current is increased further, the glow finally covers all the cathode area and often the leads as well. At this point, the current density has to increase and the voltage across the terminals increases. This is called the *abnormal glow* region. In both the normal and abnormal regions, the major part of the lamp voltage is dropped across the CF. The resulting ion bombardment increases the cathode temperature and the cathode begins to emit thermionically and makes a transition to the arc regime, which has a low CF. The abnormal glow region has a positive resistance characteristic, but this is not stable unless there is a ballast in the circuit.

For a dc discharge a series resistance R is needed to stabilize the current I. If the supply voltage is V_S and the lamp voltage V_T then

$$V_T = V_S - IR \quad (\mathrm{V}) \tag{A1.3.16}$$

The right hand side of this equation is called the load line. Load lines for three resistances are shown in figure A1.3.12. For the highest resistance the intersection point is in the normal glow region (typical of a neon indicator lamp). With the lowest resistance the intersection is in the arc region. The intermediate resistance has two intersections, the one at the lowest current is in the abnormal glow region. If the heating of the cathode is insufficient to cause a transition to an arc, then the lamp remains in the abnormal glow condition. In some cases when starting an arc the discharge sticks in the abnormal glow with a high cathode fall; the sputtering can then cause very rapid blackening of the walls and premature failure.

Despite what the manufacturers' data sheets may say, figure A1.3.12 suggests that there is no specific power at which a discharge must operate; adjusting lamp current by using ballast impedance and supply voltage means lamps may be operated at a wide range of powers—at least for a time. The consequences of operating at powers different from the rated power are usually a reduction in life; properties such as colour temperature and colour rendering and efficacy will also change. Nevertheless, for specific applications this is an option that the user can consider.

The reason for needing a ballast is best explained by using an argument given by Waymouth [21, chapter 2]. Figure A1.3.13(*a*) shows the falling arc characteristic (part of the right hand end of figure A1.3.12). This characteristic is the locus of points for which $\mathrm{d}n_e/\mathrm{d}t = 0$. The further above this line the more the rate of ionization exceeds the loss, so the current increases, and this increases $\mathrm{d}n_e/\mathrm{d}t$, with the result that the current continues to increase. If the applied voltage is below the line the loss exceeds production, the current decreases and the discharge extinguishes. Figure A1.3.13(*b*) shows the effect of a

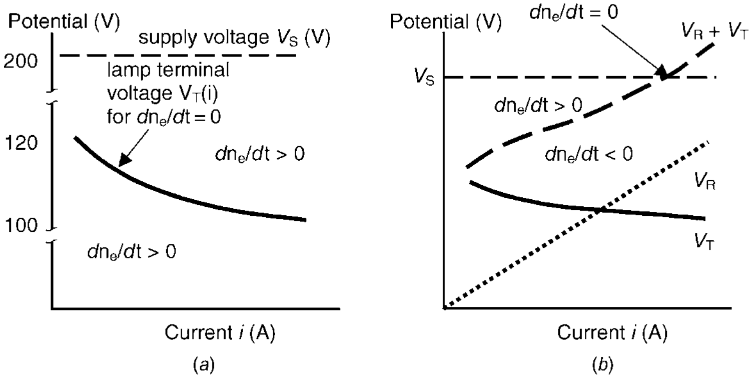

Figure A1.3.13. (*a*) A section of the arc region of figure A1.3.9. The solid curve is the locus of points for which $dn_e/dt = 0$. If a discharge without a ballast could be prepared at a point on this line small fluctuations would cause the current to increase without limit or decrease to zero. (*b*) Shows the effect of a stabilizing ballast resistor. The voltage across the circuit is now the sum of the lamp voltage V_T and the resistor voltage V_R. If the current fluctuation increases the current, the sum of resistor and lamp voltage increases into a region where $dn_e/dt < 0$ and the current immediately decreases again until $V_R + V_T = V_S$. This operating point is therefore stable against lamp current fluctuations.

series ballast resistor. The total circuit voltage $V_T + IR$ now intersects the supply voltage at a certain current. If a fluctuation causes the current to increase, then the total circuit voltage moves into a region where $dn_e/dt < 0$, thus immediately decreasing the current. If the current decreases, then the total circuit voltage decreases so that $dn_e/dt > 0$, thus increasing the current again.

A1.3.8.3 AC operation

Resistive ballasts work satisfactorily, but are lossy. Commercial lamps operate from the ac mains supply using magnetic inductances as ballasts [9, chapter 17]. Figure A1.3.14 shows the lamp voltage and current waveforms for a fluorescent lamp on a resistive ballast. At 50 Hz there is an appreciable re-striking voltage after current zero. This extra voltage is needed to restore the electron density after it has decayed during the latter part of the previous cycle. If this re-strike voltage exceeds the supply voltage the lamp will extinguish. The phase relationships in an inductive circuit mean that a large voltage is available at the time that the current reverses, so extinction is less likely. For stability on ac mains supplies with a series inductance, the rms lamp voltage should not exceed about half of the rms mains voltage.

Most lamps are now developed to operate from electronic power supplies. Although more expensive than magnetic ballasts, there are a number of benefits: in fluorescent lamps there is an improvement in efficiency of UV production because of reduction in electrode loss and an increase in PC efficiency; electronic circuits can also provide programmed start and run-up sequences that prolong lamp life; there is no perceptible 50 or 100 Hz flicker from lamps run from electronic circuits at high frequency; and there is no re-strike peak. Figure A1.3.14 shows typical waveforms at 50 kHz. In the case of HP discharges, operation at high frequencies can cause acoustic resonances that result in gross movements or distortions of the arc [10]. The electronic option is then to operate the lamp from a commutated dc—a square wave with fast transition times at frequency in the region of 90–500 Hz. For HP discharges, the lack of flicker and the ability to control lamp power (and thus colour) over life are important benefits.

The optical radiation from discharge sources fluctuates by a percent or two. Part of this is caused by small changes in the cathode termination resulting in arc movement. It has recently been found that

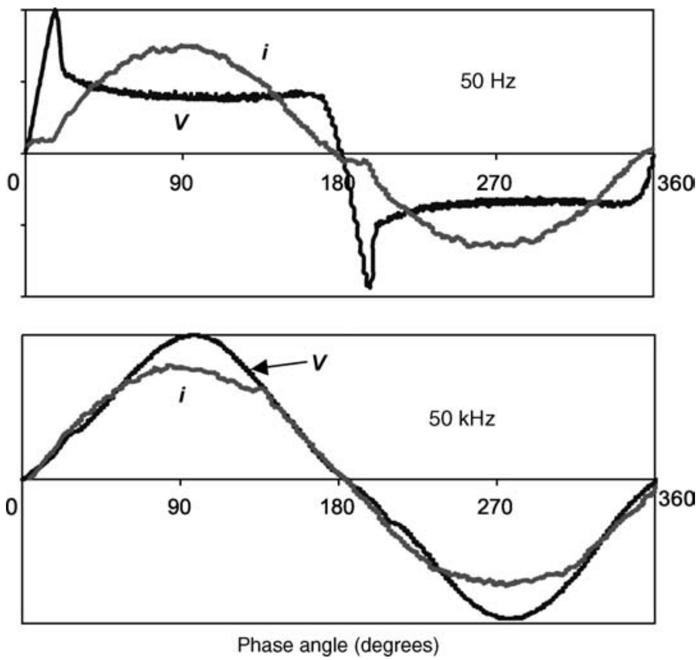

Figure A1.3.14. Measured voltage and current waveforms for a fluorescent lamp operated at frequencies of 50 Hz and 50 kHz. Noise on the waveforms is caused by oscilloscope digitization.

modified square wave supply waveforms can reduce the movement of the arc termination on current reversal [11]. A great improvement in stability can also be achieved by measuring the light output and using it to adjust the power into the lamp (appendix—Oriel Instruments, Light Intensity Control System). A similar device can also be used to control the already excellent stability of tungsten–halogen lamps.

A1.3.9 Other methods of excitation of discharges

A1.3.9.1 Pulsed light sources

A number of lamps are designed for pulsed operation [17]. The obvious example is the xenon flash tube used for photography, laser pumping, as warning beacons and as a transient source for scientific studies. The duration of the flash is of the order of microseconds with repetition frequencies up to hundreds of hertz. Operation is by discharging a capacitor through the lamp. Peak currents may reach thousands of amperes and electrodes must be constructed accordingly. The effects of using pulsed or transient output are that electron temperature can reach substantially higher values than in steady state. The result is usually due to an enhancement of the short wavelength radiation and an increase in peak radiance.

A1.3.9.2 Dielectric barrier discharges

A form of transient discharge, DBDs have been used for large-scale industrial processes such as ozone generation for water purification and for generating far UV radiation for photochemical processes. DBDs may be operated in the pressure range from about 10^2 to 10^5 Pa [16].

Recently a DBD light source, the Osram Planon lamp has been developed. This provides a very uniformly lit tile-shaped area of reasonable luminous efficiency. At present, lamps are made in square format with diagonals up to 540 mm having a uniform luminance of $>6000\,\mathrm{cd\,m^{-2}}$ (appendix—Osram) [14].

The operating principle of a DBD is as follows. High voltage pulses (of some kilovolts) are applied between two electrodes, at least one of which is covered with an insulator of high breakdown strength such as glass. On applying a high voltage pulse, electrons are accelerated towards the anode and form an avalanche that breaches the gap. Electrons arriving at the anode charge up the surface, thus reducing and finally reversing the electric field. Electron current flows first from cathode to anode and then, when the anode charges up, from anode to cathode. The discharge lasts for a time $\sim\mu\mathrm{s}$. During the off period the ionization decays, providing the starting conditions for the next pulse. The discharge therefore comprises a series of micro-discharges with lateral extent approximately equal to the electrode spacing. Microdischarges occur every time the pulse is turned on. DBDs have extremely non-Maxwellian energy distributions in which there are many high energy electrons. Because of this the excitation of resonance states of rare-gas atoms and molecules is favoured, leading to high efficiency of UV production.

The Planon lamp is formed from two glass plates. On the lower plate, a metal cathode interlaced with a metal anode structure is deposited. Both electrodes are coated with glass to form the barrier layers. This form of electrode structure results in very uniform illumination. The lamp is operated from an electronic power supply designed to produce the optimized pulse sequence that is necessary for high efficacy. The two plates are held apart by spacers and the whole structure is sealed and filled with Xe at about 1.4×10^4 (100 Torr). Xe forms an excimer $Xe_2{}^*$ (excited dimer) that radiates efficiently in the vacuum UV at about 172 nm. Phosphor on the inner walls converts the UV to visible radiation. The use of Xe means that the output is almost independent of the lamp temperature so the lamp works just as well outside in cold weather as it does in the confines of office equipment.

The main applications are in displays and office equipment applications where a uniform and high luminance is a requirement. Cylindrical lamps based on the same technology are used in multi-function copiers.

A1.3.9.3 Excitation by induction and by microwaves

In the last decade, a number of inductively coupled lamps have become available commercially from the major lamp manufacturers [9, chapter 11]. All are variants on the fluorescent lamp discharge. Figure A1.3.15 shows a particularly compact example. The coil in the centre is driven at a frequency of about 2.6 MHz. The rate of change of magnetic flux induces a voltage in the azimuthal direction. This causes a current to flow in a torus surrounding the coil. The ballasting is the result of the internal impedance of the supply. Benefits are long life and compactness. Other versions are Philips QL which, with a life of 100 000 h, is designed for use in inaccessible fixtures. Typically these will be high-bay fixtures with lumen packages between 2800 and 9600 lm. The Osram Endura or Icetron lamp which has a stretched torus configuration has higher efficacy and packages of 8000–12000 lm and a rated life of 80000 h.

Microwaves can also be used to excite discharges. Fusion Lighting has pioneered a HP sulphur discharge in which the radiation is emitted by S_2 molecules. The light is white with a CCT in the region of 6000 K and the efficiency of generation can be up to 170 lm/microwave watt—higher than any other white light source. The overall efficiency is reduced because of the relatively poor efficiency of generation of microwave power. Light output levels are very high so the source is used in lighting large buildings. The very high radiance of such sources means that optical means can be used to distribute the light efficiently around buildings.

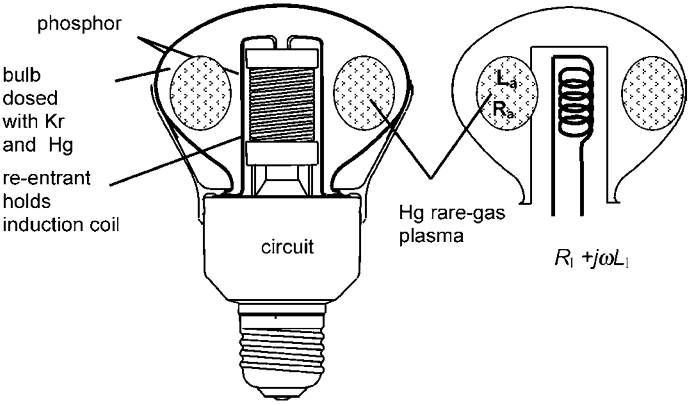

Figure A1.3.15. Inductively coupled discharge lamp (GE Genura). The schematic diagram on the left shows that the plasma is a toroid with inductance L_a and resistance R_a that acts as a secondary to the excitation coil. The primary of the circuit is an impedance $R_l + j\omega L_l$ that includes the effects of the plasma impedance, which depends on the power dissipated in the plasma.

A1.3.10 LEDs from the perspective of conventional lighting

Chapter B1.1 gives detailed information about LEDs. The generation of light by conventional lamps is limited by the black body radiance at the electron temperature. The reason is that the electron motion is randomized. In an LED, the motion of the carriers into the recombination region is far from random; the maximum radiance is therefore not limited by the Planck distribution. Already trichromatic LED [4] assemblies reaching 100 lm W^{-1} have been made. (It is not clear in [24], and in many other LED publications, if this is the flux per lamp watt or flux per wall plug watt.) Note that these lamps are colorimetrically similar to the triphosphor lamps mentioned in section A1.3.3.5. A further advantage of LEDs for many applications is their low étendue (section A1.3.3.3) which means that the light can be directed more efficiently to where it is needed.

LEDs have already made a substantial impact on the conventional lamp manufacturing businesses. There are a number of applications where LEDs are far superior to conventional lamps. The obvious example is traffic signals. The LEDs generate the coloured light only at the wavelengths needed, as compared with the filtered tungsten lamps used until recently. The required signal luminance values can therefore be met at much lower power consumption. It has been estimated that if all traffic lights in the USA were converted to LEDs, electricity consumption would be reduced by 0.4 GW [24]. Moreover, the LEDs are particularly well suited to withstand the vibration they experience as a result of heavy traffic and wind, and they may be frequently switched without damage. But the main advantage is their long life, which dramatically reduces maintenance costs compared with conventional traffic lights. A further advantage is that catastrophic failure of an LED does not have to cause the complete failure of the traffic signal, so safety is improved. All these advantages pay for the extra cost of the LED systems, so we can expect to see a complete takeover of the signal lamp market in land, sea and air transport signs.

White light LEDs are now finding many applications in decorative, aesthetic and artistic lighting where their properties are stimulating designers to produce interesting new ways of using light. There are also other niche markets such as highly localized task lighting where LEDs will make inroads, such as car interiors, desk, stairwell, path lighting etc. In any application requiring relatively low flux levels, conventional lamps can now probably be replaced by LEDs as long as the substitution is not too expensive.

The ultimate target for the LED industry must be the replacement of the huge numbers of fluorescent lamps for lighting offices and other commercial premises. Much is made of the possibility of exceeding the efficiency of present day fluorescent lamps. The future is far from clear however: the issue is the low luminous flux from LEDs. No single LED approaches the level of flux required, so any competitive installation will require many LEDs to produce the required flux levels, although the étendue advantage may reduce the flux levels required for LED installations. But the hard fact is that the cost of making an LED light source increases approximately linearly with flux, whereas the cost of making conventional lamps is very weakly dependent on flux. It is expected that manufacturing costs in both industries will be driven down by competition to comparable levels. If so, replacement of fluorescent lamps by LED equivalents on a global scale may come down to the cost of the materials used to make the lamps. In the case of fluorescent lamps, most of the material cost is in the rare-earth phosphors. Can the semiconductors used in making LEDs ever approach those costs per lumen? Will the potentially low cost organic light emitters ever be able to meet the flux requirements of commercial lighting? We shall see.

Appendix. Selected manufacturers and suppliers of lamps

The manufacturers on this list give particularly helpful data in catalogues and/or websites for lamps with actual or potential electro-optical applications.

Cathodeon	lamps for scientific instruments
Ealing Electro-Optics	lamp units for integration into optical systems
Fusion Lighting	microwave discharge lamps
GE Lighting	full range of lamps for illumination and special purposes
Harrison Electrical	cold cathode fluorescent
Heraeus Noblelight	special lamps mainly for industrial and scientific processes
Iwasaki	full range of lamps for illumination and special purposes
Osram	full range of lamps for illumination and special purposes
Oriel Instruments	lamp units for integration into optical systems, spectra of lamps
Philips Lighting	full range of lamps for illumination and special purposes
Stanley	cold cathode fluorescent
Toshiba Lighting	full range of lamps for illumination and special purposes
Ushio	wide range lamps for audio-visual, entertainment, photographic, scientific/media and industrial processes
Welch Allyn	lamps for special applications

A1.4

Detection of optical radiation

Antoni Rogalski and Zbigniew Bielecki

The birth of photodetectors can be dated back to 1873 when Smith discovered photoconductivity in selenium. Progress was slow until 1905, when Einstein explained the newly observed photoelectric effect in metals, and Planck solved the blackbody emission puzzle by introducing the quanta hypothesis. Applications and new devices soon flourished, pushed by the dawning technology of vacuum tube sensors developed in the 1920s and 1930s culminating in the advent of television. Zworykin and Morton, the celebrated fathers of videonics, on the last page of their legendary book *Television* (1939) concluded that: "when rockets will fly to the moon and to other celestial bodies, the first images we will see of them will be those taken by camera tubes, which will open to mankind new horizons". Their foresight became a reality with the Apollo and Explorer missions. Photolithography enabled the fabrication of silicon monolithic imaging focal planes for the visible spectrum beginning in the early 1960s. Some of these early developments were intended for a picturephone, other efforts were for television cameras, satellite surveillance, and digital imaging. Infrared imaging has been vigorously pursed in parallel with visible imaging because of its utility in military applications. More recently (1997), the CCD camera aboard the Hubble space telescope delivered a deep-space picture, a result of 10-days integration, featuring galaxies of the 30th magnitude—an unimaginable figure even for astronomers of our generation. Probably, the next effort will be in the big-band age. Thus, photodetectors continue to open to mankind the most amazing new horizons.

Before proceeding to the detailed description of detection of optical radiation, it is now appropriate to digress on system considerations concerning photodetection. We would like to determine how good performance is in view of fundamental limits of sensitivity and speed of response, irrespective of the actual type of detector used. Next, different application circuits used in direct detection systems together with elucidation of the design of front-end circuits and discussion of their performance are presented. The third part of the chapter is devoted to advanced techniques in photodetection covering topics not usually found in textbooks and demonstrating how photodetection is far from being a completely explored field. In the last part, the updated information devoted to readout of signals from detector arrays and focal plane arrays (FPAs) is included. It is shown that detector focal plane technology has revolutionized many kinds of imaging in the past 25 years.

A1.4.1 Detection regimes and figures of merit

A common problem of any type of photon detector (yielding emitted electrons or internal electron–hole pairs as a response to incoming photons) is how to terminate the photodetector with a suitable load resistor, and to trade off the performance between bandwidth and signal-to-noise ratio. This is necessary for a wide family of detectors, including phototubes, photoconductors, photodiodes, CCDs, vidicon targets, etc, all of which are described by a current generator I_{ph} with a stray capacitance C across it.

Let us consider the equivalent circuit of a photodetector ending on a load resistor R_{L}, as shown in figure A1.4.1. We indicate current noise generator with diamond shape and asterisk. This is the basic circuit for detection, but, as will be shown later, it is not the best one to give a good compromise between bandwidth and noise. The output signal in voltage $V = IR_{\mathrm{L}}$ or in current I, has a bandwidth, or 3 dB high-frequency cutoff given by

$$\Delta f = \frac{1}{2\pi R_{\mathrm{L}} C}. \tag{A1.4.1}$$

Two noise contributions are added to the signal. One is the Johnson (or thermal) noise of the resistance R_{L}, with a quadratic mean value

$$I_{\mathrm{nR}}^2 = \frac{4kT\Delta f}{R_{\mathrm{L}}} \tag{A1.4.2}$$

where k is the Boltzmann constant and T is the absolute temperature.

The total current $I = I_{\mathrm{ph}} + I_{\mathrm{d}}$ is the sum of the signal current and the dark current. With this current is associated the quantum (or shot) noise arising from the discrete nature of electrons and photoelectrons. Its quadratic mean value is given by

$$I_{\mathrm{n}}^2 = 2q(I_{\mathrm{ph}} + I_{\mathrm{d}})\Delta f \tag{A1.4.3}$$

where q is the electron charge and Δf is the observation bandwidth, as in equation (A1.4.1).

A general noise equivalent circuit for a photodetector is shown in figure A1.4.1(*b*). The above two fluctuations are added to the useful signal and the corresponding noise generators are placed across the device terminals. Since the two noises are statistically independent, it is necessary to combine their quadratic mean values to give the total fluctuation as

$$I_{\mathrm{n}}^2 = 2q(I_{\mathrm{ph}} + I_{\mathrm{d}})\Delta f + \frac{4kT\Delta f}{R_{\mathrm{L}}}. \tag{A1.4.4}$$

From equations (A1.4.1) and (A1.4.4) it can be seen that bandwidth and noise optimization impose opposite requirements on the value of R_{L}. To maximize Δf one should use the smallest possible R_{L}, whilst to minimize I_{n}^2 the largest possible R_{L} is required. A photodetector can have a good sensitivity using very high load resistances (up to GΩs), but then only modest bandwidths (≈ kHz or less), or it can be made fast by using low load resistances (e.g. $R_{\mathrm{L}} = 50\,\Omega$) but at the expense of sensitivity.

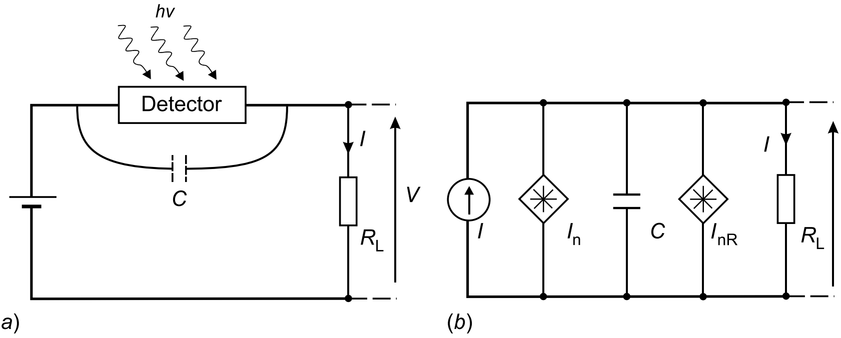

Figure A1.4.1. General circuit (*a*) of a photodetector and its equivalent circuit (*b*) including noise generators (noise generators shown with asterisk).

Using equation (A1.4.4), we can evaluate the relative weight of the two terms in total noise current. In general, the best possible sensitivity performance is achieved when the shot noise is dominant compared to the Johnson noise, i.e.

$$2q(I_{\mathrm{ph}} + I_{\mathrm{d}})\Delta f \geq \frac{4kT\Delta f}{R_{\mathrm{L}}}$$

which implies the condition

$$R_{\mathrm{Lmin}} \geq \frac{2kT/q}{I_{\mathrm{ph}} + I_{\mathrm{d}}}. \tag{A1.4.5}$$

From this equation at room temperature, then

$$R_{\mathrm{L\,min}} \geq \frac{50\,\mathrm{mV}}{I_{\mathrm{ph}} + I_{\mathrm{d}}}.$$

So, at low signal levels (for $I_{\mathrm{ph}} \ll I_{\mathrm{d}}$), very high values of resistance are required; for example, for $I_{\mathrm{d}} = 5\,\mathrm{pA}$, not an unusually low dark current, then $R_{\mathrm{Lmin}} = 10\,\mathrm{G\Omega}$. However, if we are using a resistor termination value $R_{\mathrm{L}} < R_{\mathrm{Lmin}}$ then, the total noise can be written as

$$I_{\mathrm{n}}^2 = 2q(I_{\mathrm{ph}} + I_{\mathrm{d}})\Delta f\left(1 + \frac{R_{\mathrm{Lmin}}}{R_{\mathrm{L}}}\right). \tag{A1.4.6}$$

This means that the noise performance is degraded by factor $R_{\mathrm{Lmin}}/R_{\mathrm{L}}$, compared to the intrinsic limit allowed by the dark current level. Thus, using $R_{\mathrm{L}} < R_{\mathrm{Lmin}}$ means that the shot-noise performance is reached at a level of current not less than

$$I_{\mathrm{ph}} + I_{\mathrm{d}} \geq \frac{2kT/q}{R_{\mathrm{L}}}. \tag{A1.4.7}$$

From this equation, we see that for a fast photodiode with a $50\,\Omega$ load at $T = 300\,\mathrm{K}$, this current has very large value of 1 mA.

The above considerations are valid for photodetectors without any internal gain, G. Let us now extend the calculation of the signal-to-noise ratio (S/N) to photodetectors having internal gain. In this case, the shot noise can be expressed in the form

$$I_{\mathrm{n}}^2 = 2q(I_{\mathrm{ph}} + I_{\mathrm{d}})\Delta f G^2 F \tag{A1.4.8}$$

where F is the excess noise factor to account for the extra noise introduced by the amplification process. Of course, in a non-amplified detector, $F = 1$ and $G = 1$. The total noise is a sum of shot noise and thermal noise

$$N = \left[2q(I_{\mathrm{ph}} + I_{\mathrm{d}})\Delta f G^2 F + \frac{4kT\Delta f}{R_{\mathrm{L}}}\right]^{1/2} \tag{A1.4.9}$$

and then we obtain a S/N ratio

$$\frac{S}{N} = \frac{I_{\mathrm{ph}}}{\left[2q(I_{\mathrm{ph}} + I_{\mathrm{d}})\Delta f F + (4kT\Delta f/R_{\mathrm{L}}G^2)\right]^{1/2}}. \tag{A1.4.10}$$

If we now introduce a critical value I_{ph0}, called the *threshold of quantum regime*

$$I_{\mathrm{ph0}} = I_{\mathrm{d}} + \frac{2kT/q}{R_{\mathrm{L}}FG^2}$$

then, equation (A1.4.10) becomes

$$\frac{S}{N} = \frac{I_{\mathrm{ph}}}{[2q(I_{\mathrm{ph}} + I_{\mathrm{ph0}})\Delta fF]^{1/2}}. \tag{A1.4.11}$$

Analysing equation (A1.4.11), two detection regimes can be found, according to whether the signal I_{ph} is larger or smaller than I_{ph0}. For the signals, $I_{\mathrm{ph}} > I_{\mathrm{ph0}}$, and $F = 1$

$$\frac{S}{N} = \left(\frac{I_{\mathrm{ph}}}{2q\Delta f}\right)^{1/2}. \tag{A1.4.12}$$

This *S/N* is called the *quantum noise limit* of detection. This limitation cannot be overcome by any detection system, whether operating on coherent or incoherent radiation. In fact, equation (A1.4.12) is a direct consequence of the quantitative nature of light and the Poisson photon arrival statistics.

In the small signal regime, $I_{\mathrm{ph}} < I_{\mathrm{ph0}}$, we have

$$\frac{S}{N} = \frac{I_{\mathrm{ph}}}{(2qI_{\mathrm{ph0}}\Delta f)^{1/2}}. \tag{A1.4.13}$$

That is, the S/N ratio is proportional to the signal, and the noise has a constant value, primarily given by the load resistance. This is the *thermal regime of detection*.

Figure A1.4.2 shows the trend of the S/N ratio (standardized to $(2q\Delta f)^{1/2}$), as a function of the signal amplitude $I_{\mathrm{ph}}/I_{\mathrm{ph0}}$. We can notice that in the thermal regime, the slope is 20 dB per decade up to the threshold $I_{\mathrm{ph}}/I_{\mathrm{ph0}} = 1$, and from here onward the slope becomes 10 dB per decade in the quantum regime. The effect of an excess noise factor F is also shown in figure A1.4.2.

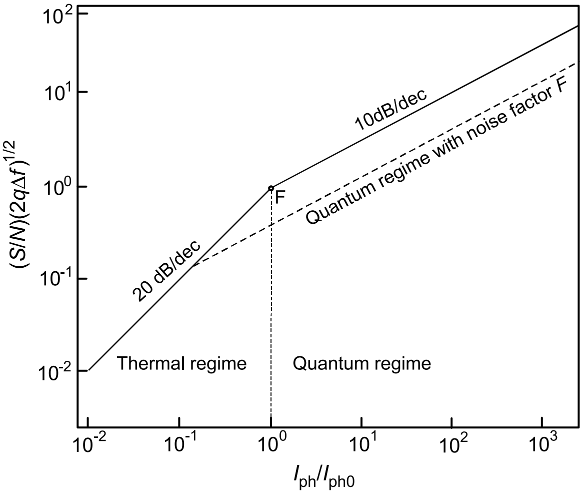

Figure A1.4.2. The S/N ratio of a photodetector, as a function of the input signal, in the thermal and quantum regimes of detection. Reproduced from [1].

The threshold of the quantum regime $I_{\mathrm{ph}} = I_{\mathrm{ph0}} = I_{\mathrm{d}} + (2kT/q)/R_{\mathrm{L}}FG^2$ is the signal level that corresponds to the break point between thermal and quantum regimes. When the dark current is very small, the second term is the dominant one; any eventual internal gain greatly helps because it scales the load resistance as G^2.

In all cases, I_{ph0} can be interpreted as the equivalent dark current level of the photodetector and has value of

$$I_{\mathrm{ph0}} = \frac{2kT/q}{R_{\mathrm{eq}}G^2} \tag{A1.4.14}$$

with

$$\frac{1}{R_{\mathrm{eq}}} = \frac{1}{R_{\mathrm{F}}} + \frac{q}{2kT}G^2 I_{\mathrm{d}}.$$

We define R_{eq} as the noise-equivalent load resistance of the photodetector.

To provide ease of comparison between detectors, certain figures of merit, computed from the measured data, have been defined.

The voltage (or analogous current) responsivity is given by

$$R = \frac{Q_{\mathrm{u}}}{P} \tag{A1.4.15}$$

where Q_{u} is the output quantity supplied by the detector (e.g. a current I_{u}, a voltage V_{u}, or any other physical quantity) and P is the incident radiant power.

At equal responsivity, the detector with the smallest output noise Q_{u} on the useful signal is the most sensitive. Therefore, the first figure of merit for a detector is the NEP—noise equivalent power—defined as the ratio of output noise to responsivity:

$$\mathrm{NEP} = \frac{g_{\mathrm{n}}}{R}. \tag{A1.4.16}$$

So, the NEP represents the input power that gives a unity signal to noise ratio, $S/N = 1$ at the output; that is, a marginal condition of detection.

The better the detector performance is, since the smaller the NEP is. Therefore, it is more convenient to define its inverse as a merit figure. In addition, it should be taken into consideration that whatever the noise source is, it can be expected that the noise quadratic total value is proportional to observation bandwidth Δf and detector area A. Thus it is even better to take, as the intrinsic noise parameter of a detector, the ratio $\mathrm{NEP}/(A\Delta f)^{1/2}$ normalized to unit area and bandwidth. In order to simplify the comparison of different detectors and to have a parameter that increases as the performance improves, the detectivity D^* (called *D-star*) is defined as:

$$D^* = \frac{(A\Delta f)^{1/2}}{\mathrm{NEP}}. \tag{A1.4.17}$$

This is the fundamental figure of merit used for detectors. It can be transformed to the following equation

$$D^* = \frac{(A\Delta f)^{1/2}}{P}\frac{S}{N}. \tag{A1.4.18}$$

D^* is defined as the rms signal-to-noise ratio (S/N) in a 1 Hz bandwidth, per unit rms incident radiation power, per square root of detector area. D^* is expressed in cm $\mathrm{Hz}^{1/2}\,\mathrm{W}^{-1}$, a unit which has recently been called a ‘Jones’.

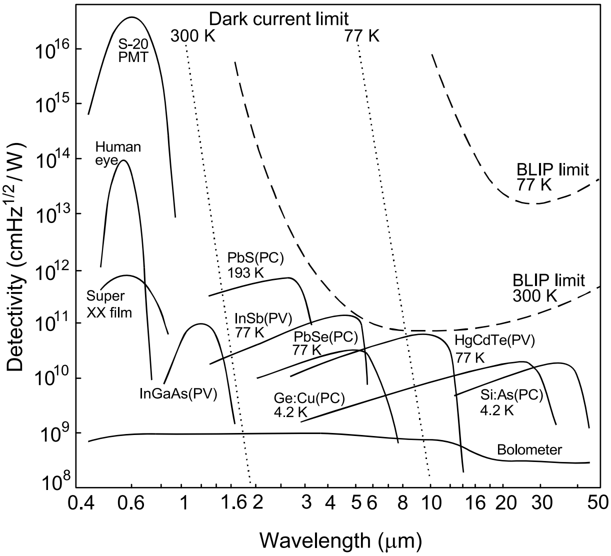

Figure A1.4.3. Detectivity as a function of wavelength for a number of different photodetectors. The BLIP and the dark current limits are indicated. PC—photoconductive detector and PV—photovoltaic detector, PMT—photomultiplier tube.

As mentioned already, the ultimate performance of infrared detectors is reached when the detector and amplifier noise are low compared to the photon noise. The photon noise is fundamental, in the sense that it arises not from any imperfection in the detector or its associated electronics but rather from the detection process itself, as a result of the discrete nature of the radiation field. The radiation falling on the detector is a combination of that from the target (signal) and that from the background. The practical operating limit for most infrared detectors is the background fluctuation limit, also known as the background limited infrared photodetector (BLIP) limit.

Figure A1.4.3 compares typical D^*s of different detectors as a function of wavelength. Also the BLIP and the dark current limits are indicated.

A1.4.2 Direct detection systems

A1.4.2.1 Introduction

A receiver of optical radiation consists of a photodetector, preamplifier, and signal processing circuit (figure A1.4.4). In a photodetector, the optical signal is converted to an electrical one, which is amplified before further processing. The sensitivity of an optical detection systems depends primarily on the first stage of a photoreceiver, i.e. the photodetector and preamplifier.

A preamplifier should have low noise and a sufficiently wide bandwidth to ensure faithful reproduction of the temporal shape of an input signal. Figure A1.4.4 shows the so-called, direct detection system. It is necessary to minimize the noises from various sources, i.e. background noise, photodetector noise, biasing resistors noise, and any additional noises of signal processing. If further minimization of noise of the first photoreceiver stages is not possible, advanced methods of optical signal detection can sometimes be used to still recover information carried by optical radiation signals of extremely low power. Heterodyne and homodyne detection can be used to reduce the effects of amplifier noise. Post detection methods are: phase-sensitive detection and synchronous integration of a signal.

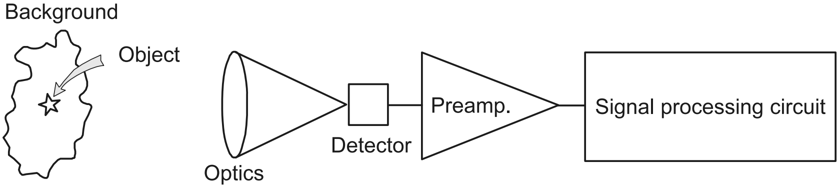

Figure A1.4.4. Block diagram of an optical radiation receiver.

A1.4.2.2 Selection of active amplifying elements

Several types of discrete devices or ICs are suitable for the active element in preamplifiers: bipolar (BJT) or field-effect transistor (FET) or an integrated circuit (IC) with an input bipolar, FET or MOSFET transistor can be used.

The most important parameter of each receiving device is its signal-to-noise ratio (S/N). Because low-level signals reach the photoreceiver, the noise optimization of a system, i.e. to obtain maximum S/N is a very important problem [2]. Optimum design of a preamplifier can be obtained by analysis of particular noise sources in a detector–preamplifier circuit. The equivalent input noise V_{ni} will be used to represent all noise sources. A scheme of detector–preamplifier noise circuit is shown in figure A.1.4.5. A level of equivalent noise at the input of this circuit is determined by the detector noise V_{nd}, the background noise V_{nb}, and the preamplifier noise. The preamplifier noise is represented completely by the zero impedance voltage generator V_{n} in series with the input port, and the infinite impedance current generator I_{n} in parallel with the input. Typically, each of these terms is frequency dependent. For non-correlated noise components, the equivalent noise at the input of a photodetector–preamplifier circuit is described by the formula

$$V_{\mathrm{ni}}^2 = V_{\mathrm{nd}}^2 + V_{\mathrm{nb}}^2 + V_{\mathrm{n}}^2 + I_{\mathrm{n}}^2 R_{\mathrm{d}}^2 \tag{A1.4.19}$$

where R_{d} is the detector resistance.

This single noise source, located at V_{s}, can be substituted for all sources of the system noise. Note that V_{ni}^2 is independent of the amplifier gain and its input impedance. Thus, V_{ni}^2 is the most useful index against which the noise characteristics of various amplifiers and devices can be compared.

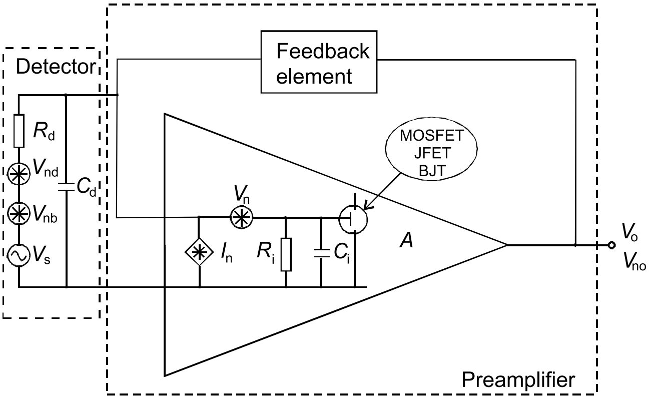

Figure A1.4.5. Noise equivalent diagram of a photodetector–preamplifier circuit; R_{i} and C_{i} is the input resistance and the capacity of a preamplifier, respectively, A is the voltage gain of the preamplifier.

The first transistor of a preamplifier is a dominant noise contributor of the input noise of signal processing circuits (figure A1.4.5). The effective contribution of this transistor noise also depends on the detector impedance. If the transistor of the input stage has a high noise current, it will be a bad choice for use with a high-resistance (current source) detector. A low-resistance detector operates best with a preamplifier of low noise voltage.

Figure A1.4.6 shows the dependence of the ratio of preamplifier (or input transistor) noise to detector thermal noise as a function of detector resistance, for bipolar, JFET, and MOSFET amplifiers, in a common emitter or common source configuration [3]. It can be noticed that there are some ranges of detector resistance for which the preamplifier noise is lower than the detector thermal noise. For any given detector, the values of the thermal noise voltage V_t and the resistance R_d are determined by the detector type (they cannot be changed). However, it is possible to change the parameters V_n and I_n of the designed preamplifier. Thus, minimization of the input noise of the circuit is possible. Changes in the values V_n and I_n are made by choosing adequate elements in the preamplifier circuit. For low-resistance detectors (from tens Ω to 1 kΩ), circuits with bipolar transistors at the input are usually used as they have low values of V_n. Sometimes, in order to decrease the value of optimal resistance R_o, a parallel connection of several active elements or even parallel connection whole amplifiers is advantageous [4]. Within the range of average detector resistances from 1 kΩ to 1 MΩ, the preamplifiers FET input stages can be used. However, for connection with high-resistance detectors (above 1 MΩ) especially recommended are the transistors of low I_n values. Such requirements fulfil JFET and MOSFET transistors.

A1.4.2.3 First stages of photoreceivers

There are two general types of photon detectors without internal gain: photoconductive and junction devices (photovoltaic ones). These photodetectors are used with many types of preamplifiers. The choice of circuit configuration for the preamplifier is largely dependent upon the system application. The two basic preamplifier structures—voltage amplifiers type and transimpedance (current in-voltage out type) will be discussed. The voltage preamplifiers can be either low impedance or high impedance ones. A simplified circuit diagram is shown in figure A1.4.7. Bias voltage is supplied by V_b. The detector signal is

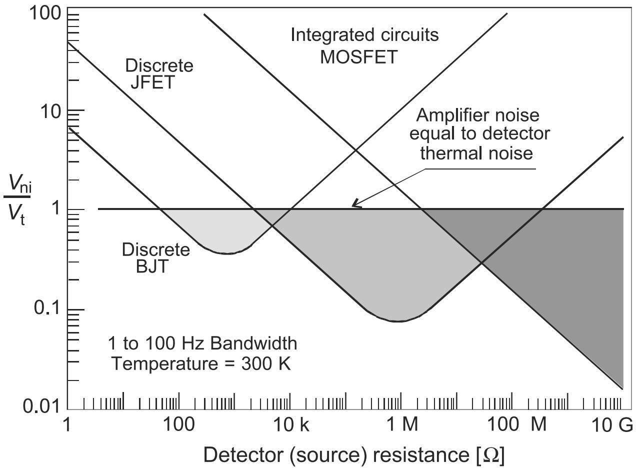

Figure A1.4.6. Dependence of the ratio of preamplifier input voltage noise to detector thermal noise, as a function of detector resistance. Reproduced from [3].

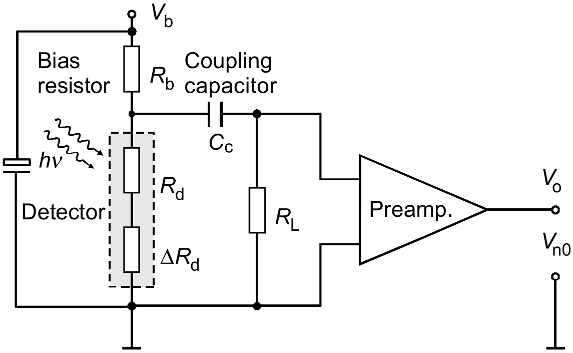

Figure A1.4.7. A simple circuit of voltage mode preamplifier.

developed as a voltage drop across R_b. The variable resistance component of the detector R_d is represented by the incremental resistance ΔR_d. The load resistance R_L provides a bias path for the amplifier input.

The simplest preamplifier structure is the low input impedance voltage preamplifier. This design is usually implemented using a bipolar transistor. Either common emitter or grounded emitter input stages may be designed with a reasonably low input impedance. In the low input impedance preamplifiers, the signal source is loaded with a low impedance (e.g. 50 Ω) input stage. The time constant of the temporal response is determined by the combined load resistance and input capacitance of the detector and preamplifier and this determines the detection bandwidth. Preamplifiers of low input resistance can provide high bandwidth but not very sensitive photoreceiver. Photoreceivers with preamplifiers of low input resistance are, therefore, usually used when wide transmission band is required.

The high-impedance preamplifier gives a significant improvement in sensitivity over the low-impedance preamplifier, but it requires considerable electronic frequency equalization to compensate for its high-frequency roll-off. The preamplifier has problems of limited dynamic range, being easily saturated at higher input power levels. When a highly sensitive photoreceiver with a low dynamic range is needed, preamplifier of high input impedance is recommended. However, for this, there is a better configuration, that we shall now discuss. This is called the transimpedance receiver.

The transimpedance preamplifier finds many applications in optical signals detection. A schematic of this is shown in figure A1.4.8. In this circuit, R_d is the detector resistance, and it can be a photodiode or a photoresistor. Depending on detector type and required application, the detector can be biased from V_b or connected directly across the input without bias. The current produced by the detector flows through the resistor R_f located in a feedback loop. The optional potentiometer R_b is used for setting the zero value of the output voltage without detector illumination [5]. It can be used for compensation of a dc level at the output of the circuit resulting from background radiation. Usually, the input bias current is negligible, so $I_{ph} = -I_f$.

The voltage at the preamplifier output is given by the formula

$$V_o = -\frac{R_f}{R_d} V_b = -I_{ph} R_f \tag{A1.4.20}$$

proper for low frequencies. The great advantage of this configuration is that the preamplifier gives low noise performance without the severe limitation on bandwidth imposed by high input impedance preamplifier. The bandwidth is much higher because the effective load resistance is very low, and has value $R_f/(A+1)$ where A is the gain of the amplifier at the appropriate frequency. It also provides greater

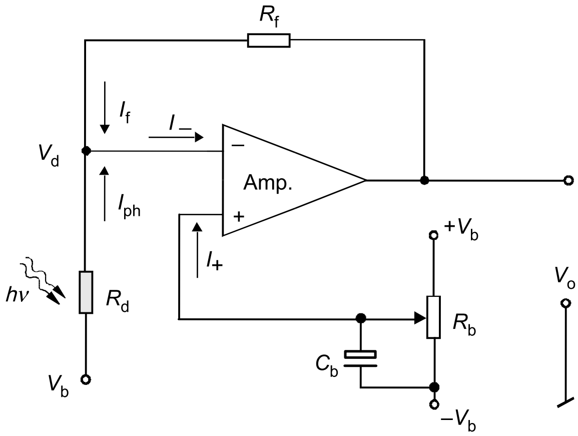

Figure A1.4.8. Schematic diagram of transimpedance amplifier.

dynamic range than the high input impedance structure. It is possible to linearly detect and process optical signals many orders of powers magnitude.

At low frequencies, using a photodiode in unbiased configuration, across the input of transimpedance preamplifier, avoids the noise and dc offset problems that dark current might otherwise cause (non-inverting input is on the ground). In this configuration, there is the small price of increased photodiode capacitance, which would be far more serious at high frequencies. For InGaAs photodiodes can have substantially lower quantum efficiencies if unbiased (due to much thinner depletion region) although the benefit to avoid dark current can be more useful here.

The effective input impedance R_i at the amplifier input as a result of the effects of the feedback circuit is given simply by

$$R_i = \frac{R_f}{A(f)+1} \approx \frac{R_f}{A(f)} \tag{A1.4.21}$$

where $A(f)$ is the frequency-dependent gain of the preamplifier. As this input impedance is effectively in parallel with the capacitance $(C_d + C_i)$, the 3 dB breakpoint $f_{-3\,\mathrm{dB}}$ in the frequency response is given by

$$f_{-3\,\mathrm{dB}} = \frac{1}{2\pi R_i(C_d + C_i)} = \frac{A(f)}{2\pi R_f(C_d + C_i)}. \tag{A1.4.22}$$

If $A(f)$ is described in terms of gain–bandwidth product $A(f)\Delta\mathrm{f}$ (or GBP) such that GBP $= \Delta f A(f)$, then

$$f_{-3\,\mathrm{dB}} = \frac{\mathrm{GBP}/f_{-3\,\mathrm{dB}}}{2\pi R_f(C_d + C_i)} \tag{A1.4.23}$$

therefore

$$f_{-3\,\mathrm{dB}} = [\mathrm{GBP}/2\pi R_f(C_d + C_i)]^{1/2}. \tag{A1.4.24}$$

A practical problem with many transimpedance designs is to achieve a sufficiency high open-loop gain product, to keep the $f_{-3\,\mathrm{dB}}$ value high, yet still maintain a sufficiently low open-loop phase shift to maintain stability. It often proves necessary, in practice, to use a value of R_L other than desired on low-noise grounds in order to achieve the necessary $f_{-3\,\mathrm{dB}}$. This gives rise to the widely held belief that transimpedance designs are inherently noisier than high impedance input design. However, this belief is not valid with good high-gain bandwidth designs. Secondly, even with sub-optimum amplifier design, achieving poorer gain bandwidth, it is always possible to perform an engineering compromise, by choosing a high value of R_L, to maintain low-noise, and use small amount of equalization after the transimpedance amplifier to compensate for the resulting roll off.

The preamplifiers described earlier are used with semiconductor detectors. Now, we would like to present exemplary preamplifiers to the photomultiplier tubes.

The operating principles, construction and characteristics of a photomultiplier are given in section B2. Now, we would like to analyse matching the preamplifier to the photomultiplier. Different pulse processing techniques are typically employed, depending on whether the arrival time or the amplitude (energy) of the detected event must be measured. Three basic types of preamplifiers are available: the current-sensitive preamplifier, the parasitic-capacitance preamplifier, and the charge-sensitive preamplifier. The simplified schematic of the current-sensitive preamplifier is shown in figure A1.4.9. The $R = 50\,\Omega$ input impedance of the current-sensitive preamplifier provides proper termination of the $50\,\Omega$ coaxial cable, and converts the current pulse from the detector to a voltage pulse. The amplitude of the voltage pulse at the preamplifier output will be

$$V_o = RI_iA \tag{A1.4.25}$$

where I_i is the amplitude of the current pulse from the detector.

For counting applications this signal can be fed to a fast discriminator, the output of which is recorded by a counter-timer. For timing application, the dominant limitation on timing resolution with photomultiplier tubes is fluctuation in the transit times of the electrons. This causes a jitter in the arrival time of the pulse at the detector output. If the detector signals are small enough to require a current-sensitive preamplifier, the effect of a preamplifier input noise on time resolution must also be considered. It is important to choose a current-sensitive preamplifier whose rise time is much faster than detector rise time. Unfortunately, the faster preamplifier does contribute extra noise, because of the unnecessarily wide bandwidth. The excess noise will increase the timing jitter. Choosing a preamplifier rise time that is much slower than the detector rise time reduces the preamplifier noise contribution but causes degradation in pulse rise time and its amplitude. Consequently, the timing jitter becomes worse. The optimum choice depends on the rise time and amplitude of the detector signal. Most current-sensitive preamplifiers designed for timing applications have ac-coupled.

The most effective preamplifier for these detectors is the parasitic-capacitance preamplifier shown in figure A1.4.10. It has a high input impedance (above $1\,M\Omega$).

The parasitic capacitance is presented by the detector and the preamplifier input (typically 10–50 pF). The resulting signal is a voltage pulse having an amplitude proportional to the total charge in the detector pulse. This type of preamplifier is sensitive to small changes in the parasitic capacitance. The rise time is equal to the duration of the detector current pulse. A resistor connected in parallel with the input capacitance causes an exponential decay of the pulse. An amplifier-follower is included

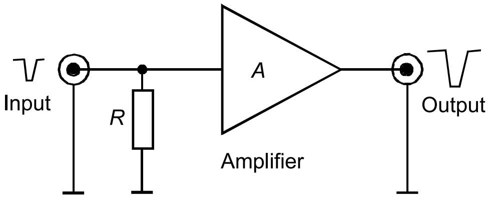

Figure A1.4.9. A simplified schematic of the current-sensitive preamplifier.

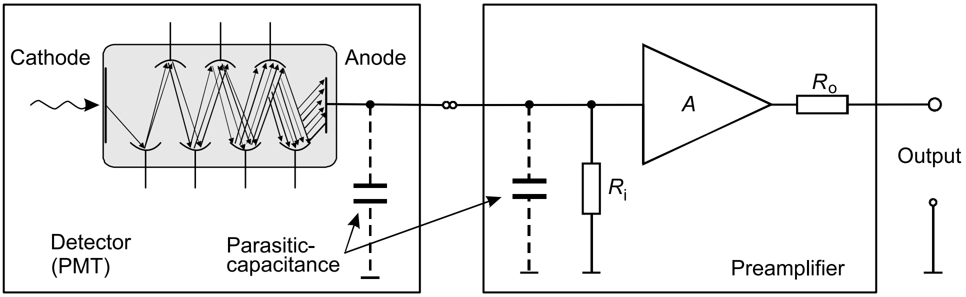

Figure A1.4.10. A simplified diagram of the parasitic-capacitance preamplifier.

as a buffer to drive the low impedance of a coaxial cable at the output. These preamplifiers are highly recommended for photomultiplier tubes, microchannel plate MPTs, and scintillation detectors.

For most energy spectroscopy applications a charge-sensitive preamplifier is preferred (figure A1.4.11). This preamplifier integrates the charge on the feedback capacitor. Its gain is not sensitive to a change in detector capacitance. The output voltage from the preamplifier (V_o) and the decay time constant (τ_f) are given respectively by

$$V_o = \frac{Q_d}{Q_f} = \frac{Eq}{\varepsilon C_f} 10^6 [\mathrm{mV}] \quad \text{and} \quad \tau_f = R_f C_f \tag{A1.4.26}$$

where Q_d is the charge of the detector, C_f is the feedback capacitor, E is the energy in MeV of the incident radiation, q is the charge of an electron, ε is the amount of energy (eV) required to produce an electron–hole pair in the detector, and 10^6 converts MeV to eV. The resistor R_f should be made consistent as much as possible with the signal energy-rate product and the detector leakage current. The input capacitance must be much greater than the other sources of capacitance connected to the preamplifier input in order for the preamplifier sensitivity to be unaffected by external capacitance changes. The stability of the preamplifier sensitivity is dependent on the stability of the feedback capacitor (C_f is selected for good temperature stability) and the preamplifier open loop gain. The open loop gain will be very large so that small changes in the C_f can be neglected.

The rise time of the output pulse of the preamplifier, in the ideal case, is equal to the charge collection time of the detector. When detectors with very fast collection times or large capacitances are used, the preamplifier itself may limit the rise time of V_o.

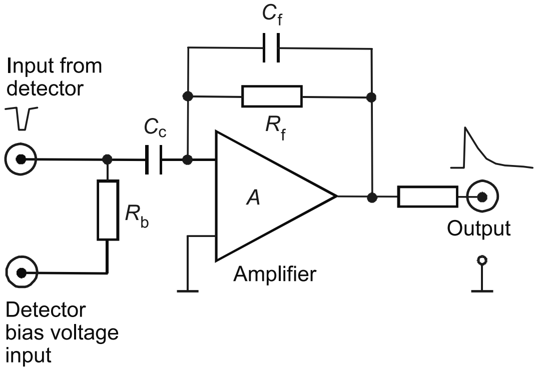

Figure A1.4.11. A simplified diagram of the charge-sensitive preamplifier.

A1.4.2.4 Photon-counting techniques

Photomultiplier tubes are also used in photon counting. Photon-counting is one effective way to use a photomultiplier tube for measuring very low light (e.g. astronomical photometry and fluorescence spectroscopy). A number of photons enter the photomultiplier tube and create an output pulse signal (figure A1.4.12(*a*)). The actual output pulse obtained by the measurement circuit is a dc with fluctuation (figure A1.4.12(*b*)).

When the light intensity becomes so low that the incident photons are separated as shown in figure A1.4.12(*c*), this condition is called a single photon event. The number of output pulses is in direct proportion to the amount of incident light and this pulse counting method is advantageous for signal-to-noise ratio and stability over the dc method averaging all the pulses. This counting technique is called the photon-counting method.

Since the photomultiplier tube output contains a variety of noise pulses in addition to signal pulses representing photoelectrons, simply counting of the pulses, without some form of noise elimination, will not result in an accurate measurement. The most effective approach to noise elimination is to investigate the height of the output pulses. Figure A1.4.13 shows the output pulse and discriminator level.

A typical pulse height distribution (PHD) of the output of the photomultiplier tubes is shown in figure A1.4.14. In this PHD method, the low level discrimination (LLD) is set at the valley and the upper level discrimination (ULD) at the foot. Most pulses smaller than the LLD are noises and pulses larger then ULD result from interference (e.g. cosmic rays). Therefore, by counting the pulses between the LLD and UPD, accurate light measurements are made possible. In the PHD, H_m is the mean height of pulses. It is recommended that the LLD be set at 1/3 of H_m and the ULD a triple H_m.

In addition, the avalanche photodiodes (APDs) can get output pulses for each detected photon and thus potentially very high sensitivities, comparable to that of photomultipliers. They are selected based on having extremely low noise and low bulk dark-current. They are intended for ultra-low light level application (optical power less than 1 pW) and can be used in either their normal linear mode (polarization voltage $V_R <$ breakdown voltage V_{BR}), or as photon counters in the 'Geiger' mode ($V_R > V_{BR}$) where a single photoelectron may trigger an avalanche pulse of about 10^8 carriers.

In the linear mode operation, the APD is well suited for application which requires high sensitivity and fast response time; for example: laser rangefinders, fast receiver modules, lidar, and ultrasensitive spectroscopy.

When biased above the breakdown voltage, an avalanche photodiode will normally conduct a large current. However, if this current is limited to less than the APD's 'latching' current, there is a strong statistical probability that the current will fluctuate to zero in the multiplication region, and the APD will then remain in the 'off' state until an avalanche pulse is triggered by either a bulk or photo-generated carrier. If the number of bulk carrier generated pulses is low, the APD can therefore, be used to count individual current pulses from incident photons. The value of the bulk dark current is, therefore, a

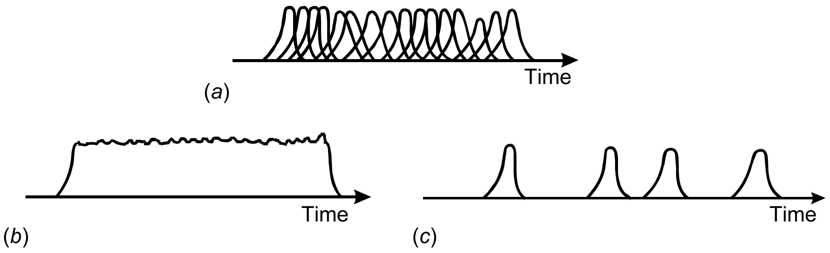

Figure A1.4.12. Pulse signals at the output of a photomultiplier tube.

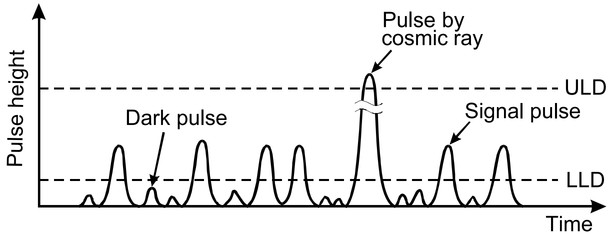

Figure A1.4.13. Output pulse and discriminator level.

significant parameter in selecting an APD for photocounting, and can be reduced exponentially by cooling.

The APDs can be used in the Geiger mode using either 'passive' or 'active' pulse quenching circuits.

A passive quench takes the current from the diode and passes it through a load resistor and a series resistor, causing the bias voltage to drop. An active quench uses a transistor to lower the bias voltage. Passive quench circuits, although simple, limit the rate at which photons can be counted, because time has to be allowed for the quench and for the return of the voltage to break down before the next photon arrives. This characteristic time is basically given by RC, where R is the series resistance and C is device capacitance. Because R must be sufficiently large to trigger the quench, the time is limited by device capacitance to typically hundreds of nanoseconds, and time resolution is at best about 400 ps.

The simplest, and in many cases a perfectly adequate method of quenching a breakdown pulse, is through the use of a current-limiting load resistor. An example of such a passive quenching circuit is shown in figure A1.4.15(*a*). The load-line of the circuit is shown in figure A1.4.15(*b*).

To be in the conducting state at V_{BR}, two conditions must be met:

- the avalanche must have been triggered by either a photoelectron or a bulk-generated electron entering the avalanche region of the APD, to continue to be in the conducting state, and
- a sufficiently large current, called latching current must be passing through the device so there is always an electron or hole in the avalanche region.

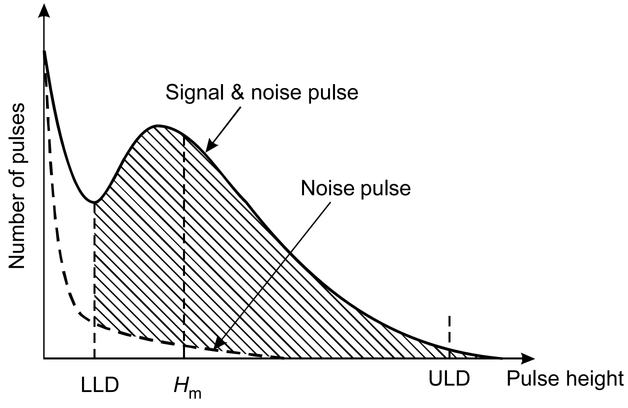

Figure A1.4.14. Typical PHD.

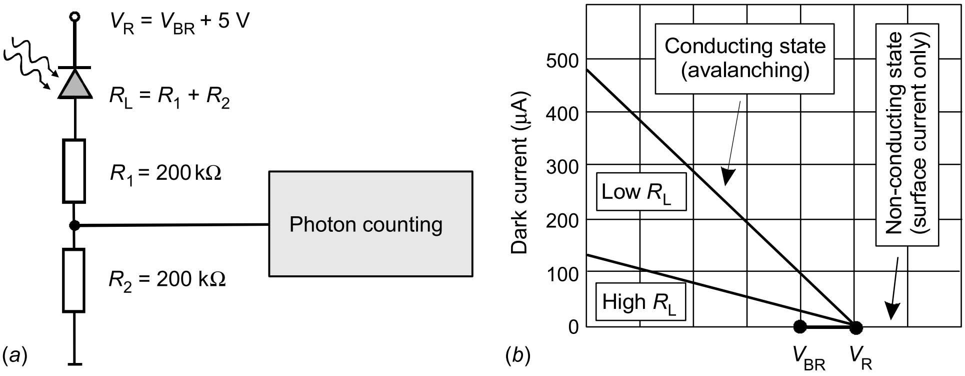

Figure A1.4.15. Passive quenched circuit (*a*) and the load-line of the circuit (*b*).

For the currents $(V_R - V_{BR})/R_L$ much greater than I_{latch}, the diode remains conducting. If the current $(V_R - V_{BR})/R_L$ is much less than I_{latch}, the diode switches almost immediately to the non-conducting state. When R_L is large, the photodiode is non-conducting, and the operating point is at $V_R - I_d R_L$ in the non-conducting state. Following an avalanche breakdown, the device recharges to the voltage $V_R - I_d R_L$ with the time constant CR_L where C is the total device capacitance including stray capacitance.

The rise-time is fast (e.g. 5–50 ns), decreases as $V_R - V_{BR}$ increases, and is very dependent on the capacitances of the load resistors, leads, etc. The jitter is typically the same order of magnitude as the rise-time.

To avoid an excessive dead-time when operating at a large voltage above V_{BR}, an 'actively quenched' circuit can be used. Active quenching can greatly increase this performance and has become commercially available over the last few years. Now, recharging can be very rapid through a small load resistor. Alternatively, the bias voltage can be maintained but the load resistor is replaced by a transistor that is kept off for a short time after an avalanche, and turned on for a period sufficient to recharge the photodiode. The response time is limited by the transistor switching rather than an *RC* circuit and has been reduced to as low as 50 ns, and the timing of photons can be made with resolution as high as 20 ps. In this mode, no amplifiers are necessary and single photon detection probabilities of up to approximately 50% are possible.

Photon-counting is also advantageous where gating coincidence techniques are employed for signal retrieval. Other applications in which APD operates in this mode are used in: lidar, astronomical observation, optical fibre test and fault location, optical range finding, ultrasensitive fluorescence, etc.

A1.4.2.5 High-speed photoreceivers

A variety of different applications and measurement techniques have been developed for high-speed detection. Most of them are described in section B2.5. Here we focus mainly on the speed limitation of the response of p–i–n junction and Schottky barrier—two types of photodiodes which have the highest speed response.

In general, in comparison with Schottky barriers, the p–n junction photodiodes indicate some important advantages. The thermionic emission process in a Schottky barrier is much more efficient than the diffusion process and therefore for a given built-in voltage, the saturation current in a Schottky diode is usually several orders of magnitude higher than in the p–n junction. In addition, the built-in voltage of a Schottky diode is smaller than that of a p–n junction with the same semiconductor.

However, high-frequency operation of p–n junction photodiodes is limited by the minority-carrier storage problem. In other words, the minimum time required to dissipate the carriers injected by the forward bias is dictated by the recombination lifetime. In a Schottky barrier, electrons are injected from the semiconductor into the metal under forward bias if the semiconductor is n-type. Next they thermalize very rapidly ($\approx 10^{-14}$ s) by carrier–carrier collisions, and this time is negligible compared to the minority-carrier recombination lifetime.

In p–i–n photodiode an undoped i-region (p^- or n^-, depending on the method of junction formation) is sandwiched between p^+ and n^+ regions. Because of the very low density of free carriers in the i-region and its high resistivity, any applied bias drops entirely across the i-region, which is fully depleted at zero bias or very low value of reverse bias.

The response speed of p–i–n photodiode is ultimately limited either:

- by transit time across i-region;
- or by circuit parameters (*RC* time constant).

Influence of diffusion time (τ_d) of carriers to the depletion region, which is inherently a relatively slow process, can be neglected since the generation of carriers occurs mainly in high-field i-region. If the photodetector is not fully depleted, this time is taken for collection of carriers generated outside the depletion layer. Carrier diffusion may result in a tail (a deviation between input and output signal) in the response time characteristics.

The transit time of the p–i–n photodiode is shorter than that obtained in a p–n photodiode even though the depletion region is longer than in the p–n photodiode case due to carriers travel at near their saturation velocity virtually the entire time they are in the depletion region (in p–n junction the electric field peaked at the p–n interface and then rapidly diminished).

The transit time of carriers across i-layer depends on its width and the carrier velocity. Usually, even for moderate reverse biases the carriers drift across the i-layer with saturation velocity. The transit time can be reduced by reducing the i-layer thickness. The fast photodiode must be thin to minimize the time that it takes for the photogenerated electrons and holes to traverse the depletion region. A thin photodiode has high capacitance per unit area and therefore must also be small in diameter to reduce the *RC* time constant.

The second component of the response time (t_r) is dependent mainly on the photodetector capacitance and input resistance of the preamplifier. The detector capacitance is a function of the area (A), the zero bias junction potential V_0, dielectric constant ($\varepsilon_0\varepsilon_s$), impurity concentrations of acceptors (N_a) and donors (N_d), and the bias voltage (V_b). If we assume that the external bias V_b is large compared to the V_0, and we have p^+–n abrupt junction, then the diode has a capacitance given by

$$C_d = \frac{A}{2}(2q\varepsilon_s\varepsilon_0 N_d)^{1/2} V_b^{-1/2}. \tag{A1.4.27}$$

In this case, lower *RC* time constant, and therefore, improved bandwidth can be achieved with the use of smaller detectors area and higher bias voltage. In practice, junctions are rarely abrupt; however, it still remains true that the capacitance decreases with increasing reverse bias.

The time constant is given by

$$\tau_{RC} = \frac{(R_L + R_s)R_{sh}}{R_L + R_s + R_{sh}} C = R_{eq} C \tag{A1.4.28}$$

where R_s is the series resistance of the photodiode, C is the sum of the photodiode and input preamplifier capacitances, R_{eq} is the equivalent resistance of the photodiode and load resistance.

The rise time dependent on time constant is described by the formula

$$t_r = 2R_{eq}C. \tag{A1.4.29}$$

The p–i–n photodiode has a 'controlled' depletion layer width, which can be tailored to meet the requirements of photoresponse and bandwidth. A tradeoff is necessary between response speed and quantum efficiency. For high response speed, the depletion layer width should be small but for high quantum efficiency (or responsivity) the width should be large.

Increases in bias voltage will usually increase carrier velocities and, therefore, reduce transit times but result in higher dark current and noise.

The detector response time is of the form

$$t_T = (t_r^2 + t_t^2 + t_d^2)^{1/2}. \tag{A1.4.30}$$

If we take equation (A1.4.29), the 3 dB cut-off frequency is given by

$$f_{-3\,dB} = (2\pi R_{eq}C)^{-1}. \tag{A1.4.31}$$

Usually, a designer can increase the bandwidth only by using smaller detectors and/or by reducing the amplifier's input resistance.

A good figure of merit for comparing sensitivity to high-speed signals of similar photodiodes is the *Response factor* × *Bandwidth product*. Response factor is the photodiode responsivity multiplied by the impedance seen by the photodiode. Assuming that two photodiodes have single pole high frequency roll-off, the one with the highest *Response factor* × *Bandwidth product* will provide the greatest response to an ultra fast pulse.

A1.4.2.6 Noise models of first stages of photoreceivers

A noise equivalent circuit of the first stage of a photoreceiver with a voltage type preamplifier is shown in figure A1.4.16. The signal current generator I_{ph} represents the detected signal. Noises in a detector (photodiode) are represented by three noise generators: I_{nph} is the shot noise originating from a photocurrent, I_{nd} is the shot noise of a dark current, I_{nb} is the shot noise from a background current. If the input resistance of a preamplifier is high, the value of the load resistance depends on the chosen bias resistor. The load (bias) resistor R_L affects both the level of the detector signal and its noise. The noise current generator I_{nR} is the thermal noise current and excess noise of the load resistance R_L. Since the

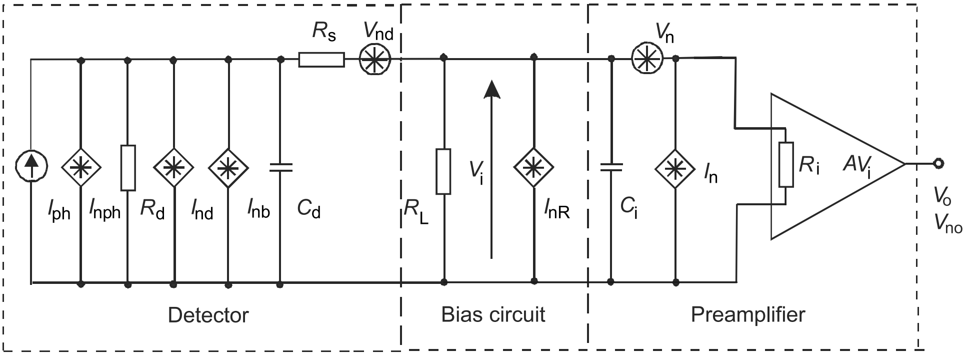

Figure A1.4.16. Equivalent scheme of photodetector–voltage type preamplifier circuit (C_d is the detector capacity, R_i and C_i are the input resistance and capacitance of the preamplifier, respectively).

thermal noise of I_{nR} is inversely related to the square root of the resistance, so R_{L} must be large. For the lowest noise system, at very low frequency, the detector will be the dominant noise source, but at higher frequencies amplifier noise becomes increasingly important.

Expression for signal-to-noise ratio at the first stage of a photoreceiver with voltage type preamplifier results from scheme A1.4.16:

$$\frac{S}{N}=\frac{I_{\mathrm{ph}}}{\left[I_{\mathrm{nph}}^2+I_{\mathrm{nd}}^2+I_{\mathrm{nb}}^2+I_{\mathrm{n}}^2+\frac{4kT\Delta f}{R_{\mathrm{L}}}+\left(\frac{V_{\mathrm{n}}}{R_{\mathrm{L}}}\right)^2\right]^{1/2}}. \tag{A1.4.32}$$

The numerator represents the photocurrent and the denominator represents the equivalent input noise of photodetector–preamplifier circuit. The first three components determine the noise originating from the photocurrent, the dark current and the background, the fourth component is the current noise of the preamplifier, the fifth is the thermal noise of the resistance R_{L} and the last one is the voltage noise contribution of the preamplifier.

The noise in electrical circuits is often a function of frequency. For high frequencies, the noise equivalent signal current, $I_{\mathrm{n\,total}}$, is given by

$$I_{\mathrm{n\,total}}^2=I_{\mathrm{nph}}^2+I_{\mathrm{nd}}^2+I_{\mathrm{nb}}^2+V_{\mathrm{nd}}^2\omega^2C_{\mathrm{d}}^2+I_{\mathrm{n}}^2+\frac{4kT\Delta f}{R_{\mathrm{L}}}+V_{\mathrm{n}}^2\omega^2(C_{\mathrm{d}}+C_{\mathrm{i}})^2 \tag{A1.4.33}$$

where V_{nd} is the voltage noise of the serial resistance, R_{s}.

The input capacitance of the preamplifier, C_{i}, may be considered to lie across the amplifier input on the photodiode side of the noise generator, V_{n}. Thus, with this assumption the noise generator, V_{n}, is not a true input noise generator as generally understood, as it should normally lie on the input side of all components (except, possibly, the noise current generator, which would have the same effect whichever side V_{n} it were to be connected to). The justification for this approach is firstly, that the amplifier capacitance is conveniently grouped with C_{d}, but secondly it enables V_{n} to be a 'white' noise generator.

Re-writing equation (A1.4.33) we obtain

$$I_{\mathrm{n\,total}}^2=\left[I_{\mathrm{nph}}^2+I_{\mathrm{nd}}^2+I_{\mathrm{nb}}^2+I_{\mathrm{n}}^2+\frac{4kT\Delta f}{R_{\mathrm{L}}}\right]+\omega^2[V_{\mathrm{nd}}^2C_{\mathrm{d}}^2+V_{\mathrm{n}}^2(C_{\mathrm{d}}+C_{\mathrm{i}})^2]. \tag{A1.4.34}$$

There are thus two terms, a white noise term in the first setoff square brackets and a second term that gives a noise current increasing in proportional to frequency. Although a capacitor does not add noise, the detector noise voltage (V_{nd}), and preamplifier noise voltage (V_{n}) is increased by the C_{d} and the $C_{\mathrm{d}}+C_{\mathrm{i}}$ respectively, as is evident from the coefficient of that term in equation A1.4.34. Analysing equation A1.4.34, we see that for matching an amplifier to a detector, it is important to minimize the sum of $I_{\mathrm{n}}+V_{\mathrm{n}}^2\omega^2(C_{\mathrm{d}}+C_{\mathrm{i}})^2$.

The sensitivity of an optical receiver is most conveniently expressed in terms of its NEP. This is defined as the optical power necessary to make the signal current, I_{ph} equal to the noise current $I_{\mathrm{n\,total}}$, i.e.

$$\mathrm{NEP}=(I_{\mathrm{n\,total}}^2)^{1/2}\frac{h\nu}{\eta q}. \tag{A1.4.35}$$

Many data sheets show the NEP figure for a detector, unfortunately. If we connected a preamplifier, the performance will often dependent on the amplifier noise source, critically combined with parasitic features of the photodiode, particularly its capacitance and parallel resistance (equation (A1.4.33)).

It is possible to achieve a high value of the signal-to-noise ratio at the first stage of a photoreceiver when using a voltage type preamplifier by using a high resistance value for R_L, and ensuring low current noise I_n, and low voltage noise V_n of the preamplifier. Of course, high resistance value of a R_L causes narrowing of a photoreceiver bandwidth.

Figure A1.4.17 presents the noise equivalent scheme of the first stage of a photoreceiver using a transimpedance preamplifier. In this circuit, noise sources of a detector are identical as for the case shown in figure A1.4.16, where R_{sh} is the shunt resistance of a detector. Preamplifier noise is represented by the voltage source V_n and the current source I_n. Thermal noises from a feedback resistor are represented by the current source I_{nf}.

From the arrangement in figure A1.4.17, it can be shown that the equivalent input noise is the square root of the sum of squares of noise components from: the photocurrent I_{ph}, the dark current of a detector I_d, the background current I_b, thermal noise of the resistor R_f, the current I_n, and the voltage V_n noise from a preamplifier. Thus, the signal-to-noise ratio is of the form

$$\frac{S}{N} = \frac{I_{ph}}{\left[I_{nph}^2 + I_{nd}^2 + I_{nb}^2 + I_n^2 + \frac{4kT\Delta f}{R_f} + \left(\frac{V_n}{R_f}\right)^2\right]^{1/2}}. \tag{A1.4.36}$$

For high frequencies, the last term of the denominator should contain parallel combination of all impedances across the input of the preamplifier, e.g. R_f, R_d, $(\omega C_d)^{-1}$, and $(\omega C_i)^{-1}$.

In a photoreceiver using transimpedance preamplifier, an identical bandwidth can be obtained by choosing a feedback resistance R_f much higher than the resistance $R = R_d \| R_L \| R_i$, which would be possible in a simpler photoreceiver with a voltage type preamplifier. Thus, comparing formulae (A1.4.32) and (A1.4.36), it can be noticed that for the same bandwidth the signal-to-noise ratio is higher for transimpedance preamplifier than for a classic one. In practice, it means that transimpedance amplifiers can have wider bandwidths yet retain the low noise characteristics of high-impedance preamplifiers.

In p–n and p–i–n photodiodes, the basic source of noise is shot noise originating from the photocurrent I_{ph}, the dark current I_d, and the background radiation current I_b. In these photodetectors, the thermal noises of detector resistance and noises of active elements of a preamplifier can also play a significant role.

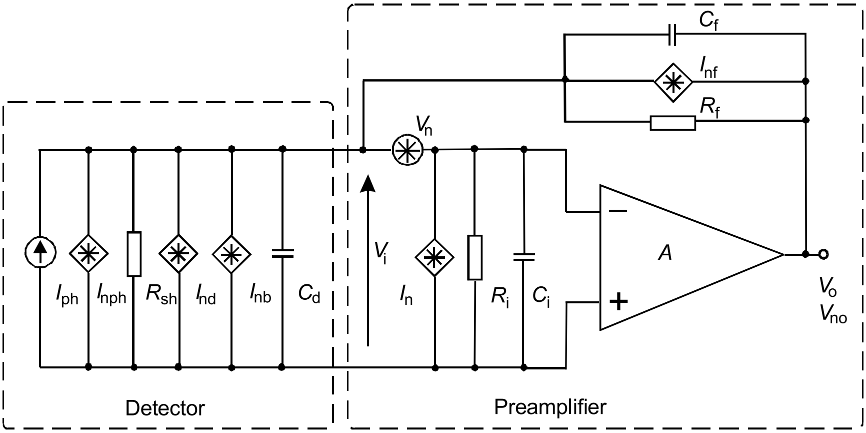

Figure A1.4.17. Equivalent scheme of the first stage of a photoreceiver with transimpedance preamplifier. Reproduced from [6].

All the preamplifier noises V_{n} and I_{n} can be substituted for one equivalent current noise:

$$I_{\mathrm{a}}^2 = \frac{1}{\Delta f}\int_0^{\Delta f}(I_{\mathrm{n}}^2 + V_{\mathrm{n}}^2|Y|^2)\mathrm{d}f \tag{A1.4.37}$$

where Y is the input admittance of an amplifier.

As stated earlier, photodiodes can operate with either voltage or transimpedance preamplifiers. For the equivalent schemes shown in figures A1.4.16 and A1.4.17, the signal-to-noise ratio is of the form:

$$\frac{S}{N} = \frac{I_{\mathrm{ph}}}{\left[2q(I_{\mathrm{ph}} + I_{\mathrm{d}} + I_{\mathrm{b}})\Delta f + \frac{4kT\Delta f}{R_{\mathrm{L}}} + I_{\mathrm{a}}^2\right]^{1/2}}. \tag{A1.4.38}$$

The first term represents the shot noise component of the photocurrent, the dark current and the background, whereas the second term is the thermal noise of load resistance of a photodetector, and the third term is the preamplifier noise. For the circuit shown in figure A1.4.17, the resistance R_{L} is the feedback resistor, R_{f}.

Let us consider a few special cases. Assuming that the signal current is higher than the dark current, I_{d} can be omitted in equation (A1.4.38). This is valid when the dark current is insignificant or if the received optical power is high. The assumption can also be made that the shot noise significantly exceeds thermal noise when the optical power has a high level. For low frequency FET transimpedance receivers, the shot noise limit is usually obtained when the output signal exceeds 50 mV. It means that the term $4kT\Delta f/R_{\mathrm{L}}$ can be omitted. If additionally $I_{\mathrm{a}}^2 \ll 2q\Delta f(I_{\mathrm{ph}} + I_{\mathrm{d}})$, the expression for signal-to-noise ratio can be simplified to the form

$$\frac{S}{N} = \left(\frac{I_{\mathrm{ph}}}{2q\Delta f}\right)^{1/2} = \left(\frac{\eta\Phi_{\mathrm{e}}\lambda}{2hc\Delta f}\right)^{1/2} = \left(\frac{\eta A E_{\mathrm{e}}\lambda}{2hc\Delta f}\right)^{1/2} \tag{A1.4.39}$$

where λ is the wavelength of incident radiation, Φ_{e} is the incident radiation flux (in W), and E_{e} is the detector's irradiance. A photoreceiver, the signal-to noise ratio of which is described by formula (A1.4.39), is limited only by a shot noise. This noise is also called quantum limited one—see equation (A1.4.12). Unfortunately, it is not always the case that the high optical power reaches a photoreceiver. If the power of an optical signal is low, the shot noise is negligible in relation to the thermal noise, then

$$\frac{S}{N} = \frac{\eta q \Phi_{\mathrm{e}}}{h\nu}\left(\frac{R_{\mathrm{L}}}{4kT\Delta f}\right)^{1/2}. \tag{A1.4.40}$$

It is evident that when a photoreceiver is limited by the thermal noise, it is thermally dependent (see equation (A1.4.13)).

When thermal noise is limited, it can be seen by analysing equation (A1.4.40) that the signal-to-noise ratio increases directly in proportion to the received optical power. Thus, in the range of a thermally dependent photoreceiver, small changes, e.g. of path transmission efficiency will cause significant differences in the signal-to-noise ratio of the received signal. In the quantum limited systems, an increase in the optical power by $\Delta\Phi_{\mathrm{e}}$ [dB] gives an improvement in the signal-to-noise ratio of only half the change $\Delta\Phi_{\mathrm{e}}$ when expressed in dB.

One way of overcoming the preamplifier noise is to use a detector having a high degree of internal gain, prior to connection to this device. There are two main types of detector that can be used; the photomultiplier, which is rather large and inconvenient, and the avalanche photodiode. The main advantages are apparent at high frequency, when amplifier noise contribution is more troublesome, because of stray capacitances lowering the impedance across the amplifier input.

Let us consider the signal-to-noise ratio in the first stage of photoreceiver with an avalanche photodiode. The high sensitivities of APDs can be obtained due to a phenomenon of avalanche multiplication, which significantly increases the current signal generated at the output of the detector and improves the signal-to-noise ratio. Of course it does not influence the noises from the load resistance and the amplifier noises, but increases the signal as usually only noise originating from the signal current and dark current (quantum noise) are dominant. Unfortunately, at high gain levels, the random mechanism of carrier multiplication (M) introduces excess noise, in the form of higher shot noise, which eventually exceeds the noise level resulting only from primary generation of unequilibrium carriers.

At moderate gain levels, the dominant source of the noise in an avalanche photodiode is the signal and dark current shot noises, which are multiplied. However, if the signal power is increased by a factor M^2, the noise power increases by a factor M^{2+x}. The factor x is typically between 0.3 and 0.5 for silicon APDs and between 0.7 and 1.0 for germanium and III–V alloy APDs.

Knowing the total noise, a signal-to-noise ratio can be determined as

$$\frac{S}{N} = \frac{MI_{\text{ph}}}{\left\{2q\Delta f\left[I_{\text{ph}}M^{2+x} + I_{\text{s}} + (I_{\text{b}} + I_{\text{db}})M^{2+x}\right] + \frac{4kT\Delta f}{R_{\text{L}}}F_{\text{n}}\right\}^{1/2}}. \tag{A1.4.41}$$

The numerator of this equation determines the photocurrent and denominator noises. The first term of the denominator is a shot noise term and the second one represents the thermal noise of load resistance with a preamplifier noise (F_{n} is the noise factor of preamplifier, I_{db} is the bulk leakage current component of primary dark current, and I_{s} is the surface leakage current of a dark current). Shot noise components except the surface leakage component of the dark current are multiplied, so the photocurrent, current from a background, and bulk leakage current components of the primary dark current are multiplied. When M is large, the thermal and amplifier noise term becomes insignificant and the S/R ratio decreases with increasing M. Therefore an optimum value of the multiplication factor M_{op} exists which maximizes the S/N ratio.

Figure A1.4.18 presents the typical dependence of signal current, thermal noise, shot noise and total noise on the avalanche multiplication factor [6]. For low values of multiplication factor, the signal

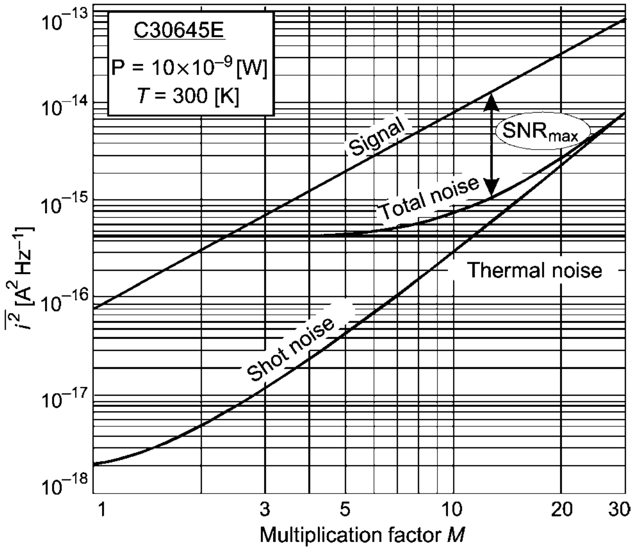

Figure A1.4.18. Dependence of signal, thermal noise, shot noise and total noise on avalanche multiplication factor.

amplitude is usually lower than the total noise amplitude. In this range, thermal noises are dominant at the low optical input levels usually used with APDs. For high multiplication values, thermal noises become less important but shot noises are then significant. There is a supply voltage for which a distance between the line representing the signal and the curve representing the total noise is the largest, corresponding to when the *S/N* ratio is maximum. Of course, these parameters will change with temperature, because the dark current of a photodiode and the avalanche multiplication factor are both strongly thermally dependent.

A1.4.3 Advanced method of signal detection

A1.4.3.1 Signal averaging

When measuring a small repetitive or steady-state signal in the presence of noise, we can often improve the results by making a number of measurements and taking their average. Figure A1.4.19 presents a scheme of signal detection system for steady-state signals with an analogue integrator.

If radiation from both a signal source and the background is incident on a detector surface, the desired signal will appear with noise at the detector output. It is amplified in a preamplifier and next reaches the integrator input. Let us assume that before beginning the measurement cycle, the voltages at inputs of both the differential amplifier of the integrator and the integrator output are all equal to zero. If a voltage V_i appears at the integrator input, a current I_1 will flow through the resistor R. This current causes changes the capacitor C, to give a voltage $V_o(T)$ at the system output, where:

$$V_o(T) = -\frac{1}{RC}\int_0^T V_i\,dt + V_o(0) \tag{A1.4.42}$$

where $V_o(0)$ is the initial voltage at the capacitor at $t = 0$ and $RC = \tau$ is the time constant of the integrator.

The voltage at the system output is inversely proportional to the time constant. In practice, the capacitor C is short-circuited at the beginning of a measuring cycle by means of the switch K. So, the second constant term of equation (A1.4.42) can be omitted. Opening the switch K initiates the measuring cycle, during which the signal integration occurs. If the assumption is taken that there is a constant voltage of the value v at the system input, then, after a time t, the output voltage will be directly proportional to the product vt. Thus, the signal-to-noise ratio at the integrator output takes a form

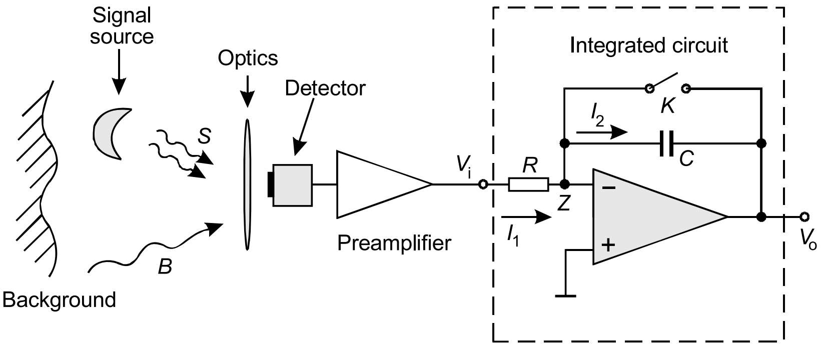

Figure A1.4.19. Analogue integrator used to collect detected signal level.

$$\frac{S}{N} = v\left(\frac{2t}{S_n}\right)^{1/2} \tag{A1.4.43}$$

where S_n is the input white noise power density. This equation tells that the signal-to-noise ratio can increase linearly with the square root of the integration time t (for $t \ll RC$).

The integrating process in mathematical form is equal taking a series of measurements and summing each of the received values. If we make N measurements, each integrated over the period t, and then the received results are added, the signal-to-noise ratio is described as

$$\frac{S}{N} = v\left(\frac{2Nt}{S_n}\right)^{1/2}. \tag{A1.4.44}$$

In this case, signal-to-noise ratio increases proportionally to square root of a number of the performed measurements (or the total measurement time Nt). Similarly as in equation (A1.4.43), the time constant of an integrator does not affect the value of a signal-to-noise ratio. In real conditions, the value of the time constant should be chosen to ensure the desired level of the output signal after an appropriate integration time t [7].

One disadvantage of the simple integrator is that $1/f$ noise, electronic offsets, and background light level charges can all degrade the performance. We shall now describe another signal recovery method that avoids these problems.

A1.4.3.2 Lock-in amplifier

A lock-in amplifier uses phase-sensitive detection to improve the signal-to-noise ratio in cw experiments. For phase-sensitive detection, the analogue signal should be modulated at some reference frequency. This enables the noise component to be filtered out, even when it may initially be many times stronger than the signal itself. If the detected signal of interest is modulated by a carrier signal of defined phase and frequency, it is possible to separate this signal from the noise component. This requires the availability of a low-noise, stable reference frequency ω_{ref} of the same frequency as the carrier signal. In optical measurements, it is usually achieved by initially modulating a stable light source with this reference frequency ω_{ref}. The light transmitted, reflected or scattered from the test sample, now heavily attenuated but still modulated with ω_{ref}, is then measured. Measurement information is provided by the amplitude of the signal that falls on the detector (figure A1.4.20). The reference signal is connected to the

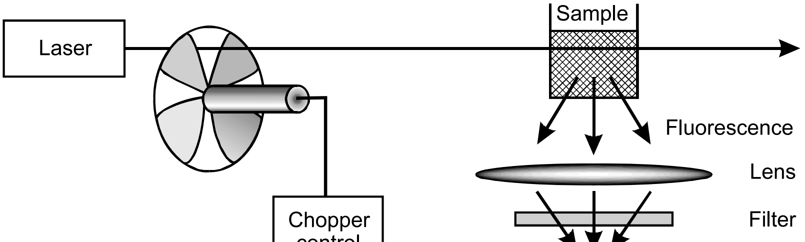

Figure A1.4.20. Use of a lock-in amplifier in fluorescence detection.

lock-in amplifier via the reference input (figure A1.4.21). The first stage of the lock-in amplifier is usually a programmable ac amplifier which matches the signal amplitude to a suitable level, ensuring it does not overload (saturate or 'clip') the following electronic components.

In the diagram below, the reference signal is a square wave of frequency ω_{ref}. This might be the clock output from a function generator. If the sine output from the function generator is used to excite the experiment, the response might be the signal waveform shown below.

In order to simplify the analysis, we shall assume that the system is noise-free.

The signal at the optical detector is

$$V_{\mathrm{d}} = V_{\mathrm{S}} \sin(\omega t + \phi) + V_{\mathrm{n}} \tag{A1.4.45}$$

where V_{S} is the signal amplitude and ϕ is the signal phase.

The bandpass filter, centred at ω_{ref}, removes all noise frequencies which are outside a defined bandwidth around ω_{ref}. This is to give some pre-filtering, to stop the following circuits being so easily overloaded by high levels of noise. The next stage is the phase sensitive demodulator (PSD). Here, the filtered signal is multiplied by a square wave signal of the same frequency ω_{ref} and, ideally, the same phase as the signal at this point.

The internal reference is

$$V_{\mathrm{H}} = V_{\mathrm{L}} \sin(\omega_{\mathrm{L}} t + \phi_{\mathrm{ref}}). \tag{A1.4.46}$$

The output of the PSD is simply the product of two sine waves

$$\begin{aligned} V_{\mathrm{psd}} &= V_{\mathrm{S}} V_{\mathrm{L}} \sin(\omega t + \phi)\sin\left(\omega_{\mathrm{L}} t + \phi_{\mathrm{ref}}\right) \\ &= \frac{1}{2} V_{\mathrm{S}} V_{\mathrm{L}} \cos\left[(\omega - \omega_{\mathrm{L}})t + \phi - \phi_{\mathrm{ref}}\right] - \frac{1}{2} V_{\mathrm{S}} V_{\mathrm{L}} \cos\left[(\omega + \omega_{\mathrm{L}})t + \phi + \phi_{\mathrm{ref}}\right]. \end{aligned} \tag{A1.4.47}$$

The PSD output is two ac signals, one at the difference frequency $(\omega - \omega_{\mathrm{L}})$ and other at the sum frequency $(\omega + \omega_{\mathrm{L}})$. The phase difference ϕ between the square wave and the signal is important here. If both signals are exactly in phase, the resulting output signal reaches a maximum (figure A1.4.22). If this is not the case, the desired ac component will not be so well detected in the subsequent processes and will actually give zero output if the phase difference is 90°. For this reason, lock-in amplifiers are equipped with a phase shifter which is used to bring the two signals into phase, either manually or automatically.

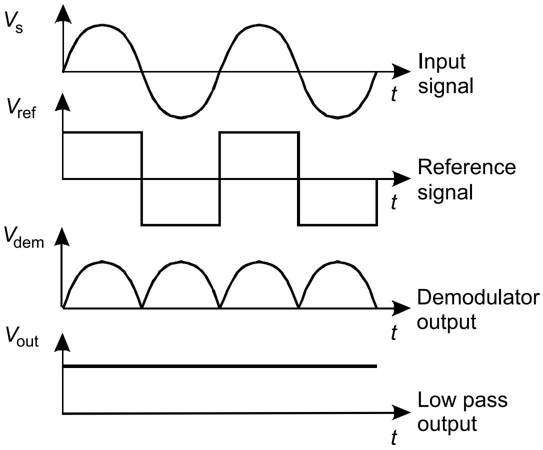

Figure A1.4.22. Signal processing where input signal and reference signal are in phase.

Sometimes these lock-ins are used with the references set 90° apart, or 'in-phase' and 'quadrature' signals are obtained. Then the desired signal is the square root of the sum of the squares of in-phase and quadrature components, and budding is not possible. The resulting signal includes contribution from the sum and difference frequencies of the two components.

A low pass filter is then used to remove any ac components from the dc signal. The lower the cut-off frequency of the filter, the better the suppression of the unwanted noise components. However, this also leads to a longer filter time constant and therefore a longer measurement time. Any changes in optical signal level that occur faster than the filter time constant can, of course, no longer be observed. The low pass filter effectively removes any high frequency noise remaining following the demodulator process. However, if ω_{ref} equals ω_{L}, the difference frequency component will be a dc signal. In this case, the filtered PSD output will be

$$V_{\mathrm{out}} = \frac{1}{2} V_{\mathrm{S}} V_{\mathrm{L}} \cos(\phi - \phi_{\mathrm{ref}}). \tag{A1.4.48}$$

The dc signal is proportional to the signal amplitude.

The final stage of the lock-in consists of a programmable dc amplifier which further amplifies the smoothed signal. At the output, the result is ideally a noise-free dc signal whose amplitude is directly proportional to the strength of ac signal at the lock-in input. A further advantage of the lock-in amplifier is that it removes '$1/f$' noise components, as only noise at frequencies close to the modulation frequency is effectively observed after the electronic processing.

In the above considerations, we have assumed that the chopped signal and the reference output share the same phase. This may not always be the case.

A1.4.3.3 Boxcar detection systems

Phase-sensitive detection systems are used for measurements of steady periodic signals or ones that have a relatively slow varying level. Frequently, it is desired to measure the amplitude envelope of periodical signals. For this purpose, various measuring methods can be used. One of these methods is the so-called 'boxcar' detection system, which performs synchronous integration (figure A1.4.23). This method allows measurement of periodical signals of complex shapes, even when the signal amplitude is lower than the

level of the first stage noise of a photoreceiver. To apply this method, two basic conditions must be fulfilled:

- the measured signal should be periodic and repeatable;
- a trigger signal should be available, which can be used to tell the measurement system when each signal cycle begins. (This latter signal could be derived using a phase-lock-loop if the periodic signal is available for a long enough time.)

The detection system consists of a signal source, detector–preamplifier system, switch, integrator and a control system. The control system includes: a clock, delay circuit and a multivibrator. Pulses from the clock generator are used to drive simultaneously an optical signal source and a delay circuit in the signal processor. The output signal from the delay circuit triggers the multivibrator, which is turn closes a switch. The switch on time of the key switch depends on the pulse duration of the multivibrator. A semiconductor laser (LD) or electro-luminescence diode (LED) is usually used as the optical source.

We shall assume that the control generator operates at a frequency $f = 1/T$. The delay time of the clock pulse controlling initiation of the multivibrator is t_d and the key-switch on time is t_m, as determined by the mono-stable multivibrator. The leading edge of each clock pulse starts the light pulse generation. Figure A1.4.24 shows the temporal variation courses of voltages at critical points of the boxcar detection system. A signal from the detector output is sent after amplification to an electronic switch and then to an integrator to average the signal.

The signal $V_k(t)$ reaching the integrator is described by the formula

$$\begin{aligned} V_k(t) &\equiv V_D(t) \qquad \text{for } t_d \le t \le t_d + t_m \\ V_k(t) &\equiv 0 \qquad \text{for other } t. \end{aligned} \tag{A1.4.49}$$

We shall now calculate the voltage at the output of the integrator. We assume that the voltage at the integrator output is initially equal to zero and that we make measurements for m periods of an input waveform. In order to simplify the initial analysis, we shall assume that the system is noise free. For this

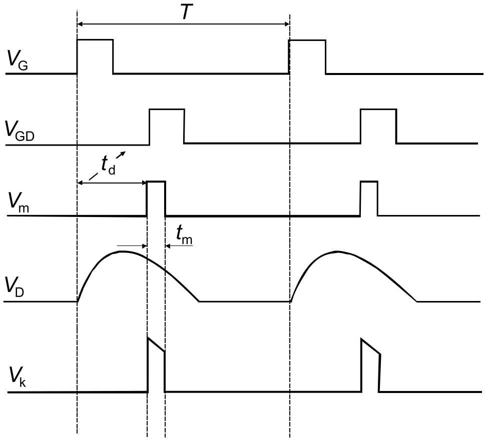

Figure A1.4.24. Control and data waveforms in phase-sensitive detection systems.

assumption, the voltage at the system output is

$$V_o(t_d) = -\frac{1}{RC} m \int_0^T V_k(t)\mathrm{d}t = -\frac{1}{RC} m \int_{t_d}^{t_d+t_m} V_D(t)\mathrm{d}t \qquad \text{(A1.4.50)}$$

where R and C determine the resistance and the capacitance values of the integrator, respectively. The minus sign in this equation is present because the voltage signal is applied to an inverting input. If the time interval is sufficiently small, the signal level will not change significantly between the times, t_d and $t_d + t_m$. Thus, formula (A1.4.50) takes the form

$$V_o(t_d) = -\frac{m}{RC} V_D(t) t_m. \qquad \text{(A1.4.51)}$$

It results from this formula that the voltage value at the output of the integrator $V_o(t)$ is directly proportional to the instantaneous value of the voltage at the preamplifier output $V_D(t)$, signal cycles m, and pulse duration t_m, but is inversely proportional to the time constant of the integrator. The boxcar detection system exhibits an increase in the amplitude of the output signal in proportion to the number of measuring cycles m.

The signal-to-noise ratio of the boxcar detection system if a white noise input voltage source is now considered to be present is given by

$$\frac{S}{N} = \frac{V_D(t)}{V_{ni}} m(2\Delta f t_m)^{1/2}. \qquad \text{(A1.4.52)}$$

An increase in the signal-to-noise ratio is obtained with a larger number of measuring cycles and longer time of key switch on, the improvement being in proportion to m.

The above measuring system is called a boxcar detection system, because the samples are added synchronously with the measuring cycles of a signal, like loading wagons (or boxcars) on a train. Boxcar detection systems are very effective in recovering information from repetitive signals when the noise level is quite high. Improvement in the signal-to-noise ratio, obtained due to signal measurement for m cycles is, of course, at the expense of greater measurement time, being given by mT.

A drawback of the method is that the integrator is disconnected from the input for most of the time. A voltage measurement at the photodetector–preamplifier system is performed only during the time interval t_m/T (i.e. when the key is switched on). So, to measure a pulse shape, we have to repeat the measurement process up to T/t_m times for each t_d value. The time required to measure a pulse shape will be mT^2/t_m. The total measurement time can be reduced by increasing the time of a single sampling t_m. However, it constrains observation of the pulse details.

The boxcar detection system is not efficient because most of the signal power is ignored during the key switch off. This drawback can be avoided by using a parallel processing scheme, involving a multiplexed array of boxcar detection systems. To achieve this, an analogue multiplexer can be used to separate into parallel channels or, more frequently with modern technology, a system with digital path of signal processing is applied. Many digital oscilloscopes are now equipped with such parallel averaging schemes.

A1.4.3.4 Coherent detection

So far, we have considered systems that were based on the modulation of the light intensity in a transmitter and direct detection of this in a photoreceiver. It was not essential for the modulated light wave to be a coherent wave and its spectrum could be wide. These systems are simple and cheap but they have constraints on their transmission possibilities. The photoreceivers decoded only the information connected with the intensity or with the square of the electromagnetic field amplitude whereas information can be carried also by its phase and frequency. The possible photoreceiver sensitivity results from the basic noise limits, as the noise of the photodetector, preamplifier, and background.

To improve the signal-to-noise ratio, it would be an advantage to increase the photocurrent at the detector output. We have already noted that using photoreceivers with APDs had constraints resulting from additional multiplication noises. To avoid problems with direct detection, coherent detection, a method of receiving based on interference of two beams of coherent laser radiation, can be used [9–11]. Figure A1.4.25 illustrates the differences between coherent detection and direct detection.

Figure A1.4.25(*a*) presents a direct detection system. To narrow the received optical bandwidth, we have applied a filter to limit the spectral range of radiation reaching the detector—figure A1.4.25(*b*). For example, optical filters based on the Bragg effect can have 5-nm bandwidth for 1.56 μm wavelengths, corresponding to a detection band, Δf, equal to 600 GHz [12]. This wide bandwidth, of what is a reasonably narrow optical filter, illustrates that application of an optical filter cannot easily ensure narrow wavelength selection of a photoreceiver. A widely spaced Fabry–Perot filter can achieve bandwidth of several hundred MHz, but is costly and difficult to stabilize, so impractical for most systems. However, the simple addition of a beam-splitter and an additional coherent light source, a so-called, local oscillator, provides a coherent detection scheme, that can use either heterodyne and homodyne detection systems (see figure A1.4.25(*c*)).

Heterodyne detection technique has been commonly used for many years in commercial and domestic radioreceivers and also for the microwave range of an electromagnetic spectrum. The main virtues of this method of detection are higher sensitivity, higher and more easily obtained selectivity, plus the possibility of detection of all types of modulation and easier tuning over wide range [13]. Coherent optical detection has been developed since 1962, but compact and stable production of this system is more difficult, and the system is more expensive and troublesome than its radio-technique equivalent. The basic block diagram of heterodyne optical receiver is shown in figure A1.4.26.

Laser radiation containing information, is after being passed through an input optical filter and beam splitter, arranged to coherently combine or ‘mix’ with a light beam of a local oscillator at the detector surface. A beam-splitter can be made in many ways, the simplest being a glass plate with adequate refraction coefficient. In a general case, a device fulfilling such a role is called a direction

coupler, as an analogy to microwave or radio devices. A detector used for signal mixing has to have a square-law characteristic to detecting electronic field of the light, but this is conveniently typical of most optical detectors (photodiode, photoconductor, photomultiplier, APD, etc). This signal is next amplified. An electrical filter of intermediate frequency (IF) extracts the desired difference component of the signal, which next undergoes a demodulation process. The design and operation principle of the subsequent electrical detector depends on the nature of the modulation of a signal. The signal from a load resistance passes through an output filter to a receiver output and by means of a local oscillator frequency controller it controls a laser. A frequency control loop is used for the local oscillator laser to maintain a constant frequency difference $\omega_L - \omega_s = \omega_p$ with the input signal. An indispensable condition

for efficient coherent detection is to match the polarisation, and the shape of both waveforms of both beams to match the profile of the detector surface.

Expression for the signal-to-noise ratio at the heterodyne detection system with APD for $P_L \gg P_S$ is given by

$$\frac{S}{N} = \frac{\sqrt{2}R_i M\sqrt{P_S P_L}}{\left(2q\Delta f M^{2+x} R_i P_L + \frac{4kT\Delta fF}{R_L}\right)^{1/2}} \approx \left(\frac{R_i P_S}{q\Delta f M}\right)^{1/2}. \tag{A1.4.53}$$

Assuming a photodiode responsivity $R_i = \eta q/h\nu$, we have

$$\frac{S}{N} = \frac{\eta P_S}{h\nu\Delta f M^x} = 2\left(\frac{S}{N}\right)_{\text{quanta}}. \tag{A1.4.54}$$

Figure A1.4.27 shows a comparison of coherent detection sensitivity (solid lines) with the sensitivity of direct p–i–n photodiode detection ($M = 1$) for the same values of signal-to-noise ratio. Significant improvement in sensitivity can be observed for weak signals. Higher sensitivity of a detector ensures qualitatively better detection as increased information bit rate can permit longer communications links to be used between each regenerator circuit. In long-distance fibre telecommunications, however, the use of optical fibre amplifier has taken much of the impetus from development of the coherent receiver, although the latter still has the unique advantage of highly selective narrowband detection.

In heterodyne detection, the spectrum of laser modulation was shifted into an IF range, so selectivity of a photoreceiver depends on the bandwidth of the IF amplifier. This is arranged

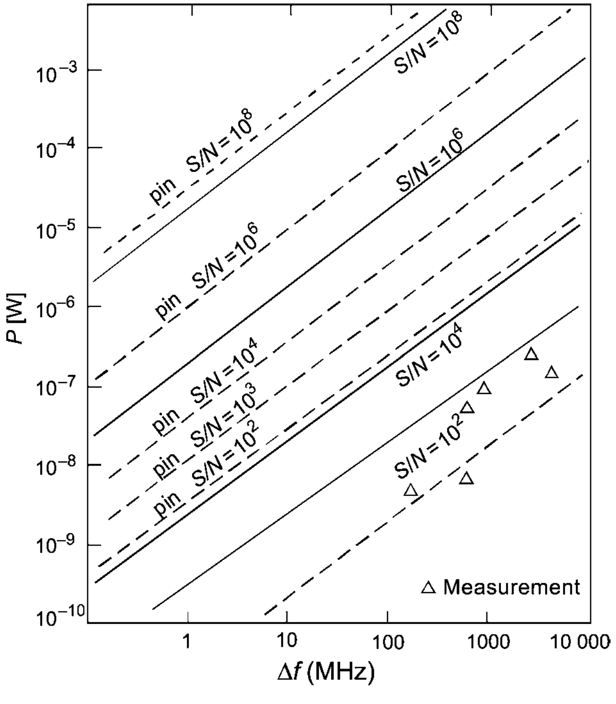

Figure A1.4.27. Sensitivity of the coherent photoreceiver (dashed line) and p–i–n photodiode (solid line). Reproduced from [14].

electronically, so it can easily be sufficiently narrow. Having narrow IF circuit bandwidth is especially important for detection of multichannel signals.

In practice, the technique of heterodyne detection is used for construction of Doppler velocimeters and laser rangefinders and as well as in spectroscopy (particular LIDAR systems). It may yet find application in more telecommunications systems.

If a signal frequency is equal to the frequency of a local oscillator, the IF frequency equals zero. It is a special case of coherent detection, so-called, homodyne detection.

In a homodyne detection optical receiver (figure A1.4.28), the incoming laser carrier is again combined with a reference wave from a local laser on a photodiode surface, but in this case both frequencies are the same. It does not contain two blocks, filter of IF frequency and demodulator which were in the heterodyne receiver.

The photodetector current in a homodyne receiver is given by:

$$I_{\mathrm{hom}} = R_{\mathrm{i}}M(P_{\mathrm{S}} + P_{\mathrm{L}}) + 2R_{\mathrm{i}}M(P_{\mathrm{S}}P_{\mathrm{L}})^{1/2}\cos\phi_{\mathrm{p}}(t). \tag{A1.4.55}$$

The first component is a direct-current component but the second one contains the useful information regarding the optical signal. The current at the detector output increases with increase in local oscillator power and with the optical receiver responsivity.

If the local oscillator power is high, the shot noise originating from a signal current, thermal noise and dark-current noise can be omitted. For amplitude modulation we have

$$\frac{S}{N} = \frac{(2R_{\mathrm{i}}M(P_{\mathrm{S}}P_{\mathrm{L}})^{1/2})^2 R_{\mathrm{L}}}{(2q\Delta f M^{2+x}R_{\mathrm{i}}P_{\mathrm{L}} + 4kT\Delta f F/R_{\mathrm{L}})R_{\mathrm{L}}} \approx \frac{2R_{\mathrm{i}}P_{\mathrm{S}}}{q\Delta f M^{x}} = \frac{2\eta P_{\mathrm{S}}}{h\nu\Delta f M^{x}}. \tag{A1.4.56}$$

As can be seen, the signal-to-noise ratio for homodyne detection is twice as high as heterodyne detection. This is basically because the homodyne detector allows direct addition or subtraction of the electrical fields, depending on whether the signal and local oscillator are in phase or 180° out of phase. With heterodyne detection, the relative phases change linearly with time, and mixing of signals is not effective when signals have 90 or 270° phase difference.

As it results from equation A1.4.55, homodyne detection derives the baseband modulation signal carrying the information directly. Thus, further electronic demodulation is not required.

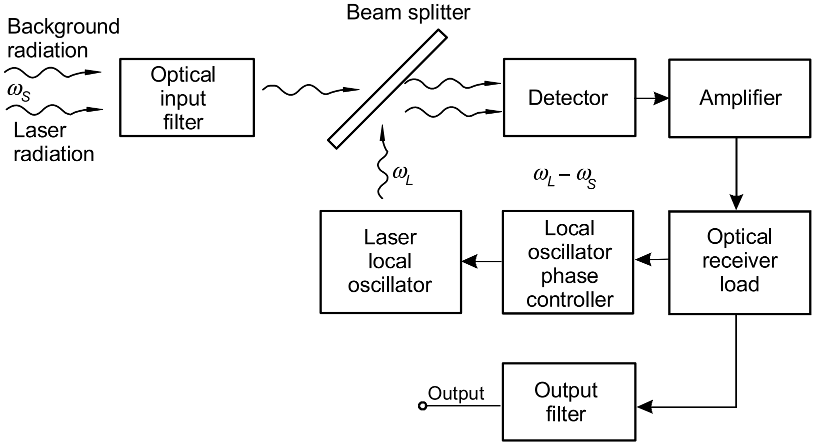

Figure A1.4.28. Block diagram of homodyne detection optical receiver.

Homodyne receivers are used in the most sensitive coherent systems. In practice, construction of such receivers is difficult because

- the local oscillator must be locked to keep a constant zero phase difference to the incoming optical signal, and this requires excellent spectral purity;
- power fluctuation of the local laser must be eliminated.

Constant difference of both laser phases can be achieved using an optical phase-locked loop.

The requirements for spectrum purity are less critical in the diversity systems [10, 12] in which the cosine component current expressed by equation A1.4.55 and also the quadrature current component proportional to $\sin \phi_p t$ are produced. A sum of vectors of these currents makes it possible to avoid influence of ϕ_p phase change, but as with the heterodyne system, the SNR suffers when phases are not identical.

It has been assumed that the local laser has no amplitude noise. In practice this type of noise is often the limiting factor, because the local laser power is strong compared with signal component $2(P_S P_L)^{1/2}$. If detecting these output waves by means of photodiodes gives the corresponding currents

$$I_1 \propto a^2 P_S + b^2 P_L + 2ab(P_S P_L)^{1/2} \cos[\omega_S t - \omega_L t + \phi_S(t) - \phi_L(t) + \pi/2] \tag{A1.4.57}$$

$$I_2 \propto b^2 P_S + a^2 P_L - 2ab(P_S P_L)^{1/2} \cos[\omega_S t - \omega_L t + \phi_S(t) - \phi_L(t) + \pi/2]. \tag{A1.4.58}$$

This noise is contained in the terms $b^2 P_L$ and $a^2 P_L$, respectively. If we assume a symmetrical beam combiner ($a = b$), and the currents I_1 and I_2 are subtracted, then the terms containing P_S and P_L cancel out, and so do their amplitude fluctuations. Due to the opposite sign of the third term in equations (A1.4.57) and (A1.4.58), the output signal from the subtractor is doubled. Using the two outputs in this way produces a balanced mixing receiver, using a beam splitter or fibre coupler (figure A1.4.29).

In order to make the interference of the signal wave and the local oscillator wave that is received more efficient, their polarization states must coincide. Due to random vibration in the fibre and temperature changes, mechanical strain in the fibre introduces birefringence, which changes with time. As a consequence, the polarization state of the signal received changes randomly.

The problems caused by a polarization mismatch can be overcome in the following ways by:

- using a polarization state controller;
- polarization scrambling (the polarization state is deliberately changed at the transmitting end);

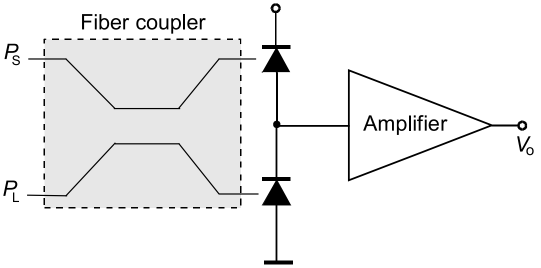

Figure A1.4.29. Balanced mixing receiver with fibre coupler and series connection of the photodiodes.

- use of polarization-maintaining fibres (this solution is more expensive);
- using polarization diversity (both the local optical wave and signal wave received are split into two orthogonal polarization states).

A1.4.4 Arrays of detectors and detectors for focal plane arrays

Many materials have been investigated to fabricate photodetectors [15–17]. Figure A1.4.30 shows the quantum efficiency of some of the detector materials used to fabricate arrays of ultraviolet (UV), visible and infrared detectors. AlGaN detectors are being developed in the UV region. Silicon p–i–n diodes are shown with and without antireflection coating. Lead salts (PbS and PbSe) have intermediate quantum efficiencies, while PtSi Schottky barrier types and quantum well infrared photodetectors (QWIPs) have low values. InSb can respond from the near UV out to 5.5 μm at 80 K. A suitable detector material for near-IR (1.0–1.7 μm) spectral range is InGaAs lattice matched to the InP. Various HgCdTe alloys, in both photovoltaic and photoconductive configurations, cover from 0.7 to over 20 μm. Impurity-doped (Sb, As, and Ga) silicon impurity-blocked conduction (IBC) detectors operating at 10 K have a spectral response cut-off in the range from 16 to 30 μm. Impurity-doped Ge detectors can extend the response out to 100–200 μm.

The term FPA refers to an assemblage of individual detector picture elements (‘pixels’) located at the focal plane of an imaging system. Although the definition could include one-dimensional (‘linear’) arrays as well as 2D arrays, it is frequently applied to the latter (see figure B8.14(*b*)). Usually, the optics part of an optoelectronic images device is limited only to focusing of the image onto the detectors array. These so-called ‘staring arrays’ are scanned electronically usually using circuits integrated with the arrays. The architecture of detector-readout assemblies has assumed a number of forms that are discussed below. The types of readout integrated circuits (ROICs) include the function of pixel deselecting, antiblooming on each pixel, subframe imaging, output preamplifiers, and may include yet other functions. Infrared imaging systems which use two-dimensional arrays belong to so-called ‘second generation’ systems.

Development in detector FPA technology has revolutionized many kinds of imaging in the past 25 years [18]. From γ rays to the infrared and even radio waves, the rate at which images can be acquired

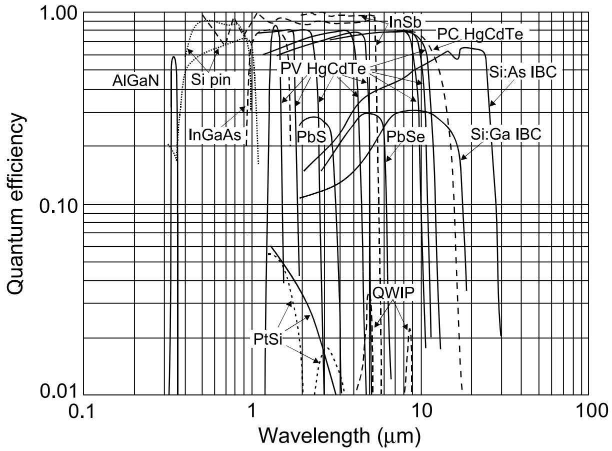

Figure A1.4.30. Quantum efficiency of UV, visible, and infrared detector arrays.

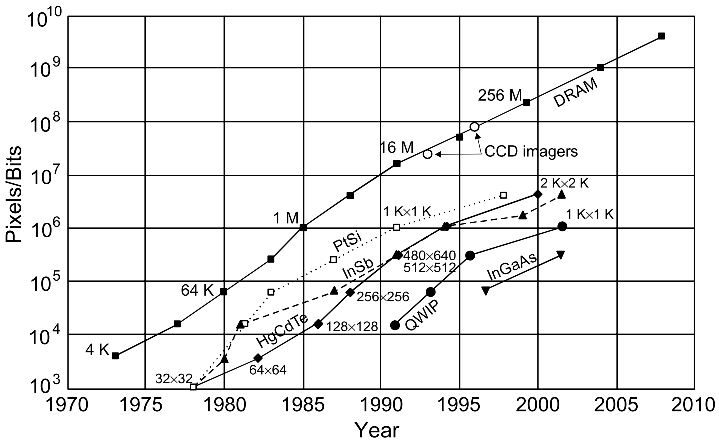

Figure A1.4.31. Increase in array format size over the past 30 years. Reproduced from [18].

has increased by more than a factor of a million in many cases. Figure A1.4.31 illustrates the trend in array size over the past 30 years. Imaging FPAs have developed in proportion to the ability of silicon ICs technology to read and process the array signals, and with ability to display the resulting image. FPAs have nominally the same growth rate as dynamic random access memory (DRAM) ICs (which have had a doubling-rate period of approximately 18 months; it is a consequence of Moore's Law, which predicts the ability to double transistor integration on each IC about every 18 months) but lag behind in size by about 5–10 years. ROICs are somewhat analogous to DRAM-only readouts, but require a minimum of three transistors per pixel, compared to one for each memory cell. Readouts are also analogous in terms of an emphasis on low noise inputs and generally maximum charge storage capacity. Charge coupled devices (CCDs) with close to 100 M pixels offer the largest formats. PtSi, InSb and HgCdTe have been following the pace of DRAM. In the infrared, 4 M pixel arrays are now available for astronomy applications.

A1.4.4.1 Monolithic arrays

In general, the architectures of FPAs may be classified as monolithic and hybrid. When the detector material is either silicon or a silicon derivative (e.g. platinum silicide, PtSi), the detector and ROIC can be built on a single wafer. There are a few obvious advantages to this structure, principally in the simplicity and lower cost associated with a directly integrated structure. Common examples of these FPAs in the visible and near infrared (0.7–1.0 μm) are found in camcorders and digital cameras. Two generic types of silicon technology provide the bulk of devices in these markets: CCDs and complementary metal–oxide–semiconductor (CMOS) imagers. CCD technology has achieved the highest pixel counts or largest formats with numbers approaching 10^8 (figure A1.4.32). CMOS imagers are also rapidly moving to large formats and are expected to compete with CCDs for the large format applications within a few years.

An example CCD array made by Dalsa is illustrated in figure A1.4.33. This array has approximately 25 M pixels, and can operate at 2.5 frames per second with 8 outputs. Although monolithic structures have been proposed for a wide variety of infrared detector materials over the past 30 years, only a few have been demonstrated. These include PtSi, and more recently PbS, PbTe, and uncooled microbolometers. Uncooled detector arrays are revolutionizing the infrared imaging community, by eliminating the need for expensive and high-maintenance coolers that are required by

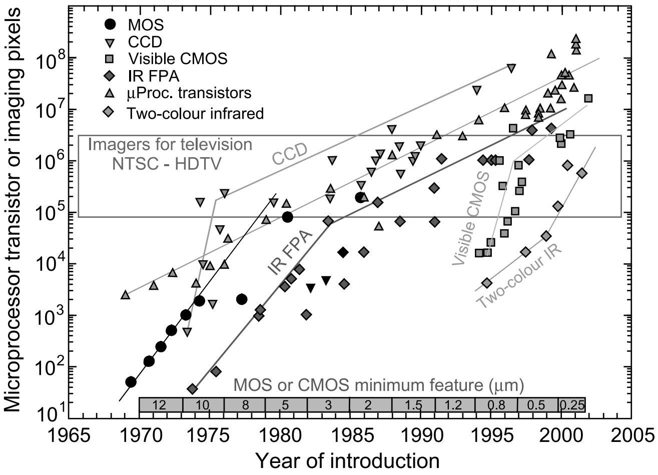

Figure A1.4.32. Imaging array formats compared with the complexity of microprocessor technology as indicated by transistor count. The timeline design rule of MOS/CMOS features is shown at the bottom. Reproduced from [18].

traditional infrared detectors. At present they can be built in formats as large as 480 × 640 array with $25 \times 25\,\mu m^2$ pixels.

CCD technology is very mature in respect to both the fabrication yield and the attainment of near-theoretical sensitivity. Figure A1.4.34 shows the schematic circuit for a typical CCD imager. The monolithic array is based on a metal–insulator–semiconductor (MIS) structure. Incident radiation generates electron–hole pairs in the depletion region of the MIS structure. The photogenerated carriers are first integrated in an electronic well at the pixel and subsequently transferred to slow and fast CCD shift registers. At the end of the CCD register, a charge carrying information on the received signal can be readout and converted into a useful signal. More information about CCD operation can be found in section B2.

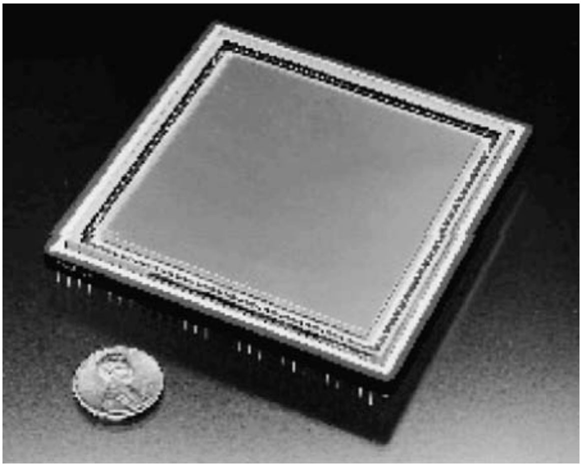

Figure A1.4.33. Silicon CCD visible array with 5040 × 5040 pixels. Pixel size is $12 \times 12\,\mu m^2$. The chip size is $60 \times 60\,mm^2$. Quantum efficiency is >20% at 900 nm. Reproduced from [19].

Figure A1.4.34. Architecture of typical CCD image. Reproduced from [20].

At present, the following readout techniques are used in CCD devices:

- floating diffusion amplifier in each pixel;
- system with correlated double sampling (CDS);
- floating gate amplifier.

The floating diffusion amplifier, a typical CCD output preamplifier, can be implemented in each unit cell as shown in dotted box in figure A1.4.35. The unit cell consists of three transistors and the detector. Photocurrent is integrated onto the stray capacitance, which is the combined capacitance presented by the gate of the source follower T2, the interconnection, and the detector capacitance. The capacitance is reset to the voltage level V_R by supplying the reset clock (Φ_R) between successive integration frames. Integration of the signal charge makes the potential of the source follower input

node lower. The source follower is active only when the transistor T3 is clocked. The drain current of the source follower T2 flows through the enable transistor T3 and load resistor outside the array.

Figure A1.4.36 shows a preamplifier, in this example the source follower per detector (SFD), the output of which is connected to a clamp circuit. The output signal is initially sampled across the clamp capacitor during the onset of photon integration (after the detector is reset). The action of the clamp switch and capacitor subtracts any initial offset voltage from the output waveform. Because the initial sample is made before significant photon charge has been integrated, by charging the capacitor, the final integrated photon signal swing is unaltered. However, any offset voltage or drift present at the beginning of integration is, by the action of the circuit, subtracted from the final value. This process of sampling each pixel twice, once at the beginning of the frame and again at the end, and providing the difference is called CDS.

The value of the initial CDS sample represents dc offsets, low frequency drift and $1/f$ noise, and high-frequency noise; this initial value is subtracted from the final value, which also includes dc offset, low-frequency drift, and high-frequency noise. Since the two samples occur within a short period of time, the dc and lower-frequency drift components of each sample do not change significantly; hence, these terms cancel in the subtraction process.

The floating gate amplifier configuration is shown in figure A1.4.37. It consists of two MOSFET transistors, the source follower T2 and the zeroing transistor T1. The floating gate (reading gate) is in the same row as the CCD transfer gates. If a moving charge is under the gate, it causes a change in the gate potential of the transistor of the gate T2. At the preamplifier output, a voltage signal appears. This manner of readout does not cause degradation or decay of a moving charge hence the charge can be detected at many places. An amplifier, in which the same charge is sampled with several floating gates is called a floating diffusion amplifier.

The configuration of CCD devices requires specialized processing, unlike CMOS imagers which can be built on fabrication lines designed for commercial microprocessors. CMOS have the advantage that existing foundries intended for application specific integrated circuits (ASICs), can be readily used by adapting their design rules. Design rules of 0.18 μm are in production, with pre-production runs of 0.13 μm design rules already underway. As a result of such fine design rules, more functionality has been put into the unit cells of multiplexers and smaller unit cells, leading to large array sizes. Figure A1.4.32 shows the timelines for minimum circuit features and the resulting CCD, IR FPA and CMOS visible imager sizes with respect to imaging pixels. Along the horizontal axis is also a scale depicting the general availability of various MOS and CMOS processes. The ongoing migration to even finer lithographies

will thus enable the rapid development of CMOS-based imagers having even higher resolution, better image quality, higher levels of integration and lower overall imaging system cost than CCD-based solutions. At present, CMOS having minimum features of ≤0.5 μm is also enabling monolithic visible CMOS imagers, because the denser photolithography allows low-noise signal extraction and high performance detection with the optical fill factor within each pixel. The silicon wafer production infrastructure which has put personal computers into many homes is now enabling CMOS-based imaging in consumer products such as digital still and video cameras.

A typical CMOS multiplexer architecture (figure A1.4.38) consists of fast (column) and slow (row) shift registers at the edges of the active area, and pixels are addressed one by one through the selection of a slow register, while the fast register scans through a column, and so on. Each photodiode is connected in parallel to a storage capacitor located in the unit cell. A column of diodes and storage capacitors is selected one at a time by a digital horizontal scan register and a row bus is selected by the vertical scan register. Therefore, each pixel can be individually addressed.

CMOS-based imagers use active or passive pixels [22–24] as shown, in simplified form, in figure A1.4.39. In comparison with passive pixel sensors (PPSs), active pixel sensors (APSs) apart from read

functions exploit some form of amplification at each pixel. PPSs have simple pixels consisting of as few as two components (a photodiode and a MOSFET switch). As a result, circuit overhead is low and the optical collection efficiency (fill factor (FF)) is high even for monolithic devices. A large optical FF of up to 80% maximizes signal selection and minimizes fabrication cost by obviating the need for microlenses. Microlenses, typically used in CCD and CMOS APS imagers for visible application, concentrate the incoming light into the photosensitive region when they are accurately deposited over each pixel (figure A1.4.40). When the FF is low and microlenses are not used, the light falling elsewhere is either lost or, in some cases, creates artefacts in the imagery by generating electrical currents in the active circuitry.

APSs incorporate transistors in each pixel to convert the photogenerated charge to a voltage, amplify the signal voltage and reduce noise. Adding these components, however, reduces the FF of monolithic imagers to about 30–50% in 0.5 μm processes at a 5–6 μm pixel pitch or in 0.25 μm processes at a 3.3–4.0 μm pixel pitch [22].

A1.4.4.2 Hybrid arrays

Ultraviolet and infrared imagers are most commonly built with a hybrid structure. Visible hybrids have also been built for specific applications. Hybrid FPAs detectors and multiplexers are fabricated on different substrates and mated with each other by flip-chip bonding or loophole interconnection (figure B8.17). In this case, we can optimize the detector material and multiplexer independently. Indium bump bonding of readout electronics, first demonstrated in the mid-1970s, provides for multiplexing the signals from thousands of pixels onto a few output lines, greatly simplifying the interface between the sensor and the system electronics.

Key to the development of ROICs has been the evolution in input preamplifier technology. This evolution has been driven by increased performance requirements and silicon processing technology improvements. A brief discussion of the various circuits is given below.

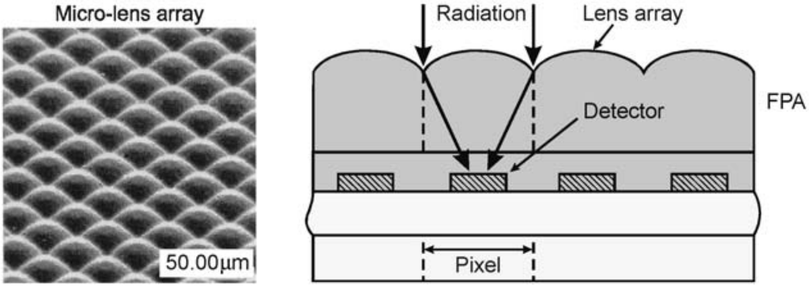

Figure A1.4.40. Micrograph and cross-sectional drawing of microlensed hybrid FPAs. Reproduced from [22].

The direct injection (DI) circuit was one of the first integrated readout preamplifiers and has been used as an input to CCDs and visible imagers for many years. This readout configuration requires the area at the unit cell (<20 × 20 μm) to be minimized. Photon current in DI circuits is injected, via the source of the input transistor, onto an integration capacitor (figure A1.4.41). As the photon current (figure A1.4.41(*b*)) charges the capacitor throughout the frame a simple charge integration takes place. Next a multiplexer reads out the final value and the capacitor voltage is reset prior to the beginning of the frame. To reduce detector noise, it is important that a uniform, near-zero-voltage bias be maintained across all the detectors.

Feedback enhanced direct injection (FEDI) is similar to direct injection except that inverting amplifier is provided between the detector node and the input MOSFET gate (figure A1.4.41 dashed line). The inverting gain provides feedback to yield better control over the detector bias at different photocurrent levels. It can maintain a constant detector bias at medium and high backgrounds. The amplifier reduces the input impedance of the DI and, therefore, increases the injection efficiency and bandwidth. The minimum operating photon flux range of the FEDI is an order of magnitude below that of the DI, thus the response is linear over a larger range than the DI circuit.

The combined source follower/detector (SFD) unit cell is shown in figure A1.4.42. The unit cell consists of an integration capacitance, a reset transistor (T1) operated as a switch, the source-follower transistor (T2), and selection transistor (T3). The integration capacitance may just be the detector capacitance and transistor T2 input capacitance. The integration capacitance is reset to a reference voltage (V_R) by pulsing the reset transistor. The photocurrent is then integrated on the capacitance during the integration period. The ramping input voltage of the SFD is buffered by the source follower and then multiplexed, via the T3 switch, to a common bus prior to the video output buffer. After the multiplexer read cycle, the input node is reset and the integration cycle begins again. The switch must have very low current leakage characteristics when in the open state, or this will add to the photocurrent signal. The dynamic range of the SFD is limited by the current voltage characteristics of the detector. As the signal is integrated, the detector bias changes with time and incident light level. The SFD has low noise for low bandwidth applications such as astronomy and still has acceptable signal-to-noise at very low backgrounds (e.g. a few photons per pixel per 100 ms). It is nonlinear at medium and high backgrounds, resulting in a limited dynamic range. The gain is set by the detector responsivity and the combined detector plus source–follower–input capacitance. The major noise sources are the kTC noise (resulting from resetting the detector), MOSFET channel thermal and MOSFET $1/f$ noise.

The capacitor–feedback transimpedance amplifier (CTIA) is a reset integrator and addresses broad range of detector interface and performance requirements across many applications. The CTIA consists of an inverting amplifier with a gain of A, the integration capacitance C_f placed in a feedback loop, and

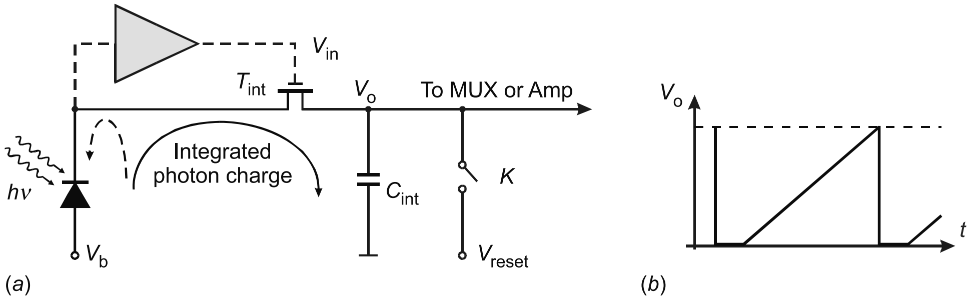

Figure A1.4.41. Direct injection readout circuit. Reproduced from [25].

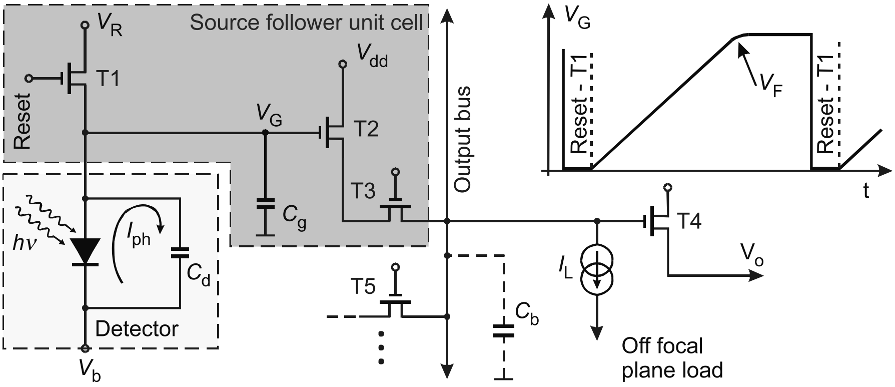

Figure A1.4.42. Schematic of source-follower per detector unit cell.

the reset switch *K* (figure A1.4.43). The photoelectron charge causes a slight change in a voltage at the inverting input node of an amplifier. The amplifier responds with a sharp reduction in output voltage. As the detector current accumulates over the 'frame time', uniform illumination results in a linear ramp at the output. At the end of integration, the output voltage is sampled and multiplexed to the output bus. Since the input impedance of the amplifier is low, the integration capacitance can be made extremely small, yielding low noise performance. The feedback, or integration, capacitor sets the gain. The switch *K* is cyclically closed to achieve reset. The CTIA provides low input impedance, stable detector bias, high gain, high frequency response and a high photon current injection efficiency. It has very low noise from low to high backgrounds.

The resistor load (RL) gate modulation circuit is shown in figure A1.4.44. It was introduced to extend the SFD performance advantages to high-irradiance backgrounds and dark currents. This circuit uses the photocurrent to modulate the gate voltage and thereby induce an output current in the MOSFET. The drain current of the MOSFET transistor accumulates onto an integration capacitor. In high background irradiance, this circuit provides a design that can reject much of these background components, as when the background alone is present on the detector, the bias on the detector or the load resistor can be adjusted to give negligible drain current or integration of a charge. When the signal is then applied, the transistor drain current increases with photon current and thereby allows some level

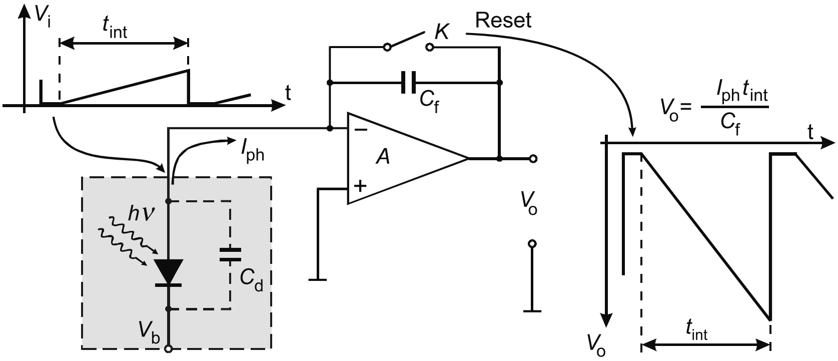

Figure A1.4.43. Schematic of a capacitive transimpedance amplifier unit cell.

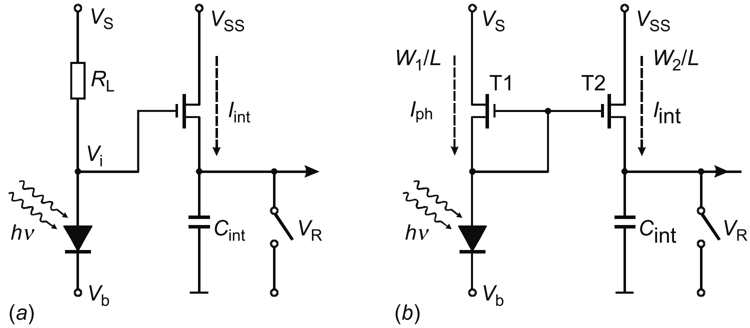

Figure A1.4.44. Resistor load gate modulation (*a*) and current mirror gate modulation (*b*).

of background flux rejection. The load resistor is designed such that it has low $1/f$ noise, excellent temperature stability, and good cell to cell uniformity.

The current mirror (CM) gate modulation, (figure A1.4.44(*b*)), extends readouts to very high background levels. In this current mirror preamplifier, the MOSFET replaces the resistor of the RL circuit. The photon current flowing into the drain of the first of two closely matched transistors includes a common gate to source voltage change in both transistors. This results in a similar current in the second transistor. If the source voltage, V_s and V_{ss}, of the two matched transistors are connected, both will have the same gate to source voltages which will induce a current in the output transistor identical to the detector current flowing through the input transistor. In this circuit, the integration current is a linear function of a detector current. This CM interfaces easily to direct access or CCD multiplexers and has low area requirements for the unit cell. The CM circuit requires gain and offset corrections for most applications. The advantages over the RL circuit include its better linearity and absence of a load resistor.

A wide variety of detector materials has been adapted to the hybrid format. UV, visible, and infrared arrays most commonly employ a photodiode structure. Photodiodes are preferred to photoconductors because of their relatively high impedance, which matches directly into the high input impedance stage of an FET readout circuit and also allows lower power dissipation. Mesa photodiodes are used in AlGaN, InSb, and HgCdTe detectors, whereas planar photodiodes are used in Si, PtSi, Ge, HgCdTe, InGaAs, and InSb detectors. A third photodiode structure—used exclusively with HgCdTe detectors—is the high-density vertically-integrated photodiode, or loophole photodiode [16].

An alternative hybrid detector for the long wavelength IR region (8–14 μm) is the quantum well infrared photoconductor (QWIP). These high impedance detectors are built from alternating thin layers (superlattices) of GaAs and AlGaAs. A distinct feature of n-type QWIPs is that the optical absorption strength is proportional to the electric-field polarization component of an incident photon in a direction normal to the plane of the quantum wells. For imaging, it is necessary to couple light uniformly to two-dimensional arrays of these detectors, so a diffraction grating is incorporated on one side of the detectors to redirect a normally incident photon into propagation angles more favourable for absorption.

Also extrinsic silicon detectors can form high impedance photoconductors in a hybrid configuration and be operated out to about 30 μm. Shallow, hydrogen-like impurities, such as phosphorus, antimony, or arsenic, provide electrons which can be ionized with photon energies in the range of 30–50 meV, depending upon the dopant and concentration used. Arrays of QWIP as well as extrinsic silicon detectors in a 1024 × 1024 format have been demonstrated [18].

The largest hybrid arrays have been principally built for astronomy where dark currents as low as 0.02 electrons per second are measured at 30 K. The most recent development is the 2 × 2 K format of

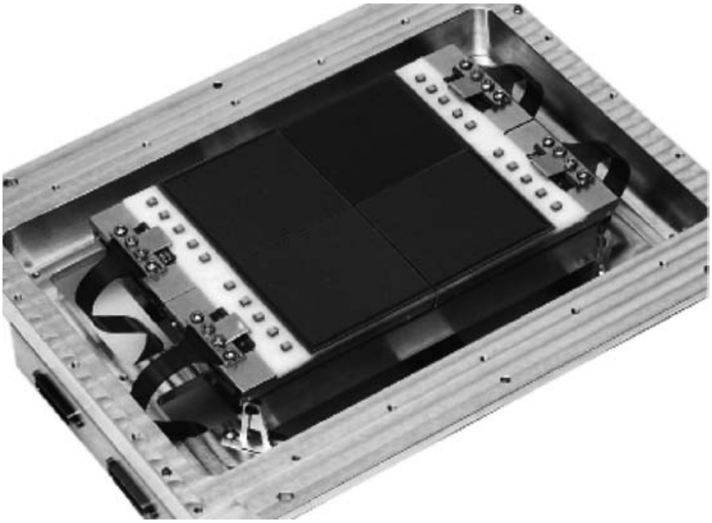

Figure A1.4.45. The three-side buttable arrays can be arranged in $2 \times n$ array configurations to build up large rectangular formats [26].

InSb (1–5 μm, 25 μm pixels) and HgCdTe (1–3 μm, 18 μm pixels). Individual arrays can be arranged in groups to give larger format configurations. Two-side buttable 2052 × 2052 arrays can be arranged in a 4104 × 4104 format, as illustrated in figure A1.4.45. The three-side buttable arrays can be arranged in $2 \times n$ array configurations to build up large rectangular formats [26].

In the infrared spectral region, third generation systems are now being developed. In this class of detector, two main competitors, HgCdTe photodiodes and QWIPs are considered. Those that provide enhanced capabilities like larger number of pixels, higher frame rates, better thermal resolution as well as multicolour functionality and other on-chip functions are considered as third generation IR systems. Multicolour capabilities are highly desirable for advanced IR systems. Systems that gather data in separate IR spectral bands can discriminate both absolute temperature and unique signatures of objects in the scene. By providing this new dimension of contrast, multiband detection also offers advanced colour processing algorithms to further improve sensitivity compared to that of single-colour devices.

Two-colour array capability is based upon stacking materials with different spectral responses on top of each other. The shorter wavelength flux is absorbed in the first layer, which then transmits the longer wavelength flux through the second layer. One such structure—a HgCdTe two-colour device, with two indium bumps per pixel—is illustrated in figure A1.4.46.

Two-colour QWIP detector structures have also been built [27]. For example, figure A1.4.47 shows the excellent imagery in each colour. Note the appearance of the front-held optical filter and the vertically-held hot soldering iron in the two bands. At present, however, imaging systems using two-colour arrays are in limited use. Some considerations have suggested that three-colour FPAs would be more generally useful. Recently, a four-colour QWIP FPA has been demonstrated by stacking different multi-quantum well structures, which are sensitive in 4–5.5, 8.5–10, 10–12, and 13–15.5 μm bands. The 640 × 512 format FPA consists of four 640 × 128 pixel areas which are capable of acquiring images in these bands.

It should be mentioned that hyperspectral arrays are distinguished from multispectral ones in typically having a hundred or more bands. HgCdTe, and other detector materials such as silicon and InSb, have been used in hyperspectral assemblies in the form of two-dimensional arrays with a closely

packed layout of rows and columns. A prism, grating, or a 'wedged' filter is used to illuminate each row with a different wavelength. Figure A1.4.48 shows an example of a hyperspectral array.

A1.4.5 Conclusions

This chapter provides an overview of the important techniques for detection of optical radiation from the UV, through visible to infrared spectral regions. In the beginning single-point devices are considered, next direct detector systems and advanced techniques including coherent detection, and finally image counterparts containing FPAs are considered. The reader should be able to gain a good understanding of the similarities and contrasts, the strengths and weaknesses of the great number of approaches that have been developed over a century of effort to improve our ability to sense photons. The emphasis is always upon the methods of operation and limitations of different techniques. In addition, currently achieved performance levels are also briefly described.

This chapter offers a rather wide coverage of detection techniques. However, for a full understanding of the technical content, basic courses in electronic devices and circuits, and the very fundamentals of semiconductors and noise is a prerequisite.

A1.5

Propagation along optical fibres and waveguides

John Love

In this Part of the Handbook, an introduction to the description of the transmission of light along dielectric optical fibres and waveguides is presented in terms of a ray analysis for multimode propagation and in terms of a modal analysis for single- and few-mode propagation. Whilst the emphasis will be on fibre propagation, the methods presented here are applicable to any type of waveguide, irrespective of material composition. To cater for a wider range of backgrounds in optics and electromagnetism, there is a low-level introduction leading into more advanced topics. Accordingly, some readers may wish to skip the earlier Sections A1.5.1 and A1.5.2. This Part is relatively self-contained and explanatory, and referencing to other material has been kept to a minimum.

A1.5.1 Historical perspective

A1.5.1.1 Light propagation

Light, as we know, is what we see and comes in a range of colours or, equivalently, wavelengths or frequencies that our eyes detect and our brain interpolates. Whatever we are looking at, whether it is this page or the distant stars, light travels in straight lines from the object to our eyes, regardless of the wavelength. This phenomenon occurs because light is a form of electromagnetic radiation and its propagation when considering waves in a uniform dielectric medium, such as air or vacuum, is described by Maxwell's equations. Sometimes though, light can play tricks on us, such as the apparently sloping water level in the swimming pool shown in figure A1.5.1.

While light travels in straight lines, a finite beam of light, whether it comes from a large-aperture torch or the narrow output face of a micron-size coherent semiconductor laser, tends to spread out with this effect being the more noticeable over short distances with the torch beam and over longer distances with the laser. If we combine this spread with the fundamental need for straight-line propagation, it is easy to see why it is not very convenient to use light in air to transmit information over long distances; it will not go around corners nor even follow the curvature of the earth. On top of this limitation, rain, fog, smoke, buildings, topographical features and other obstacles ensure that the beam will be strongly attenuated because of absorption, reflection and scattering.

These impediments notwithstanding, chains of semaphore repeater stations with large moveable wooden arms on the tops of towers were built by a number of European countries in the eighteenth century on the peaks of hills within direct line of sight of one another, i.e. about 20–25 km apart. These links provided the first purely optical, low-bandwidth, long-distance transmission systems between a country's capital and its ports, primarily for military and administrative applications.

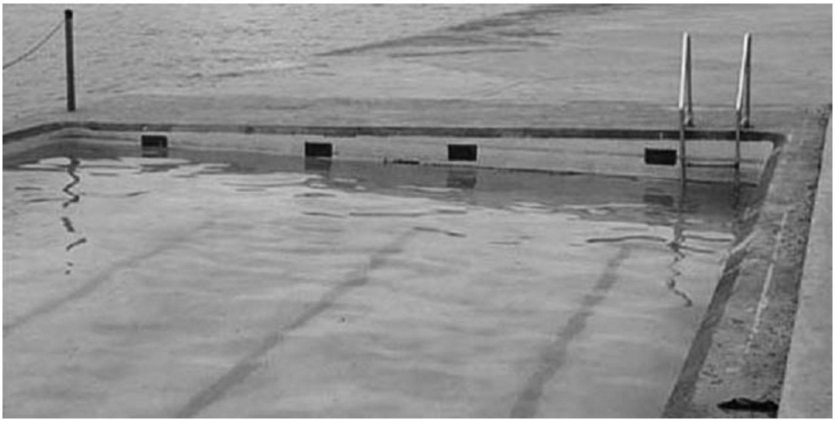

Figure A1.5.1. Swimming pool with an apparently sloping water surface.

A1.5.1.2 Light pipes

However, to provide an optical transmission system with higher bandwidth, a more effective medium was needed that was able to steer light flexibly to its destination and to insulate it from deleterious environmental effects. Following the invention of the laser in the 1950s, early attempts in the 1960s to solve this problem were based on the use of a long, evacuated light pipe, wherein a series of lenses inside the tube periodically refocused the slowly diverging output beam from a laser located at the beginning of the pipe, as shown schematically in figure A1.5.2. The lenses could also be used to steer the beam along new directions to follow the local topography.

Whilst this technology offered a high bandwidth and very low attenuation because light propagation would be predominantly in vacuum, the scheme relied on the maintenance of a good alignment over long distances, regardless of whether the pipe is supported above ground or buried beneath it. This presented a significant challenge because of ground movement due to natural and man-made phenomena. This made it clear that a more flexible and less environmentally sensitive optical guide would be preferable.

A1.5.1.3 Optical fibres

Optical fibres have been known since glass was first discovered several thousands years ago, simply as a consequence of pulling on a piece of heat-softened glass, something that most of us have probably tried in a laboratory at school or university. However, any thoughts on the use of glass fibres for transmitting

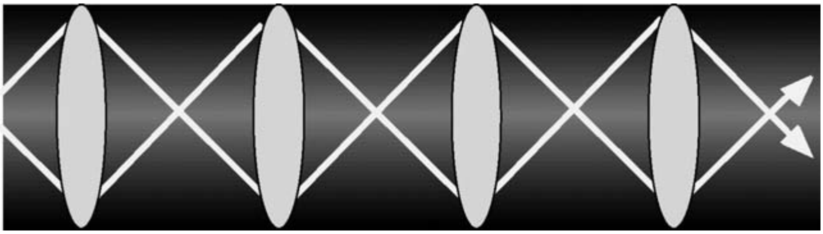

Figure A1.5.2. Schematic of a longitudinal section of a light pipe.

light for information purposes had to wait until the twentieth century and the development of suitable light sources.

The potential for guiding light along a purely dielectric optical waveguide was first demonstrated in public in 1841 by Professor Daniel Colladon at the University of Geneva in Switzerland [1]. Colladon used a jet of water emerging from the side of a barrel and illuminated the jet by focusing sunlight onto it. The water has a higher refractive index of 1.33 compared to the surrounding air with an index of 1.0. Because Snell's laws predict total internal reflection of light from the water-air boundary, the relative indices ensure the sunlight is guided along the water jet. The jet of water curves downwards because of gravity and the strong confining property of the jet determines that much of the light follows its curved path. Using more modern light sources, such as a coloured diode, enhances the appearance of the effect. We now know that Colladon's experiment is equivalent to light propagation along a highly multimode, bent optical waveguide with water as the core and air as the cladding.

Glass fibres were developed spasmodically over the next 100 years more as a curiosity than a technology solution. The first serious application of glass fibres to light transmission was motivated through medicine leading to the development of the endoscope in the 1950s with achievable transmission over one or two metres through a dense bundle of very thin fibres. However, there were two existing limitations that inhibited the use of the endoscope fibres for long-distance communications. Firstly, early fibres were single material and because light is distributed over the entire cross-section of the material, it was susceptible to transmission loss wherever the single material touched external supports. Secondly, the glass was very impure and therefore strongly absorbed and scattered light over the longer distances. One can get an idea of the degree of light absorption by looking through a sheet of window glass sideways, as illustrated in figure A1.5.3. Even a very low level of impurities in the glass, of the order of parts per million, results in a very high extinction level for the propagating light after only a few metres.

The transition from Colladon's water jet to a modern long-distance, low-loss optical communications system relied on (a) the development of two-layer, high-low-index glass optical fibres that not only transmit light but also confine it to within the central glass core well away from the outer surface and, more importantly, (b) the development of techniques for fabricating fibres with extremely low light loss from very pure materials.

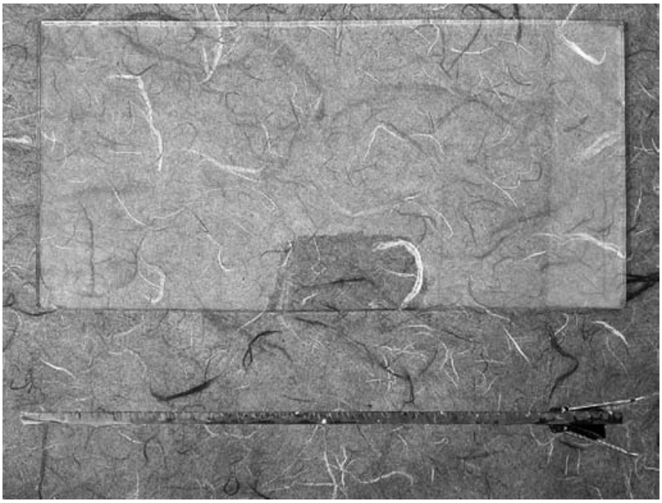

Figure A1.5.3. Top and side views of a sheet of ordinary window glass.

The first limitation was overcome by using the now-standard core-plus-cladding fibre to locate the propagating light around the fibre axis and isolate it from the fibre coating and other external influences. The second problem required the development of new fabrication techniques to produce the very pure silica-based glasses required for low-loss fibres. These goals were enshrined by the classic paper of Kao and Hockham [2], published in 1966, and generally regarded as the catalyst for the ensuing optical telecommunications revolution.

The first such fibres that appeared in the 1960s were multimode and it was not until the 1970s that the goal of low-loss, single-mode fibres and cables with much higher bandwidths than multimode fibres was realized. Contemporary fibre cables for terrestrial and submarine applications are shown in figure A1.5.4.

A1.5.1.4 Scope

In this Part of the Handbook we develop the analysis of propagation along optical fibres and other waveguiding structures to produce a basic description of light transmission. The practical development of fibres was paralleled by major theoretical developments. In the 1960s and early 1970s, much effort was extended to producing increasingly sophisticated ray-tracing and local plane-wave techniques that could adequately describe and quantify propagation and loss mechanisms in multimode fibres. Ray tracing is an accurate technique for multimode fibres because the relatively large core ensures that diffraction effects associated with the relatively short but finite wavelengths used in communications are extremely small compared to the light-guiding effect based on the variation in the transverse refractive-index profile. Conversely, the small core size associated with single-mode fibres requires a full electromagnetic analysis of propagation because diffraction effects become comparable with the confining effect of the profile (see section 10.2 of Ref. [3]).

The early ray-tracing and electromagnetic analyses of fibres concentrated predominantly on analytical solutions of the governing ray-tracing and Maxwell equations because of the limited capability of early computers. Initially, these solutions necessarily relied on refractive-index profiles, together with fibre and waveguide cross-sectional geometries, for which analytical solutions of these equations were available in terms of simple or special mathematical functions. Commercial software routines were available for the quantification of some of these special functions, otherwise home-based software had to be developed.

Over the last 20 years, this situation has been almost completely reversed with the ready availability of commercially developed software, particularly that for determining ray tracing and electromagnetic propagation for a wide range of fibre and waveguide profiles and geometries. It is fair to say that this

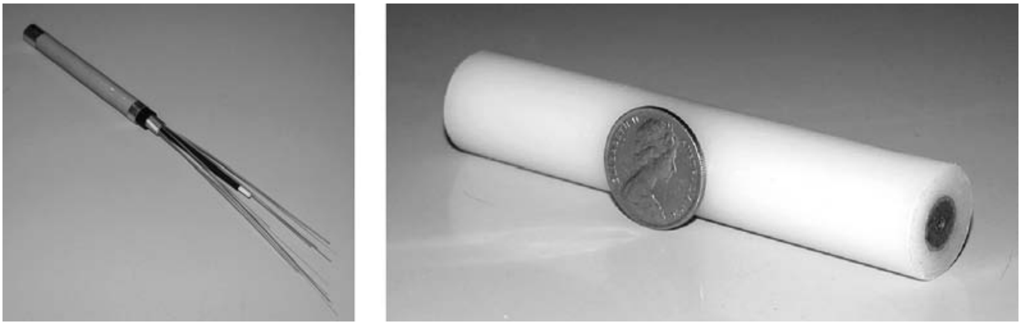

Figure A1.5.4. Terrestrial (left) and deep-ocean submarine (right) single-mode fibre cables used in long-distance optical communications systems.

evolution has considerably simplified the development and understanding of specialized fibre and waveguide designs, such as holey fibres and photonic bandgap waveguides, by moving the emphasis to the exploitation of physical phenomena for light guidance rather than being limited by the shortcomings of analytical and numerical techniques.

A1.5.2 Light propagation, plane waves and rays

Before launching into the different descriptions of light propagation and guidance along fibres and waveguides, it is helpful and insightful to examine the propagation of electromagnetic plane waves in free space as a precursor to their development into rays and modes. Light rays, whether propagating in straight lines or along curved trajectories, are formally the solution of Maxwell's equations in the limit of zero wavelength, but for practical purposes can be thought of as local plane waves propagating with a small but finite wavelength. This section provides an elementary background to the more advanced material presented in Sections A1.5.3 and A1.5.5.

A1.5.2.1 Plane waves

Consider an infinite, unbounded medium of uniform, real refractive index n that is loss-less, i.e. non-absorbing and non-scattering. Introduce the triad of Cartesian axes O-xyz, shown in figure A1.5.5, such that the z-axis defines the direction of propagation.

Assume an artificial, infinitely extended monochromatic (single-frequency) uniform light source in the *x–y plane* with angular frequency ω or, equivalently, wavelength $\lambda = 2\pi c/\omega$, where c is the speed of light in vacuum. An electromagnetic plane wave can propagate parallel to the z-axis with vector electric $\boldsymbol{E}$ and magnetic $\boldsymbol{H}$ fields that are everywhere uniform and have only a sinusoidal dependence on distance z and time t. Accordingly a simple solution of Maxwell's equations predict that these fields have the forms:

$$\boldsymbol{E}(x, y, z, t) = \boldsymbol{e}\exp\{\mathrm{i}(knz - \omega t)\}; \quad \boldsymbol{H}(x, y, z, t) = \boldsymbol{h}\exp\{\mathrm{i}(knz - \omega t)\} \tag{A1.5.1}$$

where $k = 2\pi/\lambda$ is the wavenumber, kn is the propagation constant, and $\boldsymbol{e}$ and $\boldsymbol{h}$ are *constant* orthogonal vectors. Note that the propagation constant is a continuous function of the source wavelength and decreases as the wavelength increases.

These fields propagate parallel to the z-direction with a *phase velocity* $v_{\mathrm{ph}} = \omega/kn = c/n$, i.e. the speed of light in a medium of refractive index n, which is a constant *independent* of the source wavelength or frequency, provided the medium itself is not dispersive. The forward direction of propagation corresponds to the negative sign in the exponent of equation (A1.5.1). Furthermore, the power in the

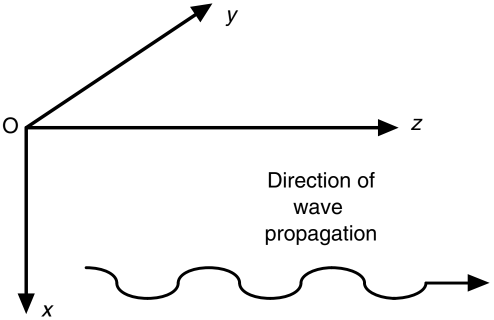

Figure A1.5.5. Orientation of Cartesian O-xyz axes.

plane wave propagates at the *group velocity*, $v_g = d\omega/dk = \omega/kn = c/n$, i.e. identical to the group velocity for a plane wave.

A plane wave is an unphysical entity because it has constant amplitude everywhere and therefore the total power propagating in the mode is infinite. Nevertheless, it provides the simplest example of light propagation in a uniform medium. It will be seen in Section A1.5.3 that the introduction of a core into the uniform medium model modifies the nature of plane-wave propagation in a constructive manner.

A1.5.2.2 Polarization

The two constant vectors $\boldsymbol{e}$ and $\boldsymbol{h}$ each have only one *non-zero* Cartesian field component transverse to the z-direction of propagation. These components lie in the x–y plane.

Relative to the Cartesian axes, these vectors can be chosen to have either of the following two orthogonal forms:

$$\boldsymbol{e} = (e, 0, 0) \quad \boldsymbol{h} = (0, h, 0) \quad \text{or} \quad \boldsymbol{e} = (0, e, 0) \quad \boldsymbol{h} = (-h, 0, 0) \tag{A1.5.2}$$

where e and h are scalar constants. Note that the second choice of components is simply the first choice rotated 90 degrees about the z-axis. Either of these two solutions consists of electric and magnetic fields that are orthogonal to the z-direction of propagation and are also orthogonal to one another. Accordingly they form *orthogonal triads* as shown in figure A1.5.6.

The direction of the electric field vector $\boldsymbol{E}$ in each case defines the *polarization* of the plane wave, i.e. it is either x-polarized or y-polarized, respectively. The description of the plane wave for either polarization can be thought of as a triad of vectors ($\boldsymbol{E}$, $\boldsymbol{H}$, and the z-axis or direction of propagation) propagating parallel to the z-axis at a speed equal to the phase velocity v_{ph}.

A1.5.2.3 Local plane waves, rays and waves

Plane waves are associated with an infinite medium of uniform index n, and they travel in straight lines and everywhere have the same electromagnetic description. However, if the refractive index of the medium varies with position so that it is *graded*, this description is modified. The plane wave can be replaced by the concept of the *local plane wave*, which describes propagation in a small region of space in terms of a wave whose fields, phase and group velocities, and polarization are determined by the local value and variation of the index.

When propagation is described in terms of ray tracing for the multimode waveguides and fibres in Section A1.5.5, there is a simple relationship between rays and waves. A ray represents the local direction of propagation of a plane wave in a uniform medium or a local plane wave in a graded

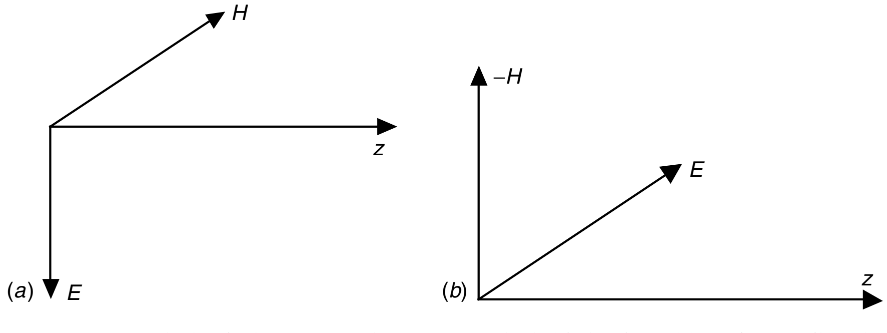

Figure A1.5.6. Polarized plane wave electromagnetic fields in the x (a) and y (b) directions.

medium. Further, the ray direction also determines the direction of local power flow. Although this propagation description is based on the zero-wavelength limit of Maxwell's equations, it provides an accurate description for the relatively short wavelengths encountered in optical communications.

A1.5.3 Electromagnetic propagation in non-uniform dielectric media

A1.5.3.1 Maxwell's equations and monochromatic sources

Propagation in dielectric media is governed by Maxwell's equations (a portrait of Maxwell is given in figure A1.5.7) so that in the absence of currents and charges the equations take the four-dimensional spatial-temporal forms:

$$\nabla \times \boldsymbol{E} = \frac{\partial \boldsymbol{B}}{\partial t}; \quad \nabla \times \boldsymbol{H} = -\frac{\partial D}{\partial t} \tag{A1.5.3}$$

where $\boldsymbol{E} = \boldsymbol{E}(x, y, z, t)$ is the vector electric field and $\boldsymbol{H} = \boldsymbol{H}(x, y, z, t)$ is the vector magnetic field. The temporal dependence is denoted by t and the spatial dependence can be expressed in terms of any convenient orthogonal coordinate system, e.g. Cartesian coordinates (x, y, z) for slab waveguides, cylindrical polar coordinates (r, ϕ, z) for circular fibres, etc. The magnetic induction vector $\boldsymbol{B}$ and the displacement vector $\boldsymbol{D}$ are related to the magnetic and electric fields, respectively, by

$$\boldsymbol{B} = \mu \boldsymbol{H}; \quad \boldsymbol{D} = \varepsilon \boldsymbol{E} = \varepsilon_0 n^2 E \tag{A1.5.4}$$

where μ is the magnetic permeability, $\varepsilon = \varepsilon(x, y, z)$ is the dielectric constant, and $n = n(x, y, z)$ is the refractive index distribution. For optical materials, μ normally takes its free-space value μ_0, and ε_0 is the free-space dielectric constant. For fibres and waveguides, the refractive index is normally assumed to be uniform (z-independent) along the fibre or waveguide and is also taken to be independent of the field amplitude, i.e. ignoring non-linear material effects as well as the source wavelength when ignoring

Figure A1.5.7. James Clerk Maxwell, 1831–1879.

material dispersion. Material dispersion is addressed in Section A1.5.6.4 and non-uniform, z-dependent propagation is discussed in Section A1.5.9.3.

Monochromatic sources

In modelling the excitation from lasers or diodes when used as sources for fibres and waveguides, it is initially assumed that their output is exactly sinusoidal and monochromatic with a fixed wavelength. Practical sources, however, have an output with a finite but small *spectral width*. For lasers this width is typically of the order of a nanometres or less. The effect of this width is of paramount importance when considering pulse dispersion (see Section A1.5.6).

Accordingly, we ascribe an angular frequency ω to the monochromatic source such that each component of the electromagnetic field is assumed to contain the implicit sinusoidal dependence $\exp(-\mathrm{i}\omega t)$. The choice of sign is arbitrary, but here is taken to be negative for convenience. If λ denotes the corresponding free-space wavelength and k is the free-space wavenumber, then these quantities are related by the expressions

$$k = \frac{2\pi}{\lambda}; \quad \lambda = \frac{2\pi c}{\omega}; \quad c = \frac{\omega}{k} \tag{A1.5.5}$$

where c is the free-space speed of light ($3 \times 10^8\,\mathrm{ms}^{-1}$). Using equations (A1.5.3–A1.5.5), the monochromatic time dependence enables us to recast Maxwell's equations so that the spatial dependence is governed by

$$\nabla \times \boldsymbol{E} = \mathrm{i}\omega\mu_0 \boldsymbol{H} = \mathrm{i}\left(\frac{\mu_0}{\varepsilon_0}\right) kH; \quad \nabla \times \boldsymbol{H} = \mathrm{i}\omega\varepsilon_0 n^2 \boldsymbol{E} = -\mathrm{i}\left(\frac{\varepsilon_0}{\mu_0}\right)^{1/2} kn^2 \boldsymbol{E} \tag{A1.5.6}$$

where $\boldsymbol{E} = \boldsymbol{E}(x, y, z)$ and $\boldsymbol{H} = \boldsymbol{H}(x, y, z)$ and implicitly contain the time dependence $\exp(-\mathrm{i}\omega t)$.

A1.5.3.2 Translational invariance, longitudinal and transverse fields

For modelling fibres and waveguides, it is usual to assume that (a) the refractive index profile and the cross-sectional geometry do not vary with longitudinal distance z and (b) the fibre or waveguide is straight and essentially infinitely long. In this situation the fibres and waveguides have *translational invariance* and hence the z-dependence in Maxwell's equations becomes separable from the transverse dependence. Accordingly we may set

$$\boldsymbol{E}(x, y, z) = \boldsymbol{e}(x, y)\mathrm{e}^{\mathrm{i}\beta z}; \quad \boldsymbol{H}(x, y, z) = \boldsymbol{h}(x, y)\mathrm{e}^{\mathrm{i}\beta z} \tag{A1.5.7}$$

where $\boldsymbol{e}(x, y)$ and $\boldsymbol{h}(x, y)$ are vector expressions that denote the transverse field dependence and the parameter β in the exponential or phase term is called the *propagation constant*. The choice of Cartesian (x, y) coordinates is appropriate for analysing slab waveguides, while polar coordinates (r, ϕ) are more appropriate for fibres.

It is sometimes convenient for analytical and other purposes to split the fields into longitudinal and transverse components. This is equivalent to decomposing the vector dependences of $\boldsymbol{e}$ and $\boldsymbol{h}$ into transverse (subscript 't') and longitudinal (subscript 'z') components, respectively perpendicular and parallel to the z-axis, according to

$$\boldsymbol{e}(x, y) = \boldsymbol{e}_{\mathrm{t}}(x, y) + e_{\mathrm{z}}(x, y)\hat{\boldsymbol{z}}; \quad \boldsymbol{h}(x, y) = \boldsymbol{h}_{\mathrm{t}}(x, y) + h_{\mathrm{z}}(x, y)\hat{\boldsymbol{z}} \tag{A1.5.8}$$

where $\boldsymbol{e}_{\mathrm{t}}$ and $\boldsymbol{h}_{\mathrm{t}}$ are vector quantities, e_{z} and h_{z} are scalar quantities, and $\boldsymbol{z}$ is the unit vector parallel to the fibre axis.

A1.5.3.3 Power density and flow

For a monochromatic source with a sinusoidal time variation, the power flow density and direction at any position in space is determined by the time-averaged Poynting vector $\boldsymbol{S}$

$$\boldsymbol{S} = \frac{1}{2}\mathrm{Re}(\boldsymbol{E} \times \boldsymbol{H}^*) \qquad \text{(A1.5.9)}$$

where * denotes complex conjugate, $\boldsymbol{x}$, the vector cross product and Re is the real part. Loss-less propagation of light in fibres and waveguides is equivalent to the direction of $\boldsymbol{S}$ anywhere in the cross-section being parallel to the z-axis, i.e. $\boldsymbol{S}$ had only a z-component S_z. This property can be readily verified for the specific examples considered in Section A1.5.4. Finally, the total guided power flow is determined by integrating S_z over the infinite cross-section of the fibre or waveguide.

A1.5.3.4 Boundary conditions

For dielectric fibres and waveguides in the absence of currents, the boundary conditions for any bound solution of Maxwell's equations between regions of different index can be stated as follows:

- continuity of all three components of the magnetic field at any interface;
- continuity of the two *tangential* components of the electric field at any interface;
- continuity of the *normal* component of the displacement vector at any interface;
- the electric and magnetic fields decrease exponentially to zero at infinite distance from the fibre or waveguide axis.

In the case of an interface between one region of uniform index and a second region of varying index, where the index values are equal on the interface, all six components of the electric and magnetic fields will be continuous across the interface.

A1.5.3.5 Electromagnetic normal modes

Starting with an unbounded uniform index medium, consider an infinitely long uniform slab or cylinder of material of higher but uniform *core* refractive index n_{co} that is introduced into the infinite medium parallel to the z-axis. If the surrounding infinite medium is now referred to as the *cladding* with index $n = n_{\mathrm{cl}} < n_{\mathrm{co}}$, then the core and cladding constitute a dielectric slab waveguide or fibre with the step refractive index profile cross-section shown in figure A1.5.8. Although practical fibres or waveguides

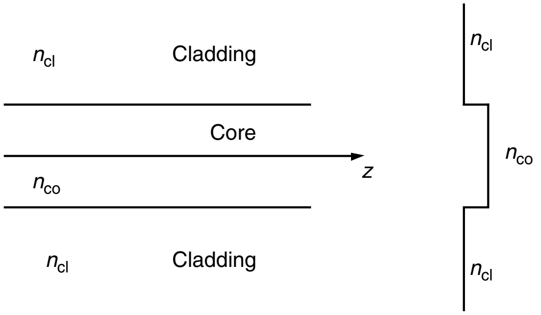

Figure A1.5.8. Step refractive index profile for a fibre or waveguide.

normally have more complex geometrical and profile structures in the cross-section, the step profile is the simplest profile to analyse that is of some practical interest and is used in single-mode telecommunications fibres such as SMF28.

Propagation along a fibre or waveguide is governed formally by Maxwell's equations, but some of the salient physical features can be elucidated by considering propagation of electromagnetic waves along this structure parallel to the z-axis.

The simple plane-wave description of propagation in the uniform medium discussed in Section A1.5.2 provides a conceptual base, but is now modified in a number of ways because of the presence of the waveguide structure.

(a) The uniformity of the structure in the z-direction or *translational invariance* ensures that waves propagate with a periodic longitudinal and temporal dependence and therefore a well-defined phase velocity ν_{ph};

(b) The value of the propagation constant is dependent on both the source wavelength λ and the length parameters of the core geometry and the refractive index values;

(c) The propagation constant is no longer uniquely specified and can take *one or more discrete values* for a given set of values of all the above parameters;

(d) The transverse dependence of the electromagnetic field vectors $\boldsymbol{e}$ and $\boldsymbol{h}$ for each discrete value of the propagation constant is now *spatially dependent* and varies with position (x, y) in the cross-section;

(e) The transverse electric and magnetic fields are no longer uniform, but are concentrated within and close to the core and decrease exponentially to zero at infinite distance from the axis;

(f) The *infinite* power travelling in the infinite cross-section of the plane wave is replaced by the *finite* power propagating along the waveguide in each propagation state;

(g) Each discrete propagation state is known as a *bound mode* or *normal mode* and is a solution (or eigenfunction) of the *electromagnetic boundary value* problem for Maxwell's equations for the waveguide or fibre.

Mechanical analogue

Normal modes are two-dimensional electromagnetic vibrations in the cross-section of the waveguide or fibre and are analogous to the mechanical vibrations of a flexible membrane fixed along its periphery, e.g. a drum. Given the source frequency, each electromagnetic vibration state corresponds to a discrete value of the propagation constant β. Each value of β corresponds to a normal or bound mode where its total longitudinal power flow (parallel to the z-axis) is constant and where its electromagnetic fields decrease exponentially with increasing distance from the z-axis and vanish at infinity.

The values of β are the discrete solutions of an *eigenvalue equation*, derived from solutions of Maxwell's equations together with appropriate boundary conditions. If the fibre core radius ρ or the waveguide cross-section 2ρ is small enough, typically a few microns for a silica-based fibre or waveguide, then as will be shown in Sections A1.5.4.4 and A1.5.4.5 there is only one solution for β, i.e. a *single-mode* waveguide or fibre.

A1.5.3.6 Mode orthogonality, normalization and orthonormal modes

Each bound mode is orthogonal to all other bound modes on a uniform, straight waveguide. This means that if only one mode is excited, it cannot excite any other modes as it propagates. Mathematically, *orthogonality* between the *j*th and *k*th bound modes is expressed by the vanishing of the integral of a triple scalar product of their vector fields over the infinite cross-section of the fibre or waveguide

$$\int_{A_\infty} \boldsymbol{e}_j \times \boldsymbol{h}_k^* \cdot \hat{z}\, \mathrm{d}A = 0 \tag{A1.5.10}$$

where A_∞ is the infinite cross-section, $\hat{z}$ is the unit vector parallel to the axis, and $*$ denotes the complex conjugate.

If we assume that the refractive index profile $n(x,y)$ is independent of field intensity, as is the case for *linear materials*, then Maxwell's equations constitute, in general, a set of coupled linear equations. The solutions of these equations together with the boundary conditions can only determine the fields for each mode to within an *arbitrary amplitude constant*. The value of this constant for each mode is normally determined from the source of excitation as discussed in Section A1.5.8.3.

For some special applications, such as in tapers, it is useful to be able to specify the value of this constant in an unambiguous manner independent of the source of excitation. This can be achieved by using the *normalization N* of a mode. This scalar quantity

$$N = \int_{A_\infty} \boldsymbol{e} \times \boldsymbol{h}^* \cdot \hat{z}\, \mathrm{d}A \tag{A1.5.11}$$

is defined in terms of the integral over the infinite cross-section of the triple scalar product of the electric field $\boldsymbol{e}$, magnetic field $\boldsymbol{h}$, and the unit vector parallel to the z-axis.

An *orthonormal mode* is then defined to be a normal mode with electric and magnetic field amplitudes such that it has unit normalization, i.e. $N = 1$. If the fields $\boldsymbol{e}$ and $\boldsymbol{h}$ of the bound mode are replaced by the following quantities

$$\hat{\boldsymbol{e}} = \frac{\boldsymbol{e}}{N^{1/2}}; \quad \hat{\boldsymbol{h}} = \frac{h}{N^{1/2}} \tag{A1.5.12}$$

then substitution into equation (A1.5.11) gives $N = 1$ and the fields are orthonormal.

A1.5.3.7 Modal phase and group velocities

The longitudinal and temporal dependence of the fields of a mode is contained in the common phase factor $\exp[\mathrm{i}(\omega t - \beta z)]$. A constant value of this expression defines a *phase front*, which is a plane of constant phase orthogonal to the z-axis. For a constant phase value, z varies linearly with t, the constant of proportionality being the ratio $\omega/\beta = v_{\mathrm{ph}}$ or the *phase velocity* of the mode. This is the speed at which the phase front propagates.

For pulse propagation, the speed with which energy is transmitted by a mode is given by the *group velocity* with the standard definition $v_{\mathrm{gr}} = \mathrm{d}\omega/\mathrm{d}\beta$. Since different modes have different values of the propagation constant β for the same source frequency, it follows that the phase and group velocities will also differ between modes. The modal group velocity determines pulse dispersion, as discussed in Section A1.5.6.

A1.5.3.8 Propagation constant, effective index and cut-off

For a given refractive index profile, the propagation constant β for every bound mode occupies a defined range of values in terms of the maximum n_{co} and minimum n_{cl} refractive index values and the source wavelength. If we assume that the modal phase velocity v_{ph} must lie between the maximum and minimum values of the speed of light in the cladding and core, i.e. $c/n_{co} < v_{ph} < c/n_{cl}$, then on setting $c = \omega/k$ it follows that

$$kn_{cl} < \beta < kn_{co} \tag{A1.5.13}$$

where $k = 2\pi/\lambda$ is the free-space wavenumber. This result applies to any waveguide independent of the number of bound modes that can propagate.

Sometimes it is more convenient physically to discuss propagation constant values in terms of an *effective index* value. If the effective index n_{eff} is defined through the relationship $\beta = kn_{eff}$, then equation (A1.5.13) is replaced by

$$n_{cl} < n_{eff} < n_{co} \tag{A1.5.14}$$

In other words, each bound mode has an effective index value that must lie between the minimum and maximum refractive index values.

When $\beta = kn_{cl}$ or, equivalently, $n_{eff} = n_{cl}$, a mode becomes *cut off* and for $\beta < kn_{cl}$ or $n_{eff} < n_{cl}$, a mode is said to be *below cut-off*.

A1.5.3.9 Waveguide, fibre and modal parameters

Waveguide and fibres are commonly characterized in terms of a number of standard dimensionless parameters that combine various basic parameters. In the following definitions, it is assumed that n_{co} denotes the uniform core index in the case of a step profile or the maximum core index in the case of a graded profile, and n_{cl} denotes the uniform cladding index. The source wavelength is λ, $k = 2\pi/\lambda$ is the free-space wavenumber and ρ is the core radius in the case of a circular fibre or the core half-width of a slab or square-core waveguide. Note that some other definitions assume that ρ is the full width of a slab or square-core waveguide.

Relative index difference

The uniform cladding index n_{cl} and the uniform or maximum core index n_{co} are often combined to define the *relative index difference* Δ

$$\Delta = \frac{n_{co}^2 - n_{cl}^2}{2n_{co}^2} \cong \frac{n_{co} - n_{cl}}{n_{co}} \tag{A1.5.15}$$

where the second expression is obtained by factorizing the numerator in the first expression and assuming that $n_{co} \sim n_{cl}$. This representation is appropriate within the weak guidance approximation discussed in Section A1.5.4.

Numerical aperture

A measure of the light-capturing capacity of a waveguide or fibre is provided by the *numerical aperture* or NA, which is defined by

$$\mathrm{NA} = (n_{co}^2 - n_{cl}^2)^{1/2} = n_{co}2\Delta^{1/2} \tag{A1.5.16}$$

A physical interpretation of numerical aperture is presented in Section A1.5.5.6.

Waveguide and fibre parameter or frequency

A second parameter V combines all the key parameters of a waveguide or fibre into a single normalized quantity known as the *waveguide* or *fibre parameter* or *frequency* that can be expressed in a number of equivalent ways

$$V = \frac{2\pi\rho}{\lambda}(n_{\mathrm{co}}^2 - n_{\mathrm{cl}}^2)^{1/2} = k\rho(n_{\mathrm{co}}^2 - n_{\mathrm{cl}}^2)^{1/2} = k\rho n_{\mathrm{co}}(2\Delta)^{1/2} \tag{A1.5.17}$$

This is an important parameter for its value determines, in particular, whether a fibre or waveguide is single mode, as discussed in Sections A1.5.4.4 and A1.5.4.5.

Modal parameters

In the examples of modal analyses of waveguides and fibres presented in Sections A1.5.4.4 and A1.5.4.5, respectively, it is convenient to introduce normalized *modal parameters* U and W for the core and cladding of a fibre or waveguide, respectively, which incorporate the propagation constant or equivalently the effective index according to

$$U = k\rho(n_{\mathrm{co}}^2 - \beta^2)^{1/2} = k\rho(n_{\mathrm{co}}^2 - n_{\mathrm{eff}}^2)^{1/2}; \quad W = k\rho(\beta^2 - n_{\mathrm{cl}}^2)^{1/2} = k\rho(n_{\mathrm{eff}}^2 - n_{\mathrm{cl}}^2)^{1/2} \tag{A1.5.18}$$

It then follows from the definition of V in equation (A1.5.17) that

$$U^2 + W^2 = V^2 \tag{A1.5.19}$$

The values of U and W are necessarily discrete for bound modes.

A1.5.3.10 Radiation modes, leaky modes and super-modes

The range of propagation constant values for bound modes satisfies equation (A1.5.14). If $\beta > kn_{\mathrm{co}}$, propagation is not possible, but if $\beta < kn_{\mathrm{cl}}$, it is possible to analyse propagation of the unguided field in the fibre or waveguide in using one of three different descriptions. These descriptions depend on the particular physical model employed and whether the cladding is unbounded or finite, but large, compared to the core size. In each case, the particular method is focused on determining the propagation characteristics of light within the waveguide that is not guided by the bound modes.

Radiation modes

In the case of a fibre or waveguide with an *unbounded cladding*, there are no bound modes with propagation constants in the range $0 < \beta < kn_{\mathrm{cl}}$ but, instead, a continuum of *radiation modes* can be derived, each mode having a continuously varying propagation constant value in this range. These modes can be used to analyse non-guided propagation in terms of an integration over each radiation mode and a sum over the integrals for different radiation modes (see chapter 25 of Ref. [4]). This approach is analytically complex and in view of the ready availability of vector-based beam propagation methods (BPM) and other techniques, a numerical analysis may be easier to implement.

Leaky modes

The continuum of radiation mode solutions can be approximated by a discrete summation of so-called *leaky modes*. A leaky mode is defined by the analytic continuation of a bound mode to propagation constant values beyond the mode's cut-off, i.e. for $\beta < kn_{\mathrm{cl}}$. However, unlike a bound mode, where the power flow is everywhere parallel to the z-axis, the local power flow is at an angle to the axis so that power flows away from the core as the mode propagates. This divergence corresponds to a complex value of the leaky mode propagation constant. Furthermore the power of a leaky mode is unbounded, so that a proper quantitative analysis of propagation cannot be undertaken, but nevertheless leaky modes can provide useful physical insight into propagation characteristics when radiation is present (see chapter 24 of Ref. [4]).

Super-modes

The cladding of any practical waveguide is necessarily finite in cross-section and may be surrounded by air or by a protective coating in the case of a fibre. In either case, it is normally possible to describe the transient field of a waveguide excited by a source using a superposition of the complete set of bound modes of the complete core-cladding-air structure. To distinguish these modes from the modes guided by the core-cladding refractive index profile, the former are often referred to as *super-modes*. The dimension of the complete cross-section is relatively large compared to that of the core ensuring that the number of super-modes is very large. In the limit of an infinitely thick cladding, the super-mode and radiation mode solutions approach one another [5].

Holey fibres

Currently there is significant interest in the light-guiding properties of *holey fibres*, which have certain attributes that are quite different to those of solid material fibres. Holey fibres differ from conventional fibres in that they are normally fabricated from a single material, such as silica or a polymer with a uniform refractive index, compared with a conventional fibre that has an index contrast between the core and the cladding materials.

Light guidance along holey fibres depends on the presence of concentric circular arrays of small longitudinal holes about the fibre axis (figure A1.5.9). Each ring of holes can be regarded as defining an annular region in which the average index is smaller than the material index and hence provides an effective index contrast with the material region around the fibre core and outside the ring.

However the core and ring of holes do not support any bound modes. The concentric region outside of the ring of holes is of the same index as the core and this enables any modal field within the holes to gradually leak from the centre across the ring of holes to the outer region. In other words, holey fibres only support *leaky modes*. Nevertheless, by judicious choice of the size, number and distribution of air holes, it is possible to design a fibre whereby the fundamental mode has virtually zero attenuation leakage but all higher-order modes have relatively large leakage rates so that their fields rapidly disappear from the central region as they propagate along the fibre. For practical purposes the holey fibre then behaves like a single-mode fibre, even over very long distances.

Photonic band-gap or *crystal* fibres also guide light, but the guidance mechanism is different to that of holey fibres. The physical basis for guidance along such fibres relies on a special arrangement of many rings of holes about the z-axis such that the rings provide a band gap in the radial direction, i.e. a barrier to the propagation of light away from the axis. One way to think of the band-gap effect qualitatively is to smear out the index contrast between the holes and the fibre material in each ring into an average reduced index. Then the quasi-periodic radial variation between the rings and the fibre material constitutes an effective radial Bragg reflection grating. At the effective Bragg wavelength in the fibre cross-section, the grating inhibits propagation and sets up a radial evanescent field that decreases radially outward. In other words, for suitably chosen fibre parameters the layers of rings can

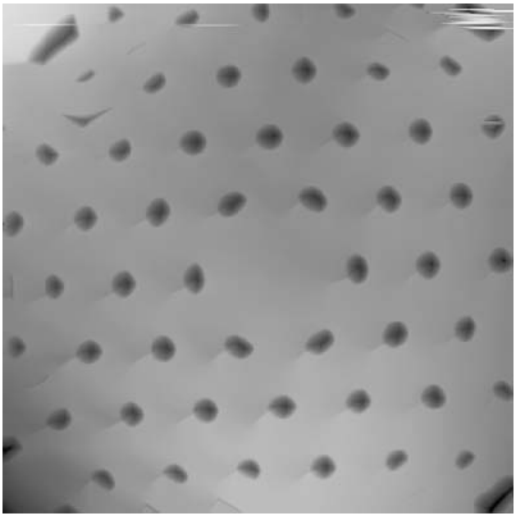

Figure A1.5.9. Cross-section of a holey fibre showing the solid core and surrounding rings of air holes.

support the evanescent field of the fundamental mode propagating along the fibre with the majority of its field close to the fibre axis. Chapter B10 provides a detailed description and analysis of both kinds of fibre.

A1.5.3.11 Polarization, mode nomenclature and birefringence

When a mode propagates along a fibre or waveguide, the magnitude and direction of the transverse components of its electric and magnetic fields remain fixed and thereby define the orientation of the modal field. The *polarization* of a mode is defined by the direction of the transverse electric field vector at each position in the waveguide or fibre cross-section. Generally this direction will vary with position so that contours of the field direction are normally curved, but in the case of two-dimensional slab waveguides, *all modes* have a transverse electric field that is parallel to a fixed direction, i.e. each mode is *plane polarized*. A similar situation pertains to the modes of weakly guiding fibres where transverse electric fields are also plane polarized.

Mode nomenclature

For two-dimensional symmetric slab waveguides, there are two distinct classes of modes, depending on their polarization. Transverse electric or TE_j modes have only a single transverse electric field component and transverse magnetic or TM_j modes have only a single transverse magnetic field component, where $j = 0, 1, 2, 3 \ldots$ denotes the mode order. The even and odd values of j denote modes with even and odd field symmetry, respectively. As the value of j increases, the number of extrema in the field patterns also increases.

In the case of circular fibres the situation is more complex because of the radial and azimuthal directions. There is a class of cylindrically symmetric TE_j and TM_j modes that have electric fields with a single radial or azimuthal transverse component, respectively, where $j = 1, 2, 3 \ldots$. In addition, there is the class of hybrid HE_{ij} and EH_{ij} modes that can be regarded as linear combinations of both TE and TM field components and therefore have a more complex electric field structure in the fibre cross-section.

Here the subscript 'i' relates to the order of the azimuthal angular dependence and 'j' refers to the radial order, the value of which increases with the number of extrema in the field. The azimuthal dependence of each mode has a $\cos(m\varphi)$ or $\sin(m\varphi)$ variation where $m = 0, 1, 2, \ldots$.

In the case of weakly guiding circular fibres, a second complimentary mode nomenclature is commonly used whereby each mode is labelled as LP_{ij}, the 'LP' denoting *linearly polarized*. The subscripts 'i' and 'j' denote azimuthal and radial orders, respectively, and in terms of HE modes in the weak guidance approximation the relationship can be expressed as $\mathrm{LP}_{ij} \leftrightarrow \mathrm{HE}_{i+1,j}$.

Within the two nomenclatures, the fundamental mode is equivalent to the HE_{11} mode for arbitrary index difference circular fibres and to either the HE_{11} or LP_{01} mode for weakly guiding fibres. For other waveguide and fibre geometries there is no generally accepted nomenclature for categorizing modes.

Birefringence

On a circular weakly guiding fibre, the fields of the fundamental mode are rotationally invariant about the fibre axis, so that any pair of orthogonal directions can be chosen for its two polarization states that have identical propagation constants. In this situation the fundamental mode is said to be *degenerate*.

However, in the case of non-circular fibres, such as the elliptical core fibre shown in figure A1.5.10, this is no longer the situation. Working within the weak guidance approximation, the two polarization directions of the planar transverse electric field are parallel to one of the *optical axes* of the fibre. For the elliptical cross-section the optical axes coincide with the major x-axis and minor y-axis and the fundamental mode has respective propagation constants β_x and β_y. Since $\beta_x > \beta_y$ the fundamental mode is *non-degenerate* and the fibre is said to be *birefringent* because of the difference in propagation constant for the two polarization states introduced by the non-circular core geometry.

Birefringence is a measure of the difference in the two propagation constants and is usually expressed in terms of the normalized parameter B that is defined by

$$B = \frac{\beta_x - \beta_y}{k} n_{\mathrm{ex}} - n_{\mathrm{ey}} \tag{A1.5.20}$$

where $\beta_x = kn_{\mathrm{ex}}$ and $\beta_y = kn_{\mathrm{ey}}$ in terms of the equivalent effective indices, and k is the free-space wavenumber. If both fundamental mode polarizations are launched simultaneously in the fibre, beating will occur between them because of the difference in propagation constants. The *beat length* or distance over which the superposition of the two modal fields repeats periodically along the length of the fibre is denoted by z_{b},

$$z_{\mathrm{b}} = \frac{2\pi}{\beta_x - \beta_y}; \quad B = \frac{2\pi}{z_{\mathrm{b}} k} = \frac{\lambda}{z_{\mathrm{b}}} \tag{A1.5.21}$$

and is therefore inversely proportional to the birefringence. Hence a measurement of the beat length together with the source wavelength will determine the birefringence.

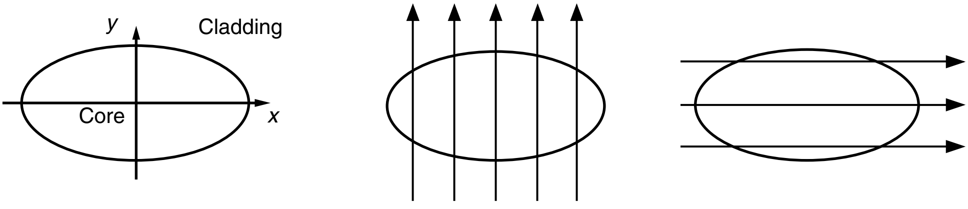

Figure A1.5.10. Cross-section and polarization states of the fundamental mode of an elliptical core fibre.

A1.5.3.12 Attenuation due to absorption and scattering loss

When light propagates in a bound mode along a straight fibre or waveguide, there is no loss of modal power provided that the materials are perfectly loss-less. However, in practical fibres and waveguides, a propagating mode steadily loses power because of two basic physical effects: (i) *bulk absorption* of optical power by the materials constituting the fibre core and cladding; and (ii) *scattering* of light by material and surface inhomogeneities, due principally to the distribution of dopants in the core of fibres and surface roughness between the core and cladding in waveguides.

In long-distance telecommunications fibres, Rayleigh scattering is the major cause of loss, absorption loss having been reduced to almost zero at the operating wavelength. The net effect of these two processes is to reduce the total light in the mode as it propagates along the length of the fibre, i.e. modal power is *attenuated*. The loss of power can be accounted for by adding an imaginary part to the refractive index value, i.e. n becomes the complex index $n^{(\mathrm{r})} + \mathrm{i}n^{(\mathrm{i})}$ where superscripts r and i denote real and imaginary parts, respectively. Although the real part of the index must necessarily vary over the core cross-section to provide guidance, the imaginary part is normally assumed to take a constant value.

Modal attenuation

In the determination of the propagation constant β of each bound mode, a real refractive index distribution $n(x, y)$ leads to a real value of β from the eigenvalue equations as is evident in the modal analyses of the step-profile slab waveguide and fibre in Sections A1.5.4.4 and A1.5.4.5, respectively. If n now becomes complex, it is evident from these eigenvalue equations that the modal parameters U and W and, therefore, the propagation constant must also become complex. Accordingly we set

$$U = U^{(\mathrm{r})} + \mathrm{i}U^{(\mathrm{i})}; \quad W = W^{(\mathrm{r})} + \mathrm{i}W^{(\mathrm{i})}; \quad \beta = \beta^{(\mathrm{r})} + \mathrm{i}\beta^{(\mathrm{i})} \tag{A1.5.22}$$

where $\beta^{(\mathrm{i})} > 0$. If we recall that the electric and magnetic field components all have the common longitudinal dependence

$$\exp(\mathrm{i}\beta z) = \exp(\mathrm{i}\{\beta^{(\mathrm{r})} + \mathrm{i}\beta^{(\mathrm{i})}\}) = \exp(\mathrm{i}\beta^{(\mathrm{r})}z)\exp(-\beta^{(\mathrm{i})}z)$$

it follows that the fields are attenuated as $\exp(-\beta^{(\mathrm{i})}z)$ and the local power density is attenuated as $\exp-(2\beta^{(\mathrm{i})}z)$. Further, since the total power density flow in a mode is the integral of the local power density over the cross-section, it follows that the power in all modes is attenuated according to

$$P(z) = P(0)\exp(-2\beta^{(\mathrm{i})}z) \tag{A1.5.23}$$

where $P(z)$ is the mode power distance z along the fibre or waveguide. The expression $2\beta^{(\mathrm{i})}$ is the *power attenuation coefficient*. The measure of attenuation is commonly expressed in decibels, or dB, where the dB value is calculated as

$$\mathrm{dB} = -10\log_{10}\left(\frac{P(z)}{P(0)}\right) = 20\beta^{(\mathrm{i})}z\log_{10}\mathrm{e} = 8.686\beta^{(\mathrm{i})}z \tag{A1.5.24}$$

The determination of the exact values of the complex propagation constant from the eigenvalue equation for a particular fibre or waveguide with a complex refractive index profile can generally only be undertaken numerically, and formally poses a two-dimensional root-finding problem.

However, for the majority of problems, $\beta^{(\mathrm{i})} \ll \beta^{(\mathrm{r})}$ so that $\beta^{(\mathrm{r})}$ can be determined straightforwardly by assuming that to the lowest order, n is pure real. For example, if the imaginary part of the index $n^{(\mathrm{i})}$ is a constant everywhere throughout the fibre or waveguide, then $\beta^{(\mathrm{i})} \sim kn^{(\mathrm{i})}$ which means that the dB loss is given, approximately, by $55n^{(\mathrm{i})}z/\lambda$ where λ is the source wavelength. This expression is identical to the power attenuation of a plane wave propagating in a uniform medium with imaginary index $n^{(i)}$. For more general situations, a perturbation approach can be adopted to determine an accurate approximation for $\beta^{(i)}$, as quantified by the example in Section A1.5.9.1.1.

For standard silica-based single-mode fibres used for telecommunications, there is a minimum loss of about 0.2 dB km^{-1} occurring at a wavelength of 1550 nm. Using the plane wave expression, this leads to an imaginary index value of approximately 5.6×10^{-12}.

A1.5.3.13 Analytical and numerical solutions

There is only a small number of waveguide geometries and refractive index profiles for which there are exact analytical solutions of Maxwell's equations for the bound mode fields and analytical expressions for the eigenvalue equation that determines the values of the propagation constant. The latter are generally transcendental and can only be solved numerically. Of these solutions, the most practical and simplest example is the step-profile slab waveguide and the step-profile circular fibre. The former has modal fields and eigenvalue equations expressed in terms of trigonometric and exponential functions while the latter has modal fields and eigenvalue equations expressed in terms of Bessel functions and modified Bessel functions (see chapter 12 of Ref. [4]). These solutions are valid for arbitrary relative index difference. In the weak guidance approximation, the corresponding analytical solutions of the scalar wave equation are less complex and are derived in detail in Sections A1.5.4.4 and A1.5.4.5.

Although there are analytical solutions of Maxwell's equations or the scalar wave equation that can be derived for certain other profiles and geometries, they involve special mathematical functions the properties of which are less familiar compared to the situation just 25 years ago. A major factor that has reduced their familiarity is the development and ready availability of reliable commercial and in-house software routines that can solve Maxwell's equations for the fields and propagation constants of bound modes given almost arbitrary refractive index profiles and waveguide geometries.

Planar and rib waveguides

There is a class of waveguides referred to generically as *planar waveguides*. This name actually refers to the planar substrate on which waveguides with a variety of core cross-sections are fabricated. One class relates to *buried channel waveguides* that generally have a nominally square or rectangular core surrounded by an effectively unbounded cladding. Another class includes *rib waveguides* that have a core where the cross-section has the shape of an inverted 'T' and is commonly surrounded by air above and a lower refractive index layer below. Provided the core index is greater than the surrounding cladding index, these waveguides support one or more bound modes, depending on the waveguide parameters and source wavelength.

For both scalar modes and vector modes, the waveguide geometry requires numerical solution for the modal fields and propagation constants, although some analytical approximation methods, such as the *effective index method* can be applied [6].

A1.5.4 Weak-guidance approximation

The solution of Maxwell's equations for the bound modes of a dielectric fibre or waveguide with arbitrary cross-sectional geometry and refractive index profile, whether investigated by analytical or numerical means, generally involves the simultaneous determination of all six scalar components of the electric and magnetic field vectors. Such solutions are therefore necessarily complex. However, there is a set of practical fibre and waveguide problems for which it is possible to make a significant simplification and replace the set of six coupled Maxwell equations with a single scalar equation for just one component of the fields. This is the basis of the *weak guidance approximation* [7, 8].

A1.5.4.1 Scalar electromagnetic fields and power flow

Many waveguides, such as solid silica-based optical fibres and planar waveguides, have a refractive index profile $n(x, y)$ across the core and cladding where the maximum variation in index is relatively small, typically below 1%. Now consider the vector wave equation satisfied by the electric field. This equation is generated by eliminating the magnetic field $\boldsymbol{H}$ between the two Maxwell equations (A1.5.3) and leads to

$$(\nabla_{\mathrm{t}}^2 + k^2 n^2 - \beta^2)E = -\nabla_{\mathrm{t}}(E_{\mathrm{t}} \cdot \nabla_{\mathrm{t}} \ln n^2) \qquad \text{(A1.5.25)}$$

where ∇_{t}^2 is the transverse *vector* Laplace operator, $k = 2\pi/\lambda$ is the free-space wavenumber and β is the propagation constant. If the overall variation in index is small, then the term on the right-hand side can be neglected.

In a general orthogonal coordinate system, the vector operator ∇_{t}^2 couples the scalar components of $\boldsymbol{E}_{\mathrm{t}}$. However, if the components of $\boldsymbol{E}_{\mathrm{t}}$ are chosen to be Cartesian, i.e. $\boldsymbol{E}_{\mathrm{t}} = (e_x, e_y) = \exp(\mathrm{i}\beta z)$ then the component equations decouple. The respective scalar components e_x or e_y for these states independently satisfy the same scalar wave equation

$$(\nabla_{\mathrm{t}}^2 + k^2 n^2 - \beta^2)e_x = 0; \quad (\nabla_{\mathrm{t}}^2 + k^2 n^2 - \beta^2)e_y = 0 \qquad \text{(A1.5.26)}$$

where ∇_{t}^2 is now the two-dimensional *scalar* Laplace operator the analytical form of which depends on the waveguide or fibre geometry.

Once the electric field component of a mode has been determined from the scalar wave equation (A1.5.26), together with the appropriate boundary conditions, the corresponding component of the magnetic field for the respective polarization states is given by a simple algebraic relationship

$$h_y = n_{\mathrm{co}} \left(\frac{\varepsilon_0}{\mu_0}\right)^{1/2} e_x; \quad h_x = -n_{\mathrm{co}} \left(\frac{\varepsilon_0}{\mu_0}\right)^{1/2} e_y \qquad \text{(A1.5.27)}$$

where ε_0 and μ_0 are, respectively, the free-space dielectric constant and permeability, and n_{co} is the maximum core index. Note that in the weak-guidance approximation, all other field components are very small compared to the dominant transverse electric and magnetic field components and can normally be ignored.

It follows from equations (A1.5.9), (A1.5.26) and (A1.5.27) that, in weak guidance, the z-directed power flow density for the x- and y-polarized fields is given, respectively, by

$$S_z = \frac{1}{2} n_{\mathrm{co}} \left(\frac{\varepsilon_0}{\mu_0}\right)^{1/2} e_x^2; \quad S_z = \frac{1}{2} n_{\mathrm{co}} \left(\frac{\varepsilon_0}{\mu_0}\right)^{1/2} e_y^2 \qquad \text{(A1.5.28)}$$

There is a strong analogy between the modes and plane waves of Section A1.5.2 in terms of the non-zero field components and the orthogonal electric field polarization directions. For the two mode polarizations the field components are

$$E = (e_x, 0, 0)\mathrm{e}^{\mathrm{i}\beta z}, H = (0, h_y, 0)\mathrm{e}^{\mathrm{i}\beta z}; \quad E = (0, \mathrm{e}_y, 0)\mathrm{e}^{\mathrm{i}\beta z}, H = (h_x, 0, 0)\mathrm{e}^{\mathrm{i}\beta z} \qquad \text{(A1.5.29)}$$

corresponding *to* x- and y-polarizations, respectively.

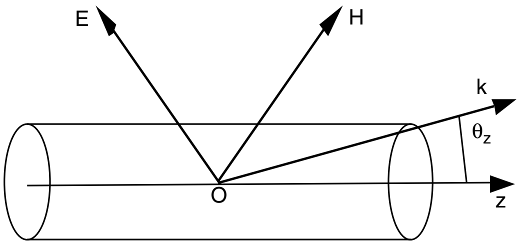

Figure A1.5.11. Triad of electric and magnetic field vectors and the local wave vector.

A1.5.4.2 Transverse nature of the electromagnetic field

The modal electromagnetic field in the core can be considered at each position in the core cross-section as a plane wave. The propagation constant β is the z-component of the local planar wave vector, i.e.

$$\beta = kn_{\mathrm{co}}\cos(\theta_z) \tag{A1.5.30}$$

where θ_z is the direction that the local plane wave vector makes with the z-axis in the core of the waveguide or fibre, and k is the free-space wavenumber. Since the propagation constant β is bounded by

$$kn_{\mathrm{cl}} < \beta < kn_{\mathrm{co}} \tag{A1.5.31}$$

and the core and cladding indices are similar, i.e. $\beta \sim kn_{\mathrm{co}} \sim kn_{\mathrm{cl}}$ leading to $\theta_z \sim 0$.

The wave vector is approximately parallel to the z-direction and hence both the vector electric and magnetic fields are approximately transverse to the z-axis. Both the longitudinal electric and magnetic field components are negligible in magnitude compared to the transverse fields. The Cartesian components of the electric and magnetic fields for either mode polarization, together with the z-axis comprise an orthogonal triad (figure A1.5.11), i.e. the same relationship satisfied by the corresponding components of a plane wave.

A1.5.4.3 Slab and circular geometries

Here the geometry, profiles, field representation, governing equations, coordinates and parameters are delineated for analysing modes on symmetric slab waveguides and circular fibres in the weak guidance approximation.

Symmetric slab waveguide

For the one-dimensional slab waveguide of figure A1.5.12, the core-cladding interfaces are parallel to the y–z plane, so that there is only the x-variation in the transverse direction, together with the usual z-dependent phase term in the z-direction of propagation. Thus for the x- and y-polarizations of the TE and TM modes, respectively, the scalar electric field components can be expressed as

$$E_x(x,z) = e_x(x)\mathrm{e}^{\mathrm{i}\beta z}; \quad E_y(x,z) = e_y(x)\mathrm{e}^{\mathrm{i}\beta z} \tag{A1.5.32}$$

where $e_x(x)$ and $e_y(x)$ are both solutions of the one-dimensional scalar wave equation

$$\left(\frac{\mathrm{d}^2}{\mathrm{d}x^2} + k^2n^2(x) - \beta^2\right)e(x) = 0 \tag{A1.5.33}$$

obtained from equation (A1.5.26) where $n(x)$ denotes the profile.

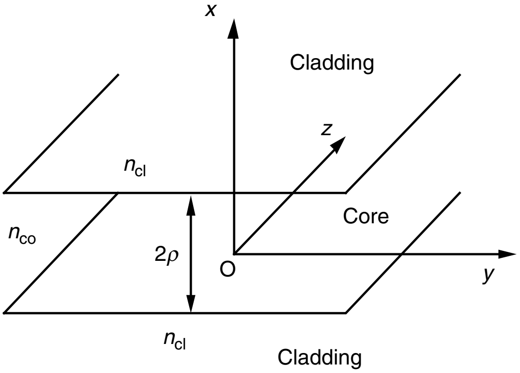

Figure A1.5.12. Geometry and parameters for the symmetric step-profile slab waveguide.

Circular fibre

Note that while either e_x and e_y is the single Cartesian *component* of the vector electric field $\boldsymbol{e}$, their spatial variation does not necessarily have to be described in *Cartesian coordinates*. For the circular fibre in figure A1.5.13 the spatial dependence of the modal fields in the cross-section is best described by polar coordinates (r, ϕ) based on the z-axis of the fibre. Thus for the x- or y-polarized modes we may set

$$e_x = e_x(r, \phi); \quad e_y = e_y(r, \phi) \tag{A1.5.34}$$

Here $e_x(r, \phi)$ and $e_y(r, \phi)$ are both solutions of the two-dimensional scalar wave equation

$$\left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial \phi^2} + k^2 n^2(r) - \beta^2\right) e(r, \phi) = 0 \tag{A1.5.35}$$

where $n(r)$ denotes an axisymmetric profile for circularly symmetric fibres.

Boundary conditions

If ψ denotes either e_x or e_y in the scalar wave equation, then the boundary conditions satisfied by the bound mode solutions of the scalar wave equation in the core and cladding are the weak-guidance limit

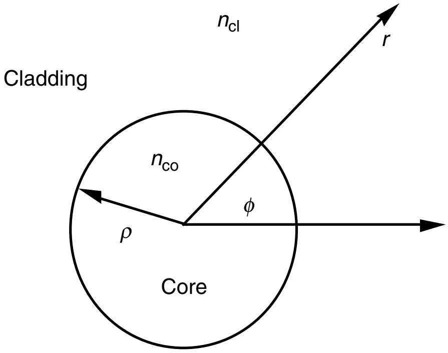

Figure A1.5.13. Geometry and parameters for circular fibres.

of the boundary conditions for Maxwell's equations. In this limit all six components of the electromagnetic field are everywhere continuous. Accordingly:

- $\Psi \rightarrow 0$ exponentially far from the fibre or waveguide core;
- Ψ is continuous across the core–cladding interface; and
- all first derivatives of ψ are continuous across the core–cladding interface.

For the one-dimensional slab waveguide both Ψ and $\mathrm{d}\Psi/\mathrm{d}x$ are continuous across both core–cladding interfaces, while for the two-dimensional fibre Ψ, $\mathrm{d}\Psi/\mathrm{d}r$ and $\mathrm{d}\Psi/\mathrm{d}\phi$ are continuous across the core–cladding interface. The solution of the scalar wave equation together with the boundary conditions constitutes an *eigenvalue problem* for the modal propagation constants, and the *eigenfunctions* determine the spatial dependence of a scalar transverse electric field. The propagation constants are determined by the *eigenvalue equation*.

A1.5.4.4 Step-profile slab waveguide

The spatial dependence of the modal fields in equation (A1.5.32) and the eigenvalue equation for the modal propagation constants are obtained by solving equation (A1.5.33) in the core and the cladding, and then matching the two solutions using the boundary conditions on the core–cladding interfaces. Because the slab waveguide profile is symmetric about the y–z plane, the solutions of the scalar wave equation for $\psi(x)$ will be accordingly either symmetric or anti-symmetric in x.

Even and odd modes

In the core $n(x) = n_{\mathrm{co}}$ and it is convenient to introduce the core modal parameter $U = \rho(k^2 n_{\mathrm{co}}^2 - \beta^2)^{1/2}$ since $\beta < kn_{\mathrm{co}}$ for bound modes, and the normalized coordinate $X = x/\rho$. With these substitutions the scalar wave equation can be written as

$$\left(\frac{\mathrm{d}^2\Psi}{\mathrm{d}X^2} + U^2\right)\Psi = 0 \tag{A1.5.36}$$

This is the harmonic equation and its solutions are proportional to $\cos(UX)$ or $\sin(UX)$. Since the former is symmetric in x, we set for the even modes:

$$\Psi(X) = A\cos(UX) \tag{A1.5.37}$$

for $0 < |X| < 1$, where A is a constant. In the cladding $n(x) = n_{\mathrm{cl}}$ and it is convenient to work with the cladding modal parameter $W = \rho(\beta^2 - k^2 n_{\mathrm{cl}}^2)^{1/2}$ since $\beta > kn_{\mathrm{cl}}$ for bound modes and the normalized $X = x/\rho$. With these substitutions, the scalar wave equation becomes

$$\left(\frac{\mathrm{d}^2\Psi}{\mathrm{d}X^2} + W^2\right)\Psi = 0 \tag{A1.5.38}$$

The solution of this equation is exponential and proportional to either $\exp(WX)$ or $\exp(-WX)$. Since we require a symmetric solution that decreases to zero as $X \rightarrow +\infty$ and $X \rightarrow -\infty$, we set

$$\Psi(X) = B\,\mathrm{e}^{-W|X|} \tag{A1.5.39}$$

for $|X| > 1$, where B is a constant.

Eigenvalue equations

The boundary conditions on ($X = 1$) ($x = \rho$) and ($X = -1$) ($x = -\rho$), which link the core and cladding solutions, are the continuity of Ψ and $\mathrm{d}\Psi/\mathrm{d}X$, which lead, respectively, to

$$A\cos U = B\,\mathrm{e}^{-W}; \quad -AU\sin U = -BW\,\mathrm{e}^{-W} \tag{A1.5.40}$$

so that on dividing the two equations, the constants A and B are eliminated and we obtain one equation linking the core and cladding modal parameters U and W. A second equation follows from the definitions of U, V and W. Hence the eigenvalue equations for the even modes are

$$W = U\tan U; \quad W^2 + U^2 = V^2 \tag{A1.5.41}$$

The derivation of the corresponding equations for the odd modes is identical to that for the even modes provided the core modal field has the anti-symmetric form

$$\Psi(X) = A\sin(UX) \tag{A1.5.42}$$

This leads to the eigenvalue equations for the odd modes

$$W = -U\cot U; \quad W^2 + U^2 = V^2 \tag{A1.5.43}$$

Both pairs of eigenvalue equations can be further simplified by eliminating U between each pair and for the even and odd modes this leads, respectively, to

$$V = \pm\frac{U}{\cos U}; \quad V = \pm\frac{U}{\sin U} \tag{A1.5.44}$$

but care needs to be exercised with the signs to identify correct solutions.

Solution of the eigenvalue equations

The eigenvalue equations for both even and odd modes are transcendental and do not possess closed-form analytical solutions for U (or W) in terms of a given value of V. Accordingly, solutions must be determined numerically and each value of U corresponds to one bound mode. This can be undertaken using a hand calculator incorporating trigonometric functions by using trial and error, i.e. given V guess U, or by using a more sophisticated computer program.

However, it may be simpler to calculate the value of V, given the value of U in equations (A1.5.44) since these are single-valued and explicit. This approach generates the V–U curve for each and every mode of the waveguide as shown in figure A1.5.14. In these plots, an even or odd subscript corresponds to a mode with an even or odd field, respectively, and also indicates mode order.

Single-mode waveguide

In figure A1.5.14 every mode, except the fundamental mode, has a finite cut-off value of U when $U = V$ below which it cannot propagate as a bound mode and becomes a leaky mode. For the mode with subscript ‘m’, the cut-off value is $V = V_{\mathrm{co}} = m\pi/2$.

The waveguide is *single mode* if $V < \pi/2$, and only the fundamental mode can propagate in either of its two polarization states (TE_0 or TM_0) with the same propagation constant β. The fundamental mode has the largest value of propagation constant or equivalently the smallest value of U for a given value of V. The fundamental mode corresponds to the TE_0 or TM_0 mode.

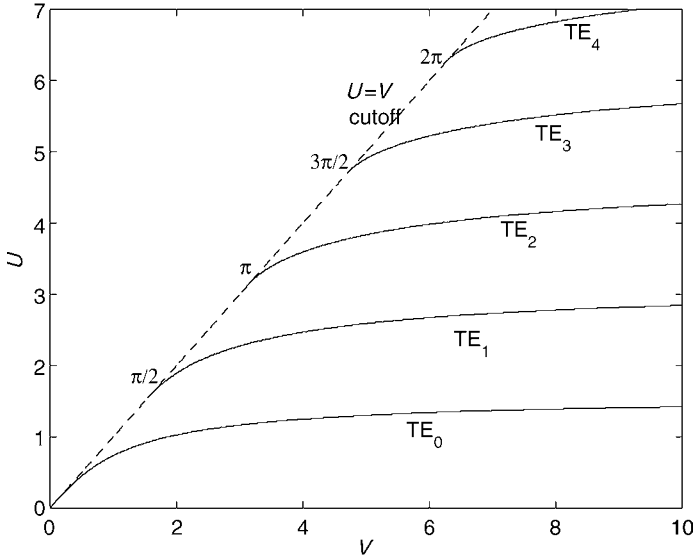

Figure A1.5.14. Plots of U against V for the modes of the symmetric step-profile slab waveguide.

Modal fields

For the TE (transverse electric) modes the electric field direction is parallel to the y-axis and transverse to the to the z-axis while for the TM (transverse magnetic) modes, the magnetic field is parallel to the y-axis and transverse to the z-axis. In the weak-guidance approximation, the pair of TE$_j$ and TM$_j$ modes has an identical propagation constant while their transverse electric and magnetic field components have identical spatial distribution, and are y- and x-polarized, respectively.

The spatial distribution of the transverse electric or magnetic fields for the first four TE or TM modes are plotted in figure A1.5.15. Note that the TE$_m$ and TM$_m$ mode fields have $m+1$ extrema, and the even mode has a maximum at the centre of the waveguide where the odd mode fields vanish. The total number of modes that can propagate for a given value of V is given by the nearest integer value below $4V/\pi$ allowing for the two possible polarization states.

A1.5.4.5 Step-profile fibre

The spatial dependence of the modal fields in equation (A1.5.34) and the eigenvalue equation for the modal propagation constants are obtained by solving equation (A1.5.35) in the core and the cladding, and then matching the two solutions using the boundary conditions on the core–cladding interface. If $\Psi(r, \phi)$ denotes either the x-polarized electric field $e_x(r, \phi)$ or the y-polarized electric field $e_y(r, \phi)$ in cylindrical polar coordinates, then, within weak guidance, $\Psi(r, \phi)$ satisfies the scalar wave equation (A1.5.34), which is more conveniently written in the normalized form

$$\left\{\frac{\partial^2}{\partial R^2}+\frac{1}{R}\frac{\partial}{\partial R}+\frac{1}{R^2}\frac{\partial^2}{\partial \phi^2}+\rho^2(k^2n(R)^2-\beta^2)\right\}\Psi=0 \qquad \text{(A1.5.45)}$$

where $R=r/\rho$ is the normalized radial coordinate, where $n(R)$ is the refractive index profile and ρ is the core radius. This equation is a second-order partial differential equation and as $n(R)$ is independent of ϕ it can be solved using *separation of variables*.

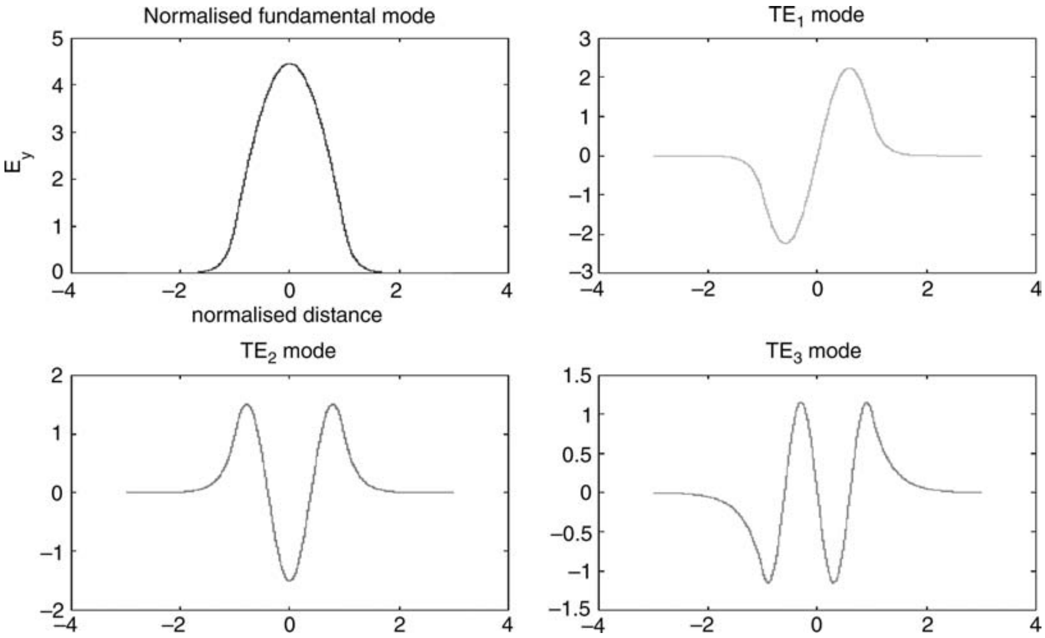

Figure A1.5.15. Plots of the transverse electric field for the first four modes of the symmetric step-profile slab waveguide.

Separation of variables

Using this technique, the two-dimensional spatial dependence of ψ is expressed as the product of the two single-variable functions

$$\Psi(R, \phi) = F(R)G(\phi) \tag{A1.5.46}$$

where $F(R)$ is a function of R only, and $G(\phi)$ is a function of ϕ only. On substituting into the scalar wave equation (A1.5.38), dividing by Ψ, and multiplying by R^2 it follows

$$\frac{R^2}{F}\left\{\frac{\mathrm{d}^2F}{\mathrm{d}R^2} + \frac{1}{R} - \frac{\mathrm{d}F}{\mathrm{d}R} + \rho^2\left[k^2n^2(R) - \beta^2\right]F\right\} + \frac{1}{G}\frac{\mathrm{d}^2G}{\mathrm{d}\phi^2} = 0 \tag{A1.5.47}$$

The right-hand expression is a function of ϕ only and can be held fixed while R varies arbitrarily. Because of the periodicity of the solution required in the azimuthal direction because of the circular geometry we set

$$\frac{\mathrm{d}^2G}{\mathrm{d}\phi^2} = -\nu^2 G; \quad G = \begin{cases} \sin(\nu\phi) \\ \cos(\nu\phi) \end{cases} \tag{A1.5.48}$$

where ν is a constant. This is the harmonic equation with sinusoidal solutions which are single-valued, provided $\nu = 0, 1, 2, 3, \ldots$. Substituting back into the scalar wave equation (A1.5.38) leads to the second-order ordinary differential equation

$$\left\{\frac{\mathrm{d}^2}{\mathrm{d}R^2}+\frac{1}{R}\frac{\mathrm{d}}{\mathrm{d}R}-\frac{\nu^2}{R^2}+\rho^2[k^2n^2(R)-\beta^2]\right\}F=0 \qquad \text{(A1.5.49)}$$

that is solved for the core and cladding regions separately.

Core solution

In the core $n = n_{\mathrm{co}}$, so that equation (A1.5.49) for F can be written as

$$\left\{\frac{\mathrm{d}^2}{\mathrm{d}R^2}+\frac{1}{R}\frac{\mathrm{d}}{\mathrm{d}R}-\frac{\nu^2}{R^2}+U^2\right\}F=0 \qquad \text{(A1.5.50)}$$

where the core modal parameter is defined by $U=\rho(k^2n_{\mathrm{co}}^2-\beta^2)^{1/2}$. Multiply this equation by R^2 and set $s = UR$ to obtain

$$\left\{s^2\frac{\mathrm{d}^2}{\mathrm{d}s^2}+s\frac{\mathrm{d}}{\mathrm{d}s}+s^2-\nu^2\right\}F=0 \qquad \text{(A1.5.51)}$$

This is *Bessel's equation* with the general solution

$$F(R)=AJ_\nu(s)+BY_\nu(s) \qquad \text{(A1.5.52)}$$

where J_ν and Y_ν are *Bessel functions* of the first and second kinds, respectively, and A and B are constants. The solution is bounded throughout the core and as Y_ν is singular on the fibre axis $R = 0$, then $B = 0$. Hence $F(R) = AJ_\nu(UR)$ and together with equation (A1.5.48) the complete core solution dependence $F(R)G(\phi)$ is given by

$$\Psi=AJ_\nu(UR)\begin{cases}\sin(\nu\phi)\\ \cos(\nu\phi)\end{cases} \qquad \text{(A1.5.53)}$$

where $\nu = 0, 1, 2, \ldots.$

Cladding solution

In the cladding $n = n_{\mathrm{cl}}$, so that the corresponding equation for F becomes

$$\left\{s^2\frac{\mathrm{d}^2}{\mathrm{d}s^2}+s\frac{\mathrm{d}}{\mathrm{d}s}-(\nu^2+s^2)\right\}F=0 \qquad \text{(A1.5.54)}$$

where $s = WR$ and the cladding modal parameter is defined by $W=\rho(\beta^2-k^2n_{\mathrm{cl}}^2)^{1/2}$. This is the *modified Bessel equation* with the general solution

$$F(R)=CI_\nu(s)+DK_\nu(s) \qquad \text{(A1.5.55)}$$

where I_ν and K_ν are *modified Bessel functions* of the first and second kinds, respectively, and C and D are constants. This solution is bounded throughout the cladding and since I_ν is singular as $R \to \infty$, then $C = 0$. Hence $F(R) = DK_\nu(WR)$ and together with equation (A1.5.48) the complete cladding solution dependence, $F(R)G(\phi)$ is

$$\Psi=DK_\nu(WR)\begin{cases}\sin(\nu\phi)\\ \cos(\nu\phi)\end{cases} \qquad \text{(A1.5.56)}$$

where $\nu = 0, 1, 2, \ldots.$

Boundary conditions

Boundary conditions at the core–cladding interface require continuity of the solution of the scalar wave equation and all first derivatives, equivalent to continuity of $\Psi(R,\phi)$ and $\mathrm{d}\Psi(R,\phi)/\mathrm{d}R$ on $R = 1$. The latter, when applied to equations (A1.5.53) and (A1.5.56), gives

$$AJ_\nu(U) = DK_\nu(W); \quad AUJ'_\nu(U) = DWK'_\nu(W) \tag{A1.5.57}$$

where the prime denotes differentiation with respect to the argument. On dividing these two equations, we obtain one eigenvalue equation for U and W

$$\frac{UJ'_\nu(U)}{J_\nu(U)} = W\frac{K'_\nu(W)}{K_\nu(W)} \tag{A1.5.58}$$

It is more convenient for computational purposes to recast this equation into an alternative form avoiding the use of derivatives by using the following recurrence relations satisfied by Bessel functions of different orders

$$J'_\nu = \frac{\nu}{U}J_\nu - J_{\nu+1}; \quad K'_\nu = \frac{\nu}{W}K_\nu - K_{\nu+1} \tag{A1.5.59}$$

where the prime denotes differentiation with respect to the argument. Thus, the final form of the eigenvalue equations for U and W are

$$U\frac{J_{\nu+1}(U)}{J_\nu(U)} = W\frac{K_{\nu+1}(W)}{K_\nu(W)}; \quad V^2 = U^2 + W^2 \tag{A1.5.60}$$

where $\nu = 0, 1, 2, \ldots.$

Solutions of the eigenvalue equations

The left-hand term in equation (A1.5.60) is transcendental and can be solved only numerically. There are standard library routines for evaluating the two types of Bessel functions required. Given the value of V, the eigenvalue equations can be solved by expressing W in terms of U and V using the second term in equation (A1.5.60) and then solving the resulting equation numerically for the discrete values of U. Each value of U corresponds to a particular bound mode. For each value of ν, there are a finite number of bound solutions of the eigenvalue equation, the number increasing with the value of V according to the closest integer below $V^2/2$ for the step profile.

Figure A1.5.16 plots the values of U as a function of V for each bound mode solution. Given the value of U, the value of the propagation constant can be determined from the definition of U given above. Every mode, except the fundamental mode, has a finite cut-off value of U when $U = V$. Below this value the mode cannot propagate as a bound mode and becomes a leaky mode. The fibre is multimode when $V \gg 1$, and many modes can propagate. For a given, large value of V, the number of bound modes which can propagate is approximately $V^2/2$.

Mode nomenclature

Because of the cylindrical geometry of the fibre, there are four possible types of bound mode solution. The TE_{01} and TM_{01} solutions, like the corresponding solutions for the slab waveguide in Section A1.5.4.4, indicate modal electric or magnetic fields that have only a radial electric or magnetic field component, respectively, and are axisymmetric. The EH_{pq} and HE_{pq} modes can be regarded as hybrid modes, their fields containing both electric and magnetic radial components. The first and second

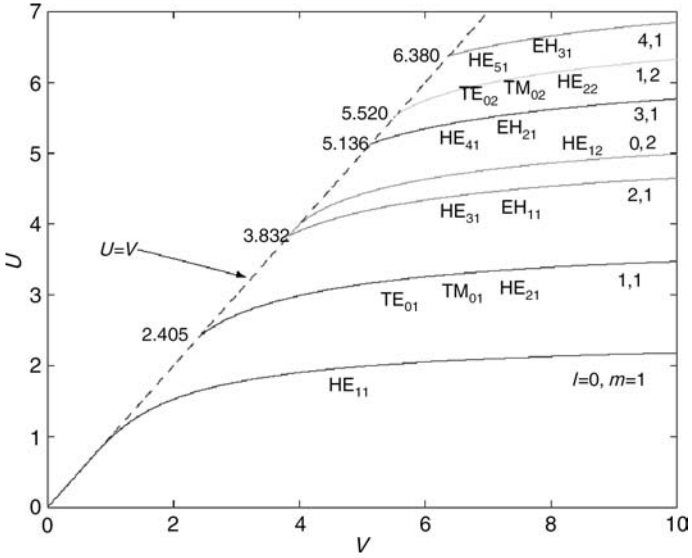

Figure A1.5.16. Plots of U against V for modes of the step-profile circular fibre.

subscripts p and q on each mode designator indicate, respectively, the azimuthal symmetry and radial order. The former has the dependence $\cos([p-1]\phi)$ or $\sin([p-1]\phi)$ for $p = 1, 2, 3 \ldots$, while the latter indicates the number of extrema in the field profile.

There is a second mode nomenclature in use that was devised specifically for weakly guiding fibres and is based on the linear polarization (LP) property of these modes. In this system the fundamental HE_{11} mode is known as the LP_{01} mode with axisymmetric field components, and the TE_{01}, TM_{01} and HE_{21} set of second modes with anti-symmetric $\sin\phi$ or $\cos\phi$ azimuthal dependence as LP_{11} modes.

Single-mode fibre

The fibre is single-mode for $V < 2.405$ when only one mode, the fundamental mode, can propagate in either of its two orthogonal but otherwise arbitrary polarization states with the same propagation constant β. The fundamental mode has the largest value of propagation constant or equivalently the smallest value of U for a given value of V. The fundamental mode corresponds to the HE_{11} or equivalent LP_{01} mode.

Fractional of modal power in the core

For a particular fibre and source wavelength, the power of each propagating mode is distributed between the core and the cladding in a ratio that depends on the mode order. It is useful to define the parameter η as the fraction of total mode power that propagates in the core, so that $0 < \eta < 1$. Figure A1.5.17 plots this fraction as a function of fibre parameter V for the first six low-order modes of the weakly guiding step profile. As V increases the value of η for each mode approaches 1 asymptotically, consistent with the zero-wavelength geometric optics limit. Note that as V approaches the mode cut-off, the fraction of core power does not always approach zero.

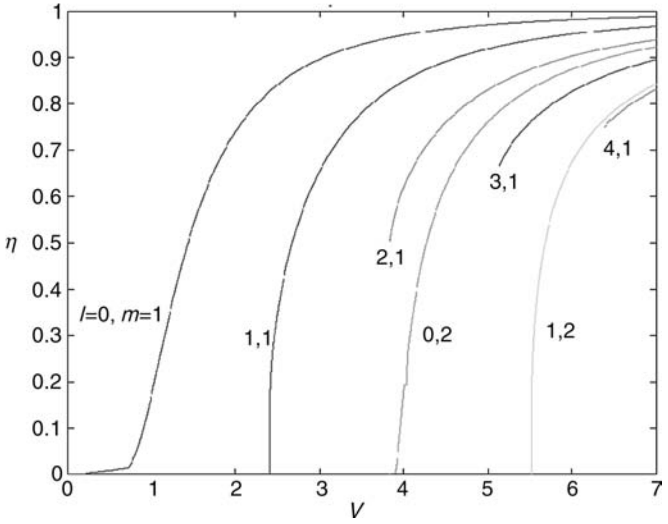

Figure A1.5.17. Fraction of modal power propagating in the fibre core.

A1.5.4.6 Fundamental mode

The mode of most interest for single-mode fibres is the fundamental HE_{11} or LP_{01} mode, i.e. the only mode that can propagate on a fibre for V values below the cut off of the second mode, namely for $V < 2.405$ in the case of the step-profile fibre. If λ_{co} denotes the cut-off wavelength of the second mode, the fundamental mode alone can propagate for wavelengths such that $\lambda > \lambda_{co}$.

Intensity distribution

The normalized fundamental mode electric field intensity $|\Psi|^2$ for typical graded- or step-index profiles has a characteristically axially symmetric bell-shaped distribution about the fibre axis. This characteristic shape is exemplified by the plots of intensity against normalized radius, $R = r/\rho$, shown in figure A1.5.18 calculated from equations (A1.5.28), (A1.5.53) and (A1.5.56) for the step-profile fibre for various values of V. In the geometric optics limit when V becomes unbounded, i.e. $\lambda \rightarrow 0$, all the modal power is concentrated in the core. The normalization is such that the geometric optics limit corresponds to unit intensity on the fibre axis.

Fibre cladding thickness

As V decreases, an increasing fraction of fundamental mode power spreads into the cladding, as is clear from figures A1.5.17 and A1.5.18. For a practical single-mode step-profile fibre operating around $V = 2.3$, the fraction of modal power in the cladding is about 25% and the cladding field, which decreases approximately exponentially with increasing radius, needs to be sufficiently small at the outer edge of the cladding so that the absorption due to the fibre coating is negligibly small. It is for this reason that a standard 125 μm cladding diameter has been adopted resulting in a ratio of cladding-to-core diameters in the range of 10–15, depending on core size.

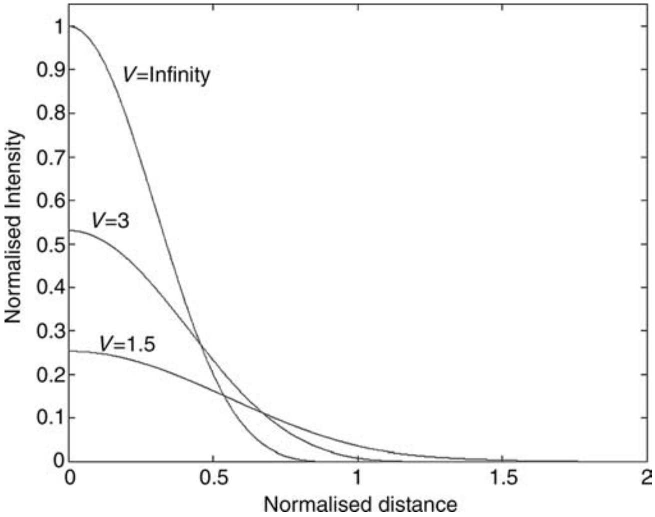

Figure A1.5.18. Plots of the fundamental mode intensity distribution on a step-profile fibre for various values of *V*.

A1.5.4.7 Spot size and Gaussian approximation

Single-mode fibres and waveguides are often characterized by the *spot size* of the fundamental mode intensity distribution, which is an experimental measurement of the diameter of the brightest part of this distribution as it appears in either the near field or far field at the end of a long length of single-mode fibre. The plots of the local power density of the fundamental mode transverse intensity distribution, as shown in figure A1.5.18, have the common characteristic of a peak on the vertical axis and a monotonic decrease with increasing radius. Accordingly, for a given wavelength, the *spot size* can be defined as the half-width of this distribution at an appropriate position on the vertical axis while the *mode field diameter* is the full width and therefore equal to twice the spot size.

As there is no immediately obvious position to choose, a number of different definitions of spot size have been proposed over the years, each being tailored to provide, indirectly, an accurate value of a particular fundamental mode property from the spot size measurement. Here we introduce a definition known as the *Gaussian approximation* based solely on the shape of the plots in figure A1.5.18 (see chapters 15 and 16 of Ref. [4]).

Gaussian approximation

Generally there is no analytical solution of the scalar wave equation for the fundamental mode field of a practical profile, but this equation can of course always be solved numerically. However, a simple but approximate analytical representation for this field can be derived by examining the intensity distribution of the fundamental mode in figure A1.5.18. At a sufficiently large normalized radial distance R from the fibre axis, the asymptotic form of the square of the modified Bessel function $K_0(WR)$ intensity decreases approximately exponentially as $\exp(-2WR)$, where W is the cladding mode parameter. Furthermore, the intensity also exhibits an approximately parabolic variation with R around its maximum on the fibre axis. This is evident for a general index profile by examining a power series solution of equation A1.5.51, and in the case of the step-profile fibre the analytical dependence of the square of the core field on $J_0(UR)$ in equation A1.5.53 exhibits this property for small values of the argument of the Bessel function.

A standard mathematical function that reflects these attributes and is algebraically tractable for integration in particular is the *Gaussian function*. It is used as an approximate representation of the fundamental mode field according to

$$\Psi(R) = A\exp\left(\frac{1}{2}\frac{r^2}{s^2}\right) = A\exp\left(\frac{1}{2}\frac{R^2}{S^2}\right) \tag{A1.5.61}$$

where A is an arbitrary constant, s is the spot size and $S = s/\rho$ is the normalized spot size. The factor of 1/2 is purely for convenience in subsequent algebraic manipulations. This function has an approximately parabolic variation in the neighbourhood of the fibre axis. In the far field at $R \gg 1$, the function has an exponential decrease that varies as R^2 rather than linearly but since the fraction of the modal power in this region is small, the additional error will be small.

The normalized spot size S is determined from the fibre profile, using standard variational methods to derive the following implicit equation (see section 15.1 of Ref. [4])

$$\frac{1}{V^2} = \int_0^\infty R^2\frac{\mathrm{d}f(R)}{\mathrm{d}R}\exp\left(-\frac{R^2}{S^2}\right)\mathrm{d}R; \quad n^2(R) = n_{\mathrm{co}}^2\{1 - 2\Delta f(r)\} \tag{A1.5.62}$$

where $f(R)$ describes the profile variation, V is the fibre parameter and Δ the relative index difference. For the step profile and the Gaussian profile with $f(R) = 1 - \exp(-R^2)$ over $0 < R < \infty$, this leads respectively to

$$S = \frac{1}{2\ln V^{1/2}}; \quad S = \frac{1}{(V-1)^{1/2}} \tag{A1.5.63}$$

with the limitation that $V > 0$ for the former and $V > 1$ for the latter. These expressions can then be used to generate analytical expressions for other modal properties of interest.

A1.5.4.8 Depressed-cladding and W-fibres, fundamental mode cut-off

The fibres and waveguides studied so far have a uniform cladding index and a core refractive index profile that is either uniform or graded but has a minimum index equal to or greater than the cladding. This type of profile is known as a *matched-cladding* profile.

Depressed-cladding fibres

By contrast, a *depressed-cladding* fibre has a depressed ring-shaped region between the core and cladding that is relatively wide compared to the core radius, as shown by the left-hand profile in figure A1.5.19. The term arises from the index miss-match that occurs between the deposited silica and the silica of the

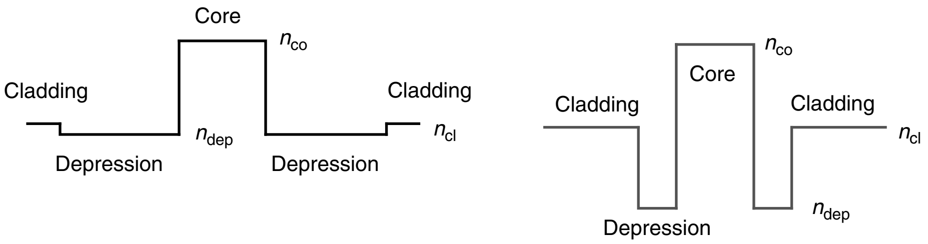

Figure A1.5.19. Schematics for depressed-cladding and W profiles.

starting preform tube used in the fibre fabrication process. The depressed ring has a slightly lower index n_{dep} compared with that of the cladding.

W-fibres

A second type of fibre with a depressed region is known as a *W-fibre*. It is characterized by a depression that is relatively narrow compared to the core radius, but has a much lower index n_{dep} compared with that of the depressed-cladding fibre, as indicated by the right-hand profile in figure A1.5.19. W-fibres were originally developed as they offer better dispersion characteristics than a matched-cladding fibre, in keeping with the discussion of pulse dispersion and multi-layered fibres for dispersion flattening in Section A1.5.6.4.

Fundamental mode cut-off

W-fibres and depressed-cladding fibres are normally designed to be single mode relative to the core–cladding index difference for a particular wavelength. Thus, they can support only the fundamental bound mode with an effective index value n_{eff} such that $n_{\mathrm{cl}} < n_{\mathrm{eff}} < n_{\mathrm{co}}$. On matched-cladding fibres the fundamental mode does not have a finite cut-off wavelength below which it cannot propagate as a bound mode, whereas on depressed-cladding and W-fibres the fundamental mode may have a finite cut-off wavelength depending on the width and depth of the depressed region.

There is a simple algebraic condition that determines whether or not the fundamental mode has a finite cut-off wavelength on a depressed-cladding or W-fibre. This condition may be expressed in terms of the following integrals for circular fibres and slab waveguides, respectively

$$I = \int_0^{\infty} \left\{ n^2(r) - n_{\mathrm{cl}}^2 \right\} r \, \mathrm{d}r; \quad I = \int_{-\infty}^{\infty} \left\{ n^2(x) - n_{\mathrm{cl}}^2 \right\} \mathrm{d}x \tag{A1.5.64}$$

where n is the complete refractive index profile and n_{cl} is the uniform cladding index. If $I > 0$, the fundamental mode does not have a finite cut-off wavelength, but if $I < 0$, there is a finite cut-off wavelength. Note that this condition does not determine the value of the cut-off wavelength; this needs to be evaluated from the appropriate eigenvalue equation by setting $\beta = kn_{\mathrm{cl}}$ and determining the corresponding wavelength. This result has obvious applications in the design of fibres.

A1.5.5 Ray tracing

The propagation of guided light along any fibre or waveguide is governed by Maxwell's equations and can be formally analysed exactly in terms of a superposition of bound modes as described in Sections A1.5.3 and A1.5.4. However, when there are a large number of modes present, as occurs in multimode waveguides and fibres, there is an alternative and accurate approach to the analysis of propagation using *ray tracing*.

Ray tracing is based on the zero-wavelength limit of Maxwell's equations and assumes: that (a) propagation is governed only by the local value of the refractive index and its variation within the core and (b) it provides a continuum solution as opposed to a summed discretized modal solution.

For real sources, the wavelengths used in optoelectronics are relatively small but non-zero, and where there are many modes present, the modal superposition and ray solutions are almost equivalent, the relative error decreasing with increasing values of V. For these situations, rays can be regarded as local plane waves. One advantage of ray tracing is that in some situations it provides a more physical description and interpretation of propagation compared to a summed modal analysis.

A1.5.5.1 Snell's laws

For refractive index distributions that are piece-wise continuous, propagation in the uniform media away from interfaces is described by straight-line ray trajectories equivalent to plane-wave propagation. At interfaces between regions of uniform but different indices, the transmission, reflection and refraction of incident rays is described by *Snell's laws*.

Consider the planar interface shown in figure A1.5.20 between uniform media of refractive indices n_{co} and n_{cl} where $n_{\mathrm{co}} > n_{\mathrm{cl}}$. A ray is incident in the medium of index n_{co} at angle θ_z relative to the interface. If $\theta_z > \theta_{\mathrm{c}}$ where θ_{c} is the *complementary critical angle* relative to the interface (rather than the normal) and is defined by

$$\sin(\theta_{\mathrm{c}}) = \left(1 - \frac{n_{\mathrm{cl}}^2}{n_{\mathrm{co}}^2}\right)^{1/2}; \quad \cos(\theta_{\mathrm{c}}) = \frac{n_{\mathrm{cl}}}{n_{\mathrm{co}}} \tag{A1.5.65}$$

then the incident ray is known as a *refracting ray* and is both reflected and refracted as shown in figure A1.5.20(*a*). The angle of reflection is equal to the angle of incidence and the angle of transmission θ_{t} satisfies $n_{\mathrm{co}}\cos\theta_z = n_{\mathrm{cl}}\cos\theta_{\mathrm{t}}$. Since $n_{\mathrm{co}} > n_{\mathrm{cl}}$, the angle of transmission is smaller than the angle of incidence. An important consequence of refraction is that only a fraction of the incident ray power is reflected and the balance is transmitted.

If $\theta_z < \theta_{\mathrm{c}}$ then the incident ray is a *reflecting ray* and is only reflected as shown in figure A1.5.20(*b*), where the angle of reflection is equal to the angle of incidence. In this situation, all the power in the incident ray enters the reflected ray.

In the weak guidance approximation, n_{co} is only slightly larger than n_{cl}, so that the complementary critical angle is relatively small and only rays incident at small angles relative to the interface are totally reflected.

A1.5.5.2 Eikonal equation

In graded media where the refractive index varies continuously with position, the ray paths are no longer straight lines and a generalized form of Snell's laws is required to determine the curved ray trajectories. Inasmuch that Snell's laws can be derived using plane-wave incidence, reflection and transmission across the interface in figure A1.5.20, the governing *eikonal equation* for curved ray paths can be derived from Maxwell's equations for a graded index distribution in the limit of zero wavelength [9]. In equation (A1.5.66) the first expression gives this equation in general three-dimensional form where $\boldsymbol{r}(x, y, z)$ is the position vector, $n(\boldsymbol{r})$ is the refractive index distribution and s is the distance along the curved path of the ray. The second and third expressions apply to a slab waveguide with a transverse variation of index $n(x)$.

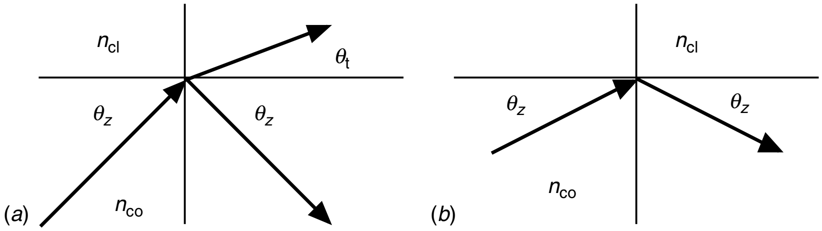

Figure A1.5.20. Snell's laws at the core–cladding interface.

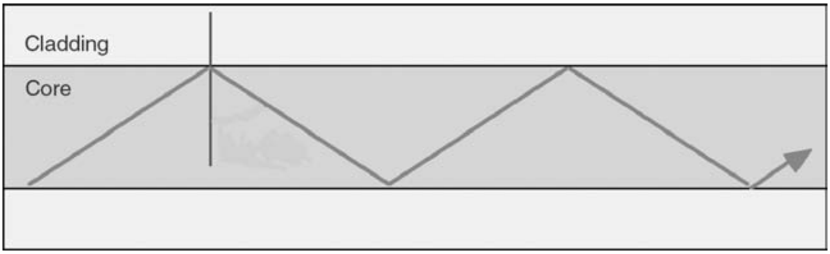

Figure A1.5.21. Zig-zag bound ray paths on a step-profile slab waveguide.

$$\frac{\mathrm{d}}{\mathrm{d}s}\{n(r)\}\frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}s} = \nabla n(r); \quad \frac{\mathrm{d}}{\mathrm{d}s}\{n(x)\}\frac{\mathrm{d}x}{\mathrm{d}s} = \frac{\mathrm{d}n(x)}{\mathrm{d}s}; \quad \frac{\mathrm{d}}{\mathrm{d}s}\{n(x)\}\frac{\mathrm{d}z}{\mathrm{d}s} = 0 \qquad \text{(A1.5.66)}$$

Similar forms apply to circular fibres.

A1.5.5.3 Step-profile multimode slab waveguide

Assuming a symmetric, step-profile slab waveguide with a core of uniform refractive index n_{co} surrounded on either side by a cladding of uniform but lower index n_{cl}, there are two types of ray paths that can propagate along the waveguide.

Bound ray paths

These are zig-zag, straight-line paths that Snell's laws predict are totally reflected from alternate core–cladding interfaces (figure A1.5.21) at a constant angle θ_z relative to the z-direction provided that this angle is smaller than the complementary critical angle, i.e. $\theta_z < \theta_{\mathrm{c}}$. If the waveguide materials are lossless, bound rays can propagate indefinitely along the straight waveguide and hence the total power carried by all bound rays must remain constant everywhere along the length of the waveguide.

Refracting ray paths

These are zig-zag, straight-line paths that are both reflected and refracted at successive core–cladding interfaces (figure A1.5.22) and make a constant angle θ_z relative to the z-direction, such that $\theta_z > \theta_{\mathrm{c}}$. However, the effect of refraction is to remove a constant fraction of power from the ray propagating within the waveguide at each reflection, which is equivalent to an approximately exponential decrease in power with distance z along the waveguide. Accordingly, refracted rays can be referred to as *leaky rays* as their power decreases along the length of the waveguide, i.e. they are attenuated.

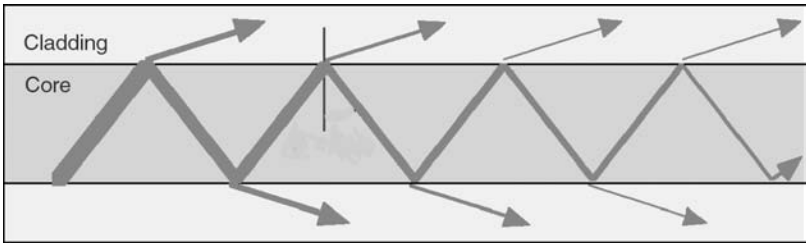

Figure A1.5.22. Zig-zag refracting ray paths on a step-profile slab waveguide.

Refracting rays with a propagation angle θ_z that is not too close to the complementary critical angle generally attenuate very quickly. This means that after a short distance along the waveguide, virtually all their power is lost to the cladding. Rays with θ_z close to the complementary critical angle attenuate more slowly and persist farther along the waveguide. After a sufficient distance essentially only the power in bound rays remains.

A1.5.5.4 Graded-profile multimode slab waveguide

Given a particular graded-index profile, the ray paths along a slab waveguide are determined from the solution of the two-dimensional form of the eikonal equation (A1.5.66). In regions where the index is decreasing away from the index, ray paths propagating away from the waveguide axis curve back towards the waveguide axis and conversely ray paths propagating towards the axis curve away from the axis. Put together, this means that bound rays follow a quasi-sinusoidal path that is periodic along the waveguide.

The distance over which the path repeats itself is known as the *ray period*, and the extremity of each path touches a line on either side of the axis, known as the *ray caustic*. This caustic and its counterpart on the opposite side of the waveguide z-axis constitute the bounding domain for all ray paths with the same angle relative to the z-axis regardless of the longitudinal starting position. In general, the ray period will vary with the angle that the ray path makes with the waveguide axis. However, there is a profile for which all ray directions have exactly the same ray period.

Hyperbolic secant profile

The hyperbolic secant profile is symmetric about the waveguide axis and is defined by

$$n^2(x) = n_{\mathrm{co}}^2 \sec^2(\kappa x) \tag{A1.5.67}$$

where x is the transverse coordinate, n_{co} is the maximum index on the waveguide axis and κ is a scaling constant. The two-dimensional eikonal equations (A1.5.66) can be solved analytically for this profile and confirm that every ray path has the *same ray period* z_{p} regardless of the angle it makes with the z-axis where $z_{\mathrm{p}} = \pi/\kappa$ (figure A1.5.23). Such a waveguide is sometimes referred to as a GRIN (for gradient-index) waveguide.

These waveguides also have the property that the ray half-period $z_{\mathrm{p}} = \pi/\kappa$ is independent of wavelength. Furthermore, the hyperbolic secant profile produces exactly zero inter-modal dispersion in

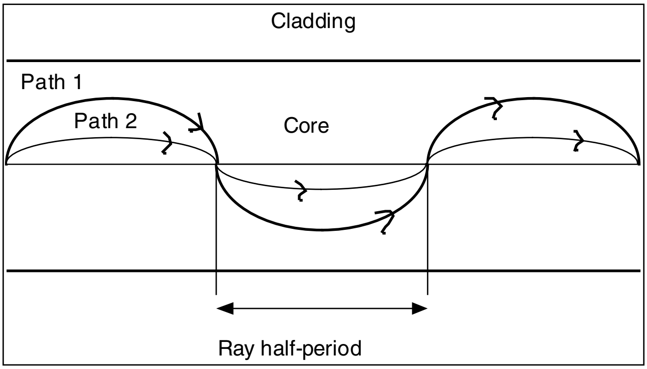

Figure A1.5.23. Bound ray paths with a common ray period on the hyperbolic-profile slab waveguide.

the slab waveguide as discussed in Section A1.5.6.5, so that waveguide and material dispersion may need to be taken into account.

A1.5.5.5 Multimode fibres

Ray tracing in step- and graded-profile multimode fibres comprises a straightforward generalization of the ray path tracing techniques for slab waveguides from two to three dimensions, but the reflection of straight-line core rays from the curved core–cladding interface of a step-profile fibre depends on wavelength. In the limit of zero wavelength, rays are either reflected or reflected/refracted depending on the angle the ray path makes with the tangential plane on the interface, independent of the curvature of the interface. However, if the wavelength is non-zero, a third class of ray paths, known as *tunnelling rays*, appears.

Tunnelling rays

If a ray, or local plane wave with a small but finite wavelength, is incident on the curved interface between the core and cladding of a step-profile fibre, it will be refracted if the angle of incidence α_i it makes relative to the normal at the reflection point is less than the classical critical angle, i.e. $\alpha_\mathrm{i} < \sin^{-1}(n_\mathrm{cl}/n_\mathrm{co})$. For $\alpha_\mathrm{i} < \sin^{-1}(n_\mathrm{cl}/n_\mathrm{co})$ there are two possible classifications of rays, depending on the angle the ray direction makes with the z-axis of the fibre, i.e. θ_z. If $\theta_z < \theta_\mathrm{c}$ where θ_c is the complementary critical angle, then the ray is totally internally reflected, but if $\theta_z < \theta_\mathrm{c}$ such that $\alpha_\mathrm{i} < \sin^{-1}(n_\mathrm{cl}/n_\mathrm{co})$ then the ray is partially reflected and transmitted and is known as a *tunnelling ray*. Accordingly, refracting and tunnelling rays are commonly referred to as *leaky rays*, since they lose power at each reflection when propagating along the core of the fibre.

The delineation between the three classes of ray is depicted in figure A1.5.24, where the dark half-cone denotes refracting rays, the light half-cone denotes reflecting rays and the two regions between them denote tunnelling rays. The left-hand curved surface denotes the core–cladding interface.

Tunnelling rays are partially reflected from the interface such that the angles of incidence and reflection are equal and the transmitted part reappears at a finite distance into the cladding (see chapter 7 of Ref. [4]). These rays are the analogue of leaky modes that have an evanescent field between the

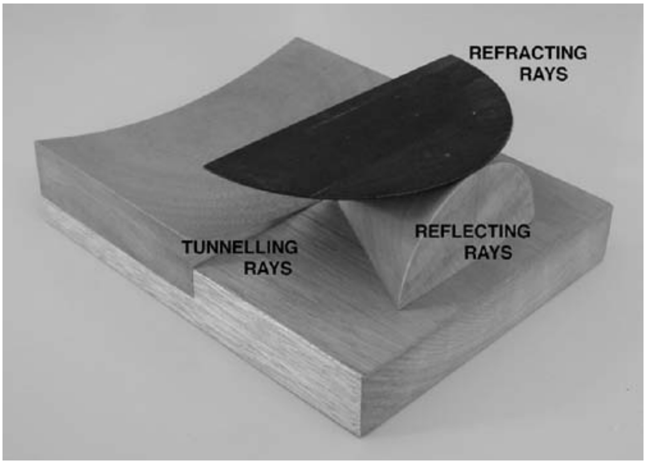

Figure A1.5.24. Representation of the three types of ray incident at a point on the curved core–cladding interface of a step-profile fibre.

core–cladding interface and the position at which the field-radiating field becomes oscillatory (see section 36.11 of Ref. [4]).

Step-profile fibre

The zig-zag ray paths of the slab waveguide become the *meridional rays* of the circular fibre and lie in planes that intersect the axis of the fibre. There is a second class of rays that follows helical-like zig-zag paths around the fibre axis without intersecting it and are know as *skew rays*. A characteristic of skew rays on the step-profile fibre is that there is an inner cylindrical surface, known as the *inner caustic*, that every straight-line segment of the ray touches periodically along its path. The radius of this caustic varies with the skewness of the ray path. The characteristic dimensions of all these ray paths can be readily quantified using simple geometry (see chapter 2 of Ref. [4]).

Graded-profile fibre

The sinusoidal-like ray paths of the graded-profile slab waveguide become the *meridional rays* of the graded-index fibre, lie in planes that intersect the axis of the fibre and are bounded by the *ray caustic*. All other rays follow continuous skew paths that have a helical-like shape, each ray path being bounded between the *outer* and *inner ray caustics* (see chapter 2 of Ref. [4]). The characteristics of each path are determined from the three-dimensional eikonal equation in cylindrical polar coordinates.

Unlike the hyperbolic-profile slab waveguide, there is no known refractive index profile that produces exactly zero dispersion in a multimode fibre for all bound ray directions. An approximately parabolic index profile fibre comes close to satisfying this goal and is known as a graded-index or GRIN fibre.

A1.5.5.6 Numerical aperture

Ray tracing provides a physical explanation for the numerical aperture (NA) of a fibre as defined by equation (A1.5.16). Using ray tracing, consider a ray from a source incident in air on the end face of a step-profile fibre at angle θ_α, as shown in figure A1.5.25. Snell's laws give

$$\sin(\theta_\alpha) = n_{\mathrm{co}} \sin(\theta_z) \tag{A1.5.68}$$

for the angle θ_z the transmitted ray makes with the fibre z-axis. Recalling that the largest angle a bound ray can subtend relative to the axis is the complementary critical angle, then the maximum angle of

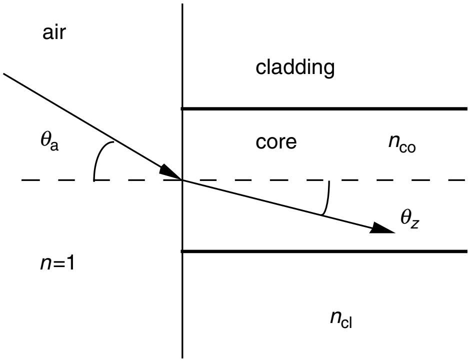

Figure A1.5.25. Ray paths refracting from air into the core of a fibre.

incidence in air for confinement within the core, θ_{max}, is given by equation (A1.5.68) with $\theta_z = \theta_c$. Recalling the definition of NA from equation (A1.5.16), this gives

$$\sin(\theta_{\text{max}}) = n_{\text{co}} \sin(\theta_c) = \text{NA} \tag{A1.5.69}$$

Assuming that NA is small, then $\theta_{\text{max}} \sim$ NA radians.

When applied to multimode fibres, this result shows that the maximum power input into bound rays (or modes) occurs when the NA is filled in a cone of angles in the range $0 < \theta_\alpha < \theta_{\text{max}}$ at every position on the end face of the core. For single-mode fibres, a ray analysis is not accurate but, nevertheless, this result suggests that filling the NA of the fibre over the core cross-section should help maximize bound mode power.

A1.5.6 Pulse dispersion

A1.5.6.1 Pulse propagation

Encoded binary information is transmitted along fibres as a sequence of discrete light pulses, normally generated by a semiconductor laser and received by a semiconductor detector at the far end of the system. Each pulse is generated by modulating the light output from the laser source, or by modulating the input into the laser itself. The bandwidth of the fibre corresponds to the number of pulses, or bits, per second, e.g. a 10 Gigabit s^{-1} bandwidth corresponds to 10^9 bits of information or pulses per second.

Dispersion is the phenomenon whereby each pulse changes its shape and effective length due to the physical properties of both the source and the fibre. As each pulse propagates along the fibre, the pulse power spreads out due to the dispersion of the fibre and its constituent materials and is also attenuated because of the losses from the fibre materials due to absorption and scattering. At the low light powers considered here (of the order of milliwatts), non-linear material effects can be neglected, i.e. dispersion caused by the effect of intense light on the fibre material, which changes the refractive index value.

The maximum distance a train of pulses can propagate data is limited because (a) the pulse spread may result in an overlap with the preceding or following pulses, so that a pulse is not unambiguously detected at the end of the fibre, leading to an error and (b) attenuation due to fibre loss is so large that a pulse has insufficient power to be detected at the end of the fibre.

The material presented here provides a background to Part C1 of this book.

Source wavelength variation

Dispersion arises because the laser source is not purely monochromatic or single wavelength; it has a finite, but small, spectral width (the variation of output power intensity with wavelength) as measured by the full width at half maximum (FWHM; figure A1.5.26). A typical laser has a spectral width that is less than one nanometre (10^{-9} metres).

To provide a qualitative description of the effect of dispersion, consider a square pulse excited by the source of excitation that has just two monochromatic wavelengths λ_1 and λ_2 (figure A1.5.27). At the beginning of the fibre, the pulses coincide. Light at the two wavelengths travels at slightly different speeds (group velocity) along the fibre, such that the pulse components at wavelengths λ_1 and λ_2 also have different speeds and thus the pulse spreads out with distance (or time). The total power in the two pulses is conserved in the absence of scattering or absorption by the fibre and the initial pulse shape becomes elongated and flattened.

To quantify the effects of dispersion on a pulse, the modal phase velocity, group velocity and group velocity dispersion need to be defined and quantified.

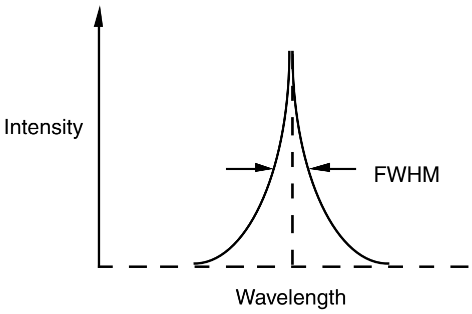

Figure A1.5.26. Schematic of laser output showing intensity variation with wavelength.

A1.5.6.2 Modal phase and group velocities

Modal phase velocity

Recall that the complete spatial and temporal dependence of the scalar fundamental mode field in the weak guidance approximation for a monochromatic source has the form

$$E(x, y, z, t) = \psi(x, y)\mathrm{e}^{\mathrm{i}(\beta z - \omega t)} \tag{A1.5.70}$$

where ω is the source frequency, related to the source (free-space) wavelength λ by $\omega = 2\pi c/\lambda$ and c is the speed of light in free space (*in vacuo*). The modal *phase velocity*, ν_{ph} is the speed with which the planar phase front of a mode in the fibre cross-section propagates along the waveguide and is expressed as

$$\nu_{\mathrm{ph}} = \frac{\omega}{\beta} = \frac{2\pi c}{\lambda\beta} = \frac{c}{n_{\mathrm{eff}}} \tag{A1.5.71}$$

where n_{eff} is the effective refractive index. The modal phase velocity is equal to the phase velocity of an infinite plane wave propagating in a uniform medium of index n_{eff}. Since the modal propagation constant β, or, equivalently, the effective index n_{eff}, depends on the source wavelength λ (or colour) through the eigenvalue equation for the fibre, the phase velocity is also wavelength dependent, i.e. $\nu_{\mathrm{ph}} = \nu_{\mathrm{ph}}(\lambda)$.

Group velocity

The speed with which the power in a pulse propagates along the fibre is given by the *group velocity*, ν_{g}, and *not* by the phase velocity. Modal group velocity is defined by the differential

$$\nu_{\mathrm{g}} = \frac{\mathrm{d}\omega}{\mathrm{d}\beta} \tag{A1.5.72}$$

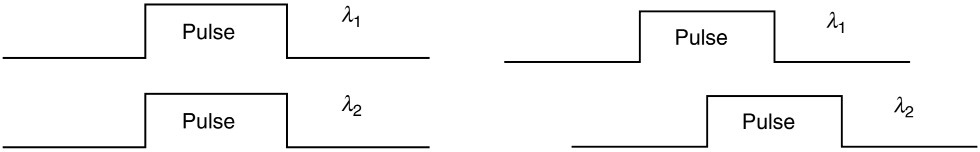

Figure A1.5.27. Pulse spread due to source spectral width.

In terms of the source wavelength λ, this definition is equivalent to

$$\nu_g = \frac{d\omega}{d\beta} = \frac{d\lambda}{d\beta}\frac{d\omega}{d\lambda} = \frac{d\lambda}{d\beta}\frac{d}{d\lambda}\left(\frac{2\pi c}{\lambda}\right) = -\frac{2\pi c}{\lambda^2}\frac{d\lambda}{d\beta} \tag{A1.5.73}$$

Setting $\beta = kn_{\text{eff}} = 2\pi n_{\text{eff}}/\lambda$ and differentiating this expression with respect to wavelength

$$\frac{d\beta}{d\lambda} = \frac{2\pi}{\lambda}\frac{dn_{\text{eff}}}{d\lambda} - \frac{2\pi n_{\text{eff}}}{\lambda^2} \tag{A1.5.74}$$

Substitution into equation (A1.5.73) leads to the expression for the modal group velocity in terms of effective index

$$\nu_g = \frac{c}{n_{\text{eff}} - \lambda\dfrac{dn_{\text{eff}}}{d\lambda}} \tag{A1.5.75}$$

The second term in the denominator accounts for the waveguide dispersion due to the finite spectral width of the source. If this term were not present then the group and phase velocities would be equal, which is the case for an infinite plane wave propagating in a uniform medium of index n_{eff}. Since β, or n_{eff}, depends on the source wavelength λ through the waveguide eigenvalue equation, the group velocity is wavelength-dependent, i.e. $\nu_g = \nu_g(\lambda)$. As the group velocity depends on the solution of the eigenvalue equation, its value is determined numerically for a general fibre profile.

A1.5.6.3 Transit time and pulse spread

If the group velocity at the central wavelength λ_c of the source of excitation is denoted by $\nu_g(\lambda_c)$, then the *transit time t* of the centre of the pulse over length L of fibre is given by

$$t = \frac{L}{\nu_g(\lambda_c)} \tag{A1.5.76}$$

In terms of the effective index n_{eff}, it is straightforward to show from equation (A1.5.75) that this expression is equivalent to

$$t = \frac{Ln_{\text{eff}}}{c} - \frac{L}{c}\lambda\frac{dn_{\text{eff}}}{d\lambda} \tag{A1.5.77}$$

where the first term on the right is the transit time for a pulse propagating the distance L in a medium of uniform index n_{eff}, and the second term accounts for the dispersion caused by the waveguide.

Group velocity dispersion

Now consider a light pulse with an initial time width τ that is excited at the beginning of the fibre. The temporal spread $\delta\tau$ in t after propagating distance L along the waveguide is due to the source spectral width $\delta\omega_s$ (in frequency units) and the corresponding spread $\delta\nu_g$ in the range of values about the mean value of the group velocity. This spread is sometimes referred to as *group velocity dispersion*. The expression for $\delta\tau$ is obtained by differentiating the transit time expression for t given above. Thus

$$\delta\tau = \frac{dt}{d\omega}\delta\omega = -\frac{L}{\nu_g^2}\frac{d\nu_g}{d\omega}\delta\omega_s = L\frac{d^2\beta}{d\omega^2}\delta\omega_s \tag{A1.5.78}$$

where the final expression on the right follows from the definition of the modal group velocity given in equation (A1.5.72).

In terms of the equivalent spectral width $\delta\lambda_s$ (in wavelength units) of the source, the above expression can be recast as

$$\delta\tau = \frac{dt}{d\lambda}\delta\lambda = -\frac{L}{\nu_g^2}\frac{d\nu_g}{d\lambda}\delta\lambda_s \tag{A1.5.79}$$

If ν_g is expressed in terms of the effective index n_{eff} of the mode using equation (A1.5.75), it is straightforward to show that

$$\delta\tau = -\frac{L\lambda}{c}\frac{d^2 n_{\mathrm{eff}}}{d\lambda^2}\delta\lambda \tag{A1.5.80}$$

If there is no net dispersion, i.e. n_{eff} is either independent of λ or varies linearly with λ, then there is no pulse dispersion.

A1.5.6.4 Sources of dispersion

When an optical pulse propagates along a practical fibre with an arbitrary index profile and cross-sectional geometry, the *total pulse dispersion* can be a combination of several different contributing effects (figure A1.5.28).

Inter-modal dispersion

This form of dispersion occurs when two or more different modes propagate simultaneously and arises because each mode has a different group velocity for the same wavelength. This phenomenon occurs regardless of the spectral width of the source. Inter-modal dispersion is the major contribution to dispersion in multimode fibres, but can be minimized using multimode fibres with a graded-index fibre as discussed in Section A1.5.5.5.

Material dispersion

In any optical material, the refractive index of the bulk material varies slightly with wavelength, i.e. $n = n(\lambda)$, in addition to any spatial variation. For example, the refractive index of the pure silica

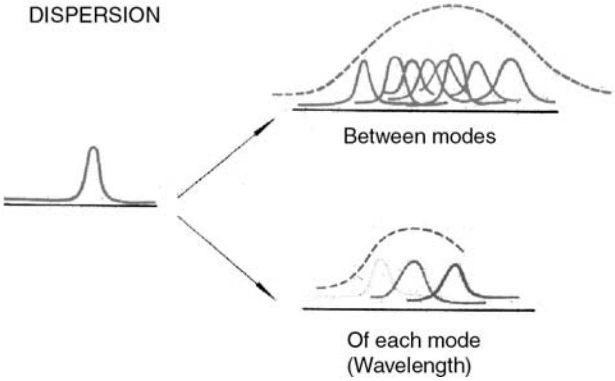

Figure A1.5.28. Dispersion includes inter-modal dispersion between different modes and the dispersion of individual modes.

cladding of a fibre decreases from 1.458 at 633 nm (wavelength of a HeNe laser) to 1.447 at 1300 nm and to 1.444 at 1550 nm. The same relative decrease in index is normally assumed for the lightly doped core material of the fibre.

Waveguide or fibre dispersion

This form of dispersion occurs in each and every mode of a fibre because of the wavelength dependence of the modal group velocity and the slight spectral width of the source. The combined effects of material and waveguide dispersion are sometimes termed *chromatic dispersion*.

Polarization-mode dispersion

In a non-circular single-mode fibre, such as a weakly guiding elliptical fibre, the two polarizations of the fundamental mode are parallel to the major and minor axes and generally have distinctly different propagation constants. Dispersion is then dominated by the inter-modal dispersion between these two polarizations. In a perfectly circular single-mode fibre, the fundamental-mode propagation constant is independent of its polarization state. Further the polarization of the mode does not change as it propagates along the fibre as long as it remains translationally invariant along its entire length.

Practical telecommunications-grade single-mode fibres are neither perfectly circular nor perfectly concentric, i.e. there are very slight non-uniformities that occur along their entire length. These non-uniformities have the effect of introducing random coupling between the two polarization states and, as a result, the accumulated group delay in each state can differ and therefore cause an overall dispersion known as *polarization-mode dispersion*. The delay difference cannot be predicted theoretically and has to be measured. In practice it is offset actively. This type of dispersion is only significant in very long single-mode fibre transmission systems over thousnds of kilometres, i.e. to submarine systems, as terrestrial systems are generally, at most, a few hundreds of kilometres long.

A1.5.6.5 Zero-dispersion, dispersion-shifted, -flattened and -compensating fibres

Zero-dispersion fibre

In principle, inter-modal dispersion can be avoided altogether if only single-mode fibres are employed. This arrangement only became a practical proposition with the development of techniques for producing low-loss single-mode fibres in the 1970s. It was then possible to design a single-mode fibre so that the combination of the fibre dispersion together with the material dispersion is zero at just one wavelength. This is a complex design procedure, as fibre and material dispersion interact with one another, i.e. they cannot be calculated separately and then simply added together. The first such designs provided a *zero-dispersion* fibre at the first fibre transmission loss minimum of 1300 nm, as shown in the left plot of figure A1.5.29.

Dispersion-shifted fibres

With the introduction of optical transmission systems operating close to the absolute minimum of silica fibre transmission loss around 1550 nm, a single-mode fibre with zero dispersion at this wavelength was required. As material dispersion is essentially fixed, an approximately triangular-shaped profile was developed to meet this need, as shown in the right plot of figure A1.5.29. Such fibres are known as *dispersion-shifted* fibres. By judicious profile design it is also possible to produce fibres that are wavelength flattened, i.e. have close to zero dispersion over the entire wavelength range of 1300–1550 nm.

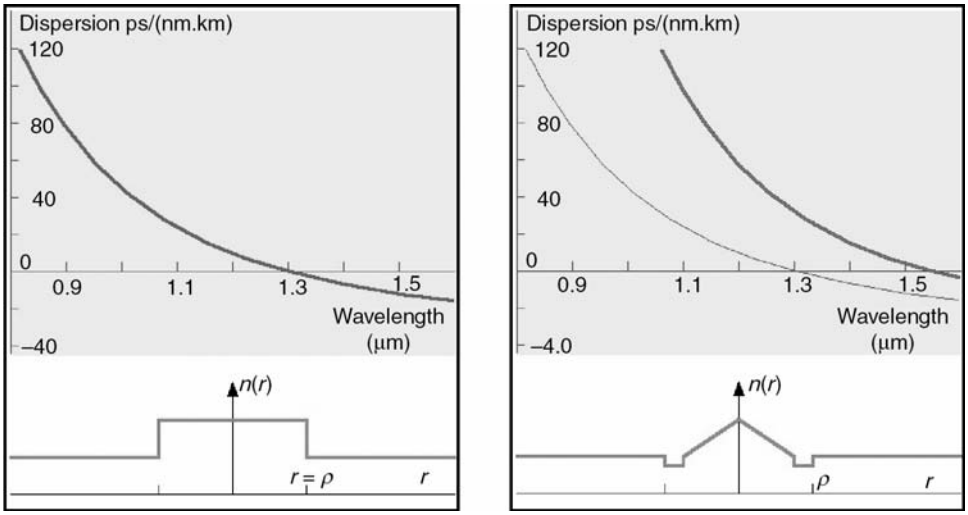

Figure A1.5.29. Plots of total dispersion against wavelength for standard fibre (left) and dispersion-shifted fibre (right).

Dispersion-compensating fibres

At the opposite extreme by combining the effects of fibre and material dispersion in such a way to enhance dispersion, single-mode fibres can be produced that have a very high and negative dispersion, of the order of $-200\,\text{ps}\,\text{nm}^{-1}\,\text{km}^{-1}$. Such fibres have application, for example, in 1300 nm transmission systems that are operated at 1550 nm to take advantage of erbium-doped optical amplifiers (EDFA). The fibres in these systems have zero dispersion at 1300 nm but a dispersion of about $20\,\text{ps}\,\text{nm}^{-1}\,\text{km}^{-1}$ when operated at 1550 nm. By inserting lengths of the large negative dispersion fibre equal to 10% of the length of the 1300 nm fibre between repeaters, the introduced dispersion can be completely offset.

A1.5.6.6 Dispersion in multimode waveguides and fibres

By definition, multimode waveguides and fibres support a large number of bound modes with propagation constants that take on almost a continuum of values in the range $kn_{\text{cl}} < \beta < kn_{\text{co}}$, where n_{cl} is the uniform cladding index and n_{co} is the maximum core index. Accordingly, pulse dispersion is strongly influenced by inter-modal dispersion but is insensitive to source wavelength. There was a flurry of research into minimizing dispersion in multimode fibres in the early 1970s prior to the development of techniques for fabricating low-loss single-mode fibres.

Step-profile multimode slab waveguide

A simple analytical example of inter-modal dispersion is provided by the step-profile slab waveguide. Consider excitation of the waveguide shown in figure A1.5.30. Assuming an incoherent source, such as a light emitting diode (LED), all bound modes are excited approximately equally, which is well modelled by assuming that all bound ray directions are equally excited within the core. As shown in Section A1.5.5.3, the range of bound ray directions for the step profile satisfies $0 < \beta_z < \beta_c$, where β_z is the angle with the z-axis.

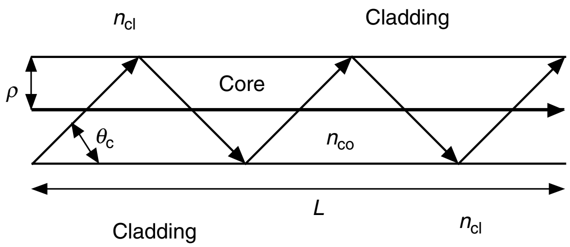

Figure A1.5.30. Bound ray path on a step-index slab waveguide.

As light propagates as a local plane wave, its phase and group velocities in the core are equal, i.e. $\nu_{ph} = \nu_g = c/n_{co}$. Accordingly, the accumulated dispersion, δt, over length L of the waveguide is given by the difference in transit times of the slowest ($\theta_z = \theta_c$) and fastest ($\theta_z = 0$) rays, which leads to

$$\delta t = \frac{Ln_{co}^2}{cn_{cl}} - \frac{Ln_{co}}{c} = \frac{L}{c}\frac{\mathrm{NA}^2}{n_{cl}} \tag{A1.5.81}$$

where NA is the numerical aperture. Note that this expression is independent of the core width. Thus, for example, for a waveguide with an NA $= 0.1$ and $n_{cl} = 1.45$, the dispersion is $23\,\mathrm{ns\,km^{-1}}$.

Zero inter-modal dispersion multimode slab waveguide

Inter-modal dispersion in slab waveguides can be totally suppressed through a judicious choice of the refractive index profile, as discussed in Section A1.5.5.4. There is a unique profile, the *hyperbolic secant* profile of equation (A1.5.67) for which the transit time for all off-axis ray paths is equal to the on-axis transit time. Note that if inter-modal dispersion is totally suppressed, both waveguide and material dispersion are still present.

Minimizing inter-modal dispersion in multimode fibres

Using ray tracing, inter-modal dispersion in circular fibres can be readily determined, by analogy, with the above analysis for the slab waveguide. Like the step-profile slab waveguide, inter-modal dispersion in a multimode step-profile fibre is relatively large. However, unlike the hyperbolic secant slab waveguide, there is no known profile for the fibre that leads to exactly zero inter-modal dispersion when all ray directions, both meridional and skew, are excited.

Nevertheless, it is possible to minimize inter-modal dispersion using a core profile that is approximately parabolic, as might be anticipated from the approximately parabolic variation of the hyperbolic secant profile. The term *graded-index fibre* is often used to denote a multimode fibre with this core profile surrounded by the normal uniform cladding. However, the bandwidth of a single-mode fibre is still significantly larger than that of a graded-index fibre.

A1.5.7 Bend loss

A mode propagating on a straight fibre or waveguide fabricated from non-absorbing, non-scattering materials will in principle propagate indefinitely without any loss of power. However, if a bend is introduced, the translational invariance is broken and power is lost from the mode as it propagates into, along and out of the bend. This applies to the fundamental mode in the case of single-mode fibres and waveguides and to all bound modes in the case of bent multimode fibres or waveguides.

It is conventional to distinguish between the two types of losses that can occur on a bend. *Transition loss* is associated with the abrupt or rapid change in curvature at the beginning and the end of a bend, and *pure bend loss* is associated with the loss from the bend of constant curvature in between.

A1.5.7.1 Transition loss

Consider an abrupt change in the curvature κ from the straight waveguide ($\kappa = 0$) to that of the bent waveguide of constant radius R_b ($\kappa = 1/R_\mathrm{b}$). The fundamental-mode field is shifted slightly outwards in the plane of the bend, thereby causing a miss-match with the field of the straight waveguide. The fractional loss in fundamental-mode power, $\delta P/P$, can be calculated from the overlap integral between the fields. Within the Gaussian approximation to the fundamental mode field and assuming that the spot size s and core radius or half-width ρ are approximately equal, this gives

$$\frac{\delta P}{P} \approx \frac{1}{16}\frac{V^4}{\Delta^2}\frac{\rho^2}{R_\mathrm{b}^2} \tag{A1.5.82}$$

where V is the fibre or waveguide parameter and Δ is the relative index difference. For typical values of $V = 2.5$, $\Delta = 0.005$, $\rho = 5\,\mathrm{mm}$ and a bend radius of 5 mm, the transition loss is about 9.8% of fundamental-mode power.

Minimizing transition loss

There are a couple of strategies for significantly reducing transition loss. In the case of planar waveguides it is often possible to fabricate the bend so that there is an abrupt offset between the cores of the straight and bent waveguides in the plane of the bend. In figure A1.5.31 this can be seen as being equivalent to displacing the bent core downwards so that the two fundamental-mode fields overlap. Alternatively, if a gradual increase in curvature is introduced between the straight and uniformly bent sections, the fundamental field of the straight waveguide will evolve approximately adiabatically into the offset field of the uniformly bent section.

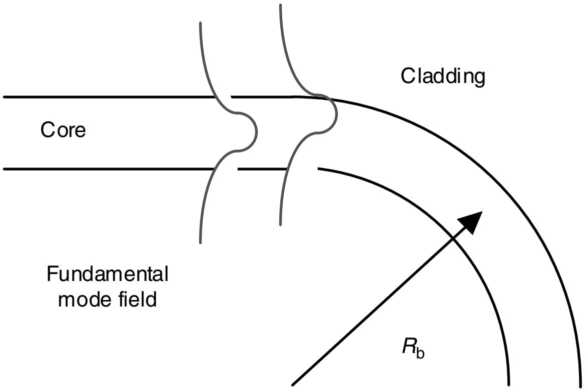

Figure A1.5.31. Outward shift in the fundamental-mode electric field on entering a bend.

A1.5.7.2 Pure bend loss

In following the curved path of the core of constant radius R_b, the fundamental mode continuously loses power to radiation, known as *pure bend loss*. In assuming that the cladding is essentially unbounded, the physical effect is analogous to radiation from a bent antenna in free space. The radiation increases rapidly with decreasing bend radius and occurs predominantly in the plane of the bend; in any other plane the effective bend radius is larger and hence the loss is very much reduced (figure A1.5.32).

The physical basis of bend loss can be interpreted in terms of the motion of the planar phase front of the fundamental mode as it rotates about an axis through the centre of the bend at C with angular velocity Ω. On the straight waveguide, the phase front travels with phase velocity $v_\phi = \omega/\beta$, where ω is the source frequency and β the propagation constant. By matching the phase velocities of the straight and bent waveguides on the fibre axis at the beginning of the bend

$$R_b\Omega = \frac{\omega}{\beta} \Rightarrow \Omega = \frac{\omega}{\beta R_b} = \frac{2\pi c}{\lambda\beta R_b} = \frac{c}{n_{\mathrm{eff}}R_b} \qquad \text{(A1.5.83)}$$

in terms of the source wavelength λ and the fundamental mode effective index n_{eff}. Along the planar phase front through C, the phase velocity increases monotonically with the distance from C, until at a radius R_{rad}, the phase velocity is equal to the speed of light in the cladding, i.e. when

$$\Omega R_{\mathrm{rad}} = \frac{c}{n_{\mathrm{cl}}} \Rightarrow R_{\mathrm{rad}} = \frac{c}{\Omega n_{\mathrm{cl}}} = \frac{n_{\mathrm{eff}}}{n_{\mathrm{cl}}}R_b \qquad \text{(A1.5.84)}$$

Since by definition $n_{\mathrm{eff}} > n_{\mathrm{cl}}$, it follows that $R_{\mathrm{rad}} > R_b$.

Radiation caustic

The phase velocity anywhere on the modal phase front rotating around the bend cannot exceed the speed of light in the cladding. Hence, beyond radius R_{rad} the modal field must necessarily radiate into the cladding, the radiation being emitted tangentially. The interface between the guided portion of the modal field around the bend and the radiated portion at R_{rad} is known as the *radiation caustic*, and is the apparent origin of radiation.

Between the core and the radiation caustic, the modal field is evanescent and decreases approximately exponentially with increasing radial distance from C. As the bend radius increases, the radiation caustic moves farther into the cladding, and the level of radiated power decreases. Conversely,

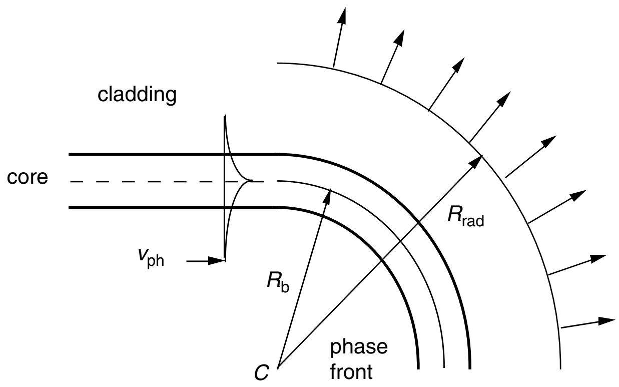

Figure A1.5.32. Rotation of the mode phase front along a bend.

as the bend radius decreases, the radiation caustic moves closer to the core and the radiation loss increases. In practical fibres, the radiated power from the bend is either absorbed by the acrylic coating surrounding the outside of the cladding or propagates through the coating into free space.

Mode attenuation

If z is the distance from the beginning of the bend relative to the fibre axis, then the total fundamental-mode power $P(z)$ attenuates according to

$$P(z) = P(0)\mathrm{e}^{-\gamma z} \tag{A1.5.85}$$

where $P(0)$ is the total fundamental mode power entering the bend and γ is the power attenuation coefficient. In decibels, this relationship is equivalent to

$$\mathrm{dB} = 10\log_{10}\left(\frac{P(z)}{P(0)}\right) = 10\log_{10}(\mathrm{e}^{-\gamma z}) = (20\log_{10}\mathrm{e})\gamma z = 8.686\gamma z \tag{A1.5.86}$$

indicating that the loss of power per unit length of bent fibre is $8.686\gamma\,\mathrm{dB}$.

Step-profile fibre

In terms of the core and cladding modal parameters U and W, respectively, relative index difference Δ, core radius ρ, fibre parameter V and the bend radius R_b, an approximate expression for γ for the fundamental mode of a step-profile fibre has the form (see chapter 23 of Ref. [4])

$$\gamma = \left(\frac{\pi\rho}{R_\mathrm{b}}\right)^{1/2}\frac{V^2W^{1/2}}{2\rho U^2}\exp\left\{-\frac{4}{3}\Delta\frac{R_\mathrm{b}}{\rho}\frac{W^3}{V^2}\right\} \tag{A1.5.87}$$

where R_b is necessarily large compared to ρ because it is not possible to bend a fibre into a radius much below 1 cm without breakage. The pure bend loss coefficient is most sensitive to the expression inside the exponent because $R_\mathrm{b} \gg \rho$. Loss decreases very rapidly with increasing values of R_b or Δ or V (since W also increases with V), and becomes arbitrarily small as $R_\mathrm{b} \to \infty$.

Consider, for example, a standard single-mode fibre such as the Corning SMF28, for which $\Delta = 0.3\%$, $\rho = 4\,\mu\mathrm{m}$, and $\mathrm{NA} = 0.12$. At a wavelength of $1.3\,\mu\mathrm{m}$, the fibre parameter is $V = 2.32$. The eigenvalue equation for the step profile gives $U = 1.66$, $W = 1.62$ and the power attenuation coefficient of equation (A1.5.87) reduces to

$$\gamma = \frac{3.48\times 10^4}{\sqrt{R_\mathrm{b}}}\exp(-0.78R_\mathrm{b}) \tag{A1.5.88}$$

where R_b is in millimetres and γ has units of m^{-1}. Accordingly, the fractional power loss from the fundamental mode due to pure bend loss in a single loop of fibre is expressible as

$$\frac{P(0) - P(2\pi R_\mathrm{b})}{P(0)} = 1 - \exp\left(-\frac{\pi\gamma R_\mathrm{b}}{500}\right) \tag{A1.5.89}$$

where R_b is in millimetres. Thus, if $R_\mathrm{b} = 150\,\mathrm{mm}$ (the radius of the standard drum on which fibre is normally spooled), then $\gamma \sim 10^{47}\,\mathrm{m}^{-1}$ and loss is totally negligible, but if $R_\mathrm{b} = 10\,\mathrm{mm}$, then $\gamma = 4.5\,\mathrm{m}^{-1}$ and the loss is almost 25% in one loop of fibre.

A1.5.7.3 Bend loss in multimode fibres and waveguides

Uniformly bent multimode waveguides lose power because each mode is attenuated as it propagates around the bend. Like the fundamental mode, the power attenuation coefficient for each mode is dominated by the common exponential dependence

$$\exp\left\{-\frac{4}{3}\Delta\frac{R_{\mathrm{b}}}{\rho}\frac{W^3}{V^2}\right\} = \exp\left\{-\frac{4}{3}kR_{\mathrm{b}}\Delta\frac{(n_{\mathrm{eff}}^2 - n_{\mathrm{cl}}^2)^{3/2}}{(n_{\mathrm{co}}^2 - n_{\mathrm{cl}}^2)}\right\} \tag{A1.5.90}$$

where the right-hand expression follows by setting $\beta = kn_{\mathrm{eff}}$ and $V = k\rho(n_{\mathrm{co}}^2 - n_{\mathrm{cl}}^2)^{1/2}$.

Recall that the effective index of every bound mode of the straight fibre mode lies in the range $n_{\mathrm{cl}} < n_{\mathrm{eff}} < n_{\mathrm{co}}$, the lower-order modes having n_{eff} values closer to n_{co} and the higher-order modes having n_{eff} values closer to n_{cl}. It follows from equation (A1.5.90) that the higher-order modes are attenuated much more quickly than the lower-order modes. However, the overall attenuation along the bent multimode waveguide is determined by the attenuation of each mode. Since the equilibrium distribution of power between modes also depends on the slight variations along the waveguide, the overall attenuation around a bend must take account of this distribution. As a result, there is no simple analytical expression for bend loss in multimode waveguides.

Numerical quantification of bend loss for multimode slab waveguides and fibres with step and parabolic profiles have been undertaken using a combination of ray tracing and loss coefficients (figure A1.5.33). The loss coefficients account for bend loss at reflections from the core–cladding interface, in the case of the step profile, and from the outer caustic in the case of the parabolic profile. For the slab waveguide this involves a two-dimensional integration over the core width and the range of ray directions, while the fibre involves a four-dimensional integration of the core cross-sectional area and all meridional and skew ray paths (see chapter 9 of Ref. [4]).

A1.5.8 Excitation, reflection, mismatch, offset and tilt

Waveguides and fibres are illuminated by a variety of sources, including lasers, light emitting diodes or light propagating out of another fibre or waveguide. Because of the relatively small core size of fibres and

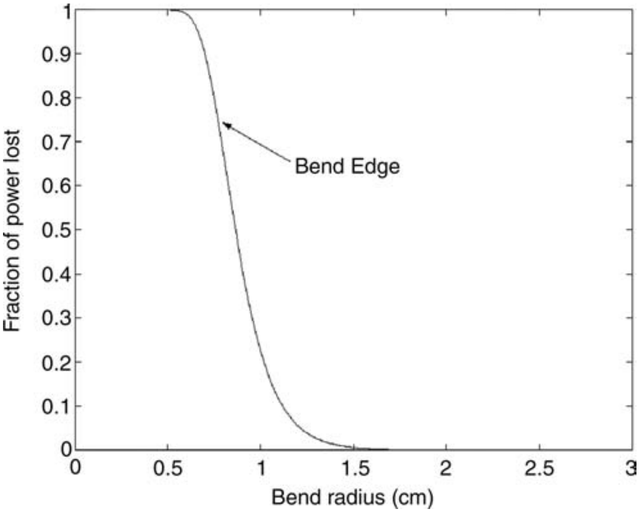

Figure A1.5.33. Bend loss as a function of bend radius.

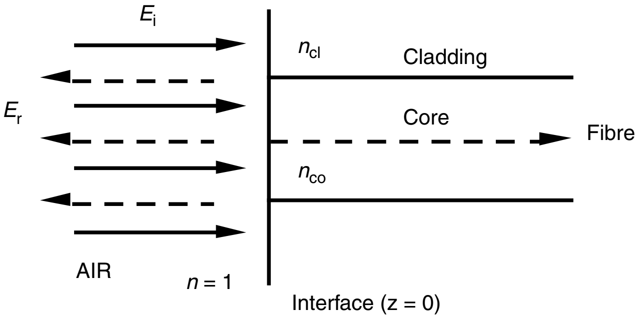

Figure A1.5.34. Reflection of light from the end of a fibre or waveguide.

waveguides, it is necessary to use an intense source to ensure that sufficient light enters the fibre to be detectable at the far end. The goal is normally to maximize the fraction of incident light that can excite the fundamental mode in the case of a single-mode fibre or all the bound modes in the case of a multimode fibre.

However, an analysis of excitation is a complex issue because of (a) reflection from the fibre end face, (b) mismatch between the source and fibre modes, (c) offset between the source and the fibre, and (d) tilt between the source and the fibre. Further, an exact mathematical formulation of the problem, even within the weak guidance approximation, would require an appropriate representation of both the reflected and transmitted bound mode and radiation fields, and the solution of an extremely complex and large matrix of equations. Fortunately for most practical applications, it is not necessary to undertake such an analysis. Here we provide some insight and methodology that provides an accurate quantification of all these effects for most practical applications.

A1.5.8.1 End-face reflection

If a fibre is excited by light propagating in air, the light will be partially reflected because of the difference in indices between air and the fibre material. Consider the simple situation shown in figure A1.5.34 where a plane wave, representing the incident light, impinges normally on the end face of the fibre with a scalar transverse electric field E_i. A fraction of the field is reflected into the backward-propagating field E_r and the balance is transmitted into the fibre or waveguide.

A simple way to estimate the fraction of reflected light is to approximate the fibre or waveguide core–cladding cross-section by a uniform, infinite medium of refractive index approximately equal to the core index n_{co} since the core and cladding indices are similar in the case of weak guidance. For the incident plane wave, Fresnel's laws determine the fraction of reflected light power according to

$$\left(\frac{n_{co} - 1}{n_{co} + 1}\right)^2 \qquad \text{(A1.5.91)}$$

For a typical fibre core with index $n_{co} = 1.46$, this formula gives around 3.5% for the fraction of incident power reflected. It should also be noted that the same fraction of light will be reflected from the propagating light impinging on the end face at the far end of the fibre, assuming it is also located in air.

A1.5.8.2 Anti-reflecting coating

The reflection of light from the end face of a fibre can be suppressed by depositing a thin anti-reflection coating with index different from that of the fibre, as shown schematically in figure A1.5.35. The coating

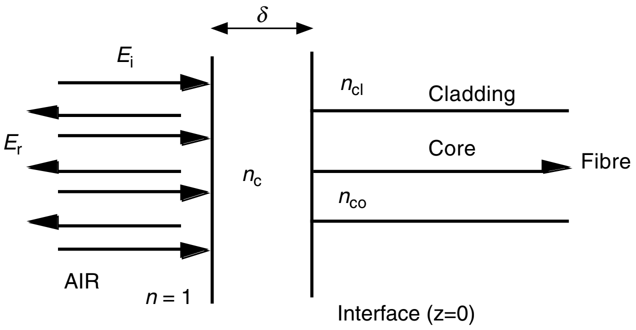

Figure A1.5.35. Schematic of an anti-reflecting coating on the end of a fibre or waveguide.

has uniform thickness δ and refractive index n_c. A simple plane-wave analysis of propagation across this layer at normal incidence from air into the fibre shows that reflection can be totally suppressed from the end face between the coating and air provided that the following two conditions are satisfied

$$d = \frac{m\lambda}{4n_c}, \ m = 1, 3, 5, \ldots; \quad n_c = \sqrt{n} \tag{A1.5.92}$$

where $m = 1,3,5,\ldots$, n is the mean fibre index and λ is the source wavelength.

A1.5.8.3 Mode excitation

Assume that the transmitted scalar electric field of the source on the fibre or waveguide side of the interface at $z = 0$ is given is by the scalar expression $\psi_s(x, y)$, where x, y are Cartesian coordinates in the cross-section (figure A1.5.36). This function is assumed to take into account any reflection loss from the interface and also contains the implicit monochromatic time dependence $\exp(-i\omega t)$.

The complete field everywhere within the core and cladding for $z > 0$ consists, in general, of the sum of the discrete set of bound modes, and the radiation field. Since radiated power is lost from the fibre through the cladding, the total bound-mode field, $\psi_s(x, y)$, is expressible as a sum over all bound modes

$$\psi_s(x, y) = \sum_{m=1}^{M} a_m \psi_m(x, y) e^{i\beta_m z} \tag{A1.5.93}$$

where the a_m are amplitude constants, $\psi_m(x, y)$ is the solution of the scalar wave equation for the field of the mth mode, β_m is the propagation constant for the mth mode and the summation is over all M-bound modes. For a single-mode fibre, $M = m = 1$, and the polarization of the exciting field is assumed to be parallel to the mode polarization.

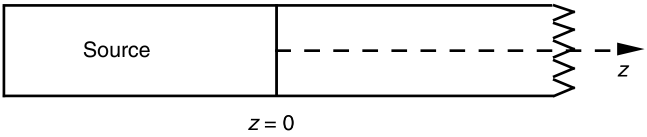

Figure A1.5.36. Schematic of a source abutting the end of a fibre or waveguide at $z = 0$.

Modal amplitudes

The expansion over bound modes and the radiation field ψ_{rad} must match the transmitted field on the end face at $z = 0$. Hence

$$\psi_{\mathrm{s}}(x, y) = \sum_{m=1}^{M} a_m \psi_m(x, y) + \psi_{\mathrm{rad}} \tag{A1.5.94}$$

The amplitude of the kth bound mode is then obtained by multiplying this equation on both sides by $\psi_k(x, y)$, and integrating over the infinite cross-section A_∞. Since, by definition, any bound-mode field is necessarily orthogonal to the radiation field

$$\int_{A_\infty} \Psi_{\mathrm{s}}(x, y)\psi_k(x, y)\,\mathrm{d}x\,\mathrm{d}y = \sum_{m=1}^{M} a_m \int_{A_\infty} \psi_m(x, y)\psi_k(x, y)\,\mathrm{d}x\,\mathrm{d}y \tag{A1.5.95}$$

The amplitude coefficient a_m of each mode is then determined by using the orthogonality property of the scalar modal fields

$$\int_{A_\infty} \psi_m(x, y)\psi_k(x, y)\,\mathrm{d}x\,\mathrm{d}y = 0 \quad \text{if}\, m \neq k \tag{A1.5.96}$$

Accordingly the right-hand side of equation (A1.5.95) reduces to a single term when $k = m$ and the amplitude of the kth excited mode is given by

$$a_k = \int_{A_\infty} \Psi_{\mathrm{s}}(x, y)\psi_k(x, y)\,\mathrm{d}x\,\mathrm{d}y \Big/ \int_{A_\infty} \psi_k(x, y)^2\,\mathrm{d}x\,\mathrm{d}y \tag{A1.5.97}$$

Note that for a circular fibre the Cartesian element of area $\mathrm{d}x\,\mathrm{d}y \rightarrow r\mathrm{d}r\mathrm{d}\phi$ in polar coordinates with $0 < r < \infty$ and $0 < \phi < 2\pi$.

Modal power

Equation (A1.5.28) determines that the total power P_k propagating in each excited mode is proportional to

$$(a_k)^2 \int_{A_\infty} (\psi_k)^2\,\mathrm{d}x\,\mathrm{d}y \tag{A1.5.98}$$

where A_∞ is the infinite cross-section of the fibre or waveguide and $k = 1, 2, \ldots, M$. On substituting a_k from equation (A1.5.97) the fraction of transmitted power in each excited mode relative to the total power exciting the fibre is given by

$$\frac{\left(\displaystyle\int_{A_\infty} \psi_k \Psi_{\mathrm{s}}\,\mathrm{d}x\,\mathrm{d}y\right)^2}{\displaystyle\int_{A_\infty} (\psi_k)^2\,\mathrm{d}x\,\mathrm{d}y \quad \int_{A_\infty} (\Psi_{\mathrm{s}})^2\,\mathrm{d}x\,\mathrm{d}y} \tag{A1.5.99}$$

The total fraction of incident power that is transmitted into bound modes is given by summing equation (A1.5.99) over all values of k. Thus, the fraction of total exciting power lost as radiation is given by

$$1-\sum_{k=1}^{M}\frac{\left(\displaystyle\int_{A_\infty}\psi_k\Psi_{\mathrm{s}}\,\mathrm{d}x\,\mathrm{d}y\right)^2}{\displaystyle\int_{A_\infty}(\psi_k)^2\,\mathrm{d}x\,\mathrm{d}y\int_{A_\infty}(\Psi_{\mathrm{s}})^2\,\mathrm{d}x\,\mathrm{d}y} \tag{A1.5.100}$$

A1.5.8.4 Fibre splicing, miss-match, offset and tilt

Optical fibres are normally spliced together by removing the coating (mechanically or chemically), cleaving the fibre ends so that their end faces are flat and perpendicular to the fibre axis and butting them together in a V-groove. The fibres are then heated by an electric arc to soften the glass and fuse them together to form a smooth continuous joint. Splicing fibres using this technique essentially requires fibres with the same cladding diameter, commonly referred to as the *outer diameter* or *o/d*, although their core refractive index profiles and radii can differ quite significantly.

Splice loss

The difference between the cross-sectional profile and geometry of the cores of the two fibres is known as the *miss-match*. For single-mode fibres the miss-match accounts for the loss of power at the splice as the fundamental mode fields of the two fibres will not be identical. Additional losses will occur if the fibres are *offset* transversely, or if their axes are no longer parallel and have a relative *tilt*.

Splice loss, due to any of the three loss mechanisms shown schematically in figure A1.5.37, can formally be calculated and quantified using the analysis of mode excitation in the previous section but with the input source being the field of the fundamental mode of the input fibre. However, such an analysis would require detailed knowledge of the refractive index profiles of both fibres and formal solution of the scalar wave equation (numerically) to determine the fields of the fundamental mode of each fibre. A simpler approach, which requires knowledge only of each fibre's spot size (taken from fibre measurement) and gives an approximate but accurate measure of splice loss, is to use the Gaussian approximation of Section A1.5.4.7 to represent the field of the fundamental mode of each fibre.

Miss-match loss

Accordingly, if ψ_1 and ψ_2 denote the fundamental fields of fibres 1 and 2, respectively, in the weak-guidance approximation then the representation of the Gaussian approximation is

$$\psi_1(r)=a_1\exp\left\{-\frac{r^2}{2s_1^2}\right\};\quad \psi_2(r)=a_2\exp\left\{-\frac{r^2}{2s_2^2}\right\} \tag{A1.5.101}$$

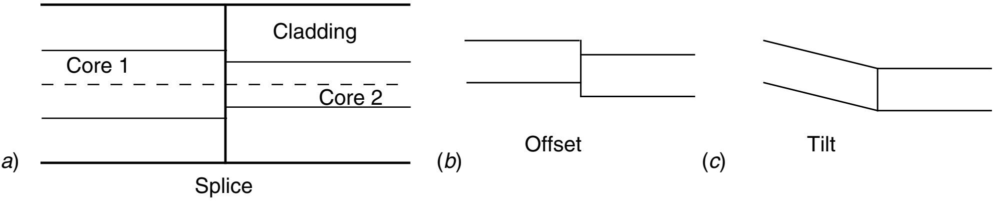

Figure A1.5.37. (*a*) Miss-match, (*b*) offset and (*c*) tilt between fibre cores.

where s_1 and s_2, a_1 and a_2 are, respectively, the spot sizes and amplitudes for fibre 1 and fibre 2, and r is the cylindrical radial coordinate measured from the fibre axis.

The power P_1 propagating in the fundamental mode in fibre 1 is obtained by integrating the local power flow power density parallel to the fibre axis over the infinite cross-section relative to polar coordinates (r, ϕ) in the fibre cross-section. In weak guidance the power flow density in the z-direction is given by equation (A1.5.28). Since ψ_1 is axisymmetric, the ϕ integration is readily performed and leads to

$$P_1 = \frac{n_{\mathrm{co}}}{2}\left(\frac{\varepsilon_0}{\mu_0}\right)^{1/2}\int_0^{2\pi} r\psi_1^2 \mathrm{d}r\,\mathrm{d}\phi = \pi n_{\mathrm{co}}\left(\frac{\varepsilon_0}{\mu_0}\right)^{1/2}\int_0^{\infty} r\psi_1^2 \mathrm{d}r \tag{A1.5.102}$$

Substituting for ψ_1 leads to a standard integral

$$P_1 = \pi(a_1)^2 n_{\mathrm{co}}\left(\frac{\varepsilon_0}{\mu_0}\right)^{1/2}\int_0^{\infty} r\exp\left\{-\frac{r^2}{s^2}\right\}\mathrm{d}r = \frac{\pi n_{\mathrm{co}}}{2}\left(\frac{\varepsilon_0}{\mu_0}\right)^{1/2} s_1^2 a_1^2 \tag{A1.5.103}$$

Similarly, the power P_2 propagating in the fundamental mode in fibre 2 is given by

$$P_2 = \frac{\pi n_{\mathrm{co}}}{2}\left(\frac{\varepsilon_0}{\mu_0}\right)^{1/2} s_2^2 a_2^2 \tag{A1.5.104}$$

There is negligible reflected power at the splice because both fibres are weakly guiding and their refractive index profile values are very similar. In the pure silica cladding the indices are of course identical.

The amplitude of the transmitted mode, a_2, is determined by using fundamental mode field ψ_1 in fibre 1 as the source of excitation (ψ_s) of the fundamental mode ψ_2 (ψ_k) for fibre 2 in equation (A1.5.97), leading to

$$a_2 = \frac{\displaystyle\int_{A_\infty} \Psi_1\psi_2 \mathrm{d}x\,\mathrm{d}y}{\displaystyle\int_{A_\infty} \psi_2^2 \mathrm{d}x\,\mathrm{d}y} = a_1\frac{\displaystyle\int_0^{\infty} r\exp\left(-\frac{r^2}{2}\left[\frac{1}{s_1^2}+\frac{1}{s_2^2}\right]\right)\mathrm{d}r}{\displaystyle\int_0^{\infty} r\exp\left(-\frac{r^2}{s_2^2}\right)\mathrm{d}r} \tag{A1.5.105}$$

By analogy with the derivation of the power integrals above, these integrals are readily evaluated and lead to

$$a_2 = a_1\frac{2s_1^2}{s_1^2+s_2^2} \tag{A1.5.106}$$

Using equations (A1.5.105) and (A1.5.106), the fractions of transmitted power and the fraction of power lost are given, respectively, by

$$\frac{P_2}{P_1} = \frac{s_2^2 a_2^2}{s_1^2 a_1^2} = \frac{4s_1^4}{(s_1^2+s_2^2)^2}\frac{s_2^2}{s_1^2}; \quad 1-\frac{P_2}{P_1} = 1-\frac{4s_1^4}{(s_1^2+s_2^2)^2}\frac{s_2^2}{s_1^2} = \left(\frac{s_1^2-s_2^2}{s_1^2+s_2^2}\right)^2 \tag{A1.5.107}$$

Thus, for example, a 1% relative difference in the two spot sizes gives rise to a power loss of only 0.01%, whereas a 10% relative difference gives a 1% loss.

Offset and tilt losses

If two identical single-mode fibres with the same spot size s are offset parallel to one another by distance d, a similar analysis to the Gaussian approximation for the miss-match loss gives the first expression in equation (A1.5.108) for the fraction of power loss. Similarly if the same two fibres have a relative tilt angle θ_s, the second expression in equation (A1.5.108) determines the fraction of power loss

$$1 - \exp\left(-\frac{d^2}{2s^2}\right); \quad 1 - \exp\left(-\frac{(kn_{\text{co}}\theta_s)^2}{2}\right) \tag{A1.5.108}$$

where k is the free-space wavenumber and n_{co} is the core index value. If both offset and tilt losses are present, then the two expressions in equation (A1.5.108) are multiplied together to determine the overall loss. Similarly, if miss-match loss is also present, then a third multiplicative factor given by the second expression in equation (A1.5.107) should be included.

A1.5.8.5 Near and far fields

The *near field* refers to the field of a fibre or waveguide on the far end face in air. In the case of a sufficiently long length of single-mode fibre, the near field will be virtually identical in shape to the fundamental-mode field within the core and cladding because the power in all higher-order cladding modes will have been absorbed and scattered by the coating material. However, the amplitude of the near field will reduced by about 1.75% to account for the 3.5% of reflected power from the end face back along the fibre. For multimode fibres, ray tracing and Snell's laws can be used to determine the near-field pattern.

Suppression of end-face reflection

When light propagating in the excited bound mode(s) of a fibre reaches the far end of the fibre, it is partly reflected back along the fibre because of the change in index from glass to air at the end face. The 3.5% of reflected power propagates back to the front face and all but 3.5% of this light is transmitted back into the source laser where it can interfere with the operation of the laser.

This reflection problem can be avoided in practice by cleaving the end face at a sufficiently large angle, typically 10°, to deflect the reflected light into the cladding and out of the fibre core as illustrated in figure A1.5.38.

Far field

The *far field* of a fibre or waveguide is the field emerging from its far end into air as measured at a sufficiently large distance from the end face. In the case of multimode fibres, the shape of the far field can be predicted using ray tracing by tracking the rays exiting the end face and taking into account their refraction at the end face.

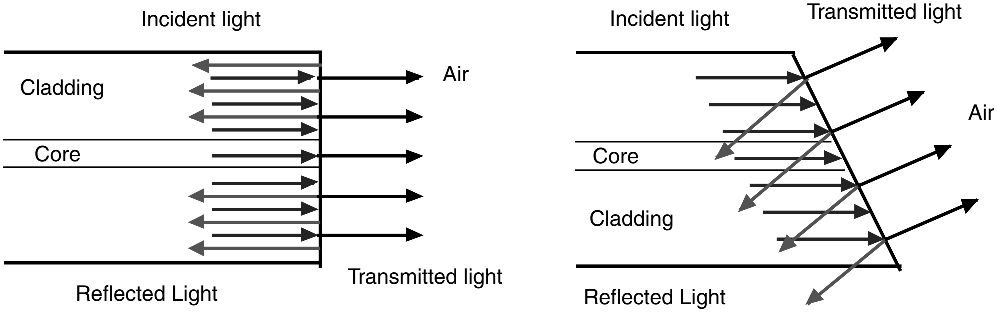

Figure A1.5.38. Reflection from the far end face of a fibre without and with an angle face.

For single-mode fibres and waveguides with relatively small core sizes of the order of a few wavelengths of the source light, the far field is *diffracted* at the end face. Because of the confining effect of the cladding on light in the core, this effect is analogous to the diffraction of a beam of light passing through a small orifice and then spreading laterally to form a series of lobes when viewed sufficiently far from the end face.

If the first lobe makes a far-field diffraction angle θ_d with the fibre axis, a shown in figure A1.5.39, standard diffraction theory can be used to relate this angle to the fibre parameters.

A1.5.9 Perturbed and non-uniform fibres and waveguides

There are two sets of problems in which (a) the cross-sectional geometry and/or the refractive index profile of a fibre or waveguide are subject to uniform longitudinal perturbations and (b) the translational invariance of a waveguide or fibre no longer holds, but a quasi-modal description of propagation is still applicable. In the first set, translational invariance still holds so that the structure supports bound modes, whereas in the second set, which includes longitudinal tapering, mode coupling necessarily occurs. In keeping with the thrust of earlier sections, an outline of the methodology employed in each of these techniques will be presented within the weak guidance approximation.

A1.5.9.1 Uniform perturbations: single core

When a fibre or waveguide has a single core for which the field and propagation constant are known for any bound mode, a simple perturbation technique enables the propagation constant to be determined when a uniform perturbation in the cross-sectional geometry and/or refractive index profile is applied to the length of the fibre or waveguide.

Consider a waveguide or fibre with known profile $n(x, y)$, scalar modal field $\psi(x, y)$ and propagation constant β, respectively. If the waveguide or fibre is slightly but uniformly distorted along its length so that it now has profile $\bar{n}(x, y)$, field $\bar{\psi}(x, y)$ and propagation constant $\bar{\beta}$, respectively, then the perturbed propagation constant can be expressed approximately in terms of the unperturbed quantities according to

$$\bar{\beta}^2 = \beta^2 + k^2 \frac{\displaystyle\int_{A_\infty} (\bar{n}^2 - n^2)\Psi^2 \mathrm{d}A}{\displaystyle\int_{A_\infty} \psi^2 \mathrm{d}A} \qquad \text{(A1.5.109)}$$

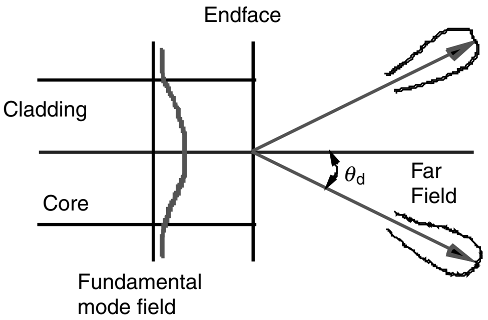

Figure A1.5.39. Fundamental mode evolving into lobes in the far field.

where k is the free-space wavenumber and the integrals are over the infinite cross-section of the waveguide or fibre (see chapter 18 of Ref. [4]).

Slight absorption

To illustrate the usefulness of the above result, consider a step-profile fibre with a loss-less cladding and core which is slightly absorbing, i.e. n_{co} is replaced by the complex expression $n_{\mathrm{co}} + \mathrm{i}\delta$, where $\delta << 1$ is a constant. By substituting into equation (A1.5.109) to the lowest order in δ gives

$$\bar{\beta}^2 = \beta^2 + 2i\delta k^2 n_{\mathrm{co}} \frac{\int_{A_{\mathrm{co}}} \psi^2 \mathrm{d}A}{\int_{A_\infty} \psi^2 \mathrm{d}A} = \beta^2 + 2i\delta\eta k^2 n_{\mathrm{co}} \tag{A1.5.110}$$

where A_{co} is the core cross-sectional area and η is the fraction of mode power propagating in the core. Upon taking the square root, setting $\beta \sim kn_{\mathrm{co}}$, then ordering δ

$$\bar{\beta} = \beta\left(1 + \frac{2i\delta\eta k^2 n_{\mathrm{co}}}{\beta^2}\right)^{1/2} \cong \beta + \frac{i\delta\eta k^2 n_{\mathrm{co}}}{\beta} \cong \beta + i\delta\eta k \tag{A1.5.111}$$

Hence the mode power $P(z)$ at distance z along the fibre is attenuated according to

$$P(z) = P(0)\exp(-2\delta\eta kz); \quad \mathrm{dB} = 8.686\delta\eta kz \tag{A1.5.112}$$

Thus, the attenuation increases with increasing absorption but decreases with increasing mode order because a larger fraction of power propagates in the cladding. In other words, the effect of absorption is most pronounced for the fundamental mode.

A1.5.9.2 Uniform perturbations: multiple cores

When more than one core is present in a fibre or waveguide, there are two essentially equivalent techniques for analysing propagation: *super-modes* and *coupled-mode theory*. This is brief background material for the more detailed applications to light processing devices discussed in Chapter B3 of this book.

Super-mode analysis

By analogy with the discussion in Section A1.5.3.10, super-modes are the bound modes associated with the multiple cores such that propagation of guided optical power can be expressed in terms of a summation over the super-modes. For example, in the case of two identical cores that in isolation from one another are single mode, there are two super-modes with even and odd symmetry, respectively, relative to the mid-plane between the two cores. If both modes are excited simultaneously, there will be interference or beating between them because of the difference in their propagation constants. Physically this leads to a coupling of optical power between the two cores.

Coupled-mode analysis

An alternative approach is to employ coupled-mode theory, the details of which are described in more detail in Section A1.5.9.4 below. Physically, this approach can be thought of as follows. When there is only one core present, the fundamental mode propagates unperturbed. If a second parallel core is now introduced supporting a second fundamental mode with a propagation constant identical to that in the first core, this situation gives rise to a resonance phenomenon and power is transferred from the first core to the second core and back again while the modes propagate. This periodic transfer of power between the two cores can be described quantitatively using coupled-mode equations and the results are formally identical to those derived using super-modes.

A1.5.9.3 Tapered fibres and waveguides

A waveguide or fibre taper corresponds to a variation of the core cross-section and/or refractive index profile with distance z along the fibre, i.e. $\rho = \rho(z)$ and/or $n = n(z)$, where ρ is either the half-side of a square-core waveguide or the the core radius of a step-profile fibre and n is the profile. If the taper is single-mode, then at each position z along the taper, only the fundamental mode is bound, but because of the variation in $\rho(z)$ the fundamental mode must lose power by coupling to radiation. However it is intuitive that if the core radius $\rho(z)$ varies sufficiently slowly along the taper, than the radiation loss should be minimal. If there were no power loss, then the taper would be described as *adiabatic*; with a small but finite loss, the taper can be described as *approximately adiabatic*.

A1.5.9.4 Local modes

If the taper is approximately adiabatic, and the fibre or the waveguide is single-mode along its entire length, it is intuitive that the fundamental mode defined by the core cross-section at the beginning of the taper will have virtually the same power as the fundamental mode at the end of the taper. However, its scalar field $\psi(x, y)$ and propagation constant β at the ends of the taper can be quite different, so how can we accommodate this change and at the same time retain the fundamental mode description?

The answer is the concept of a *local mode*. Such a mode has the property that, at each position along the taper, its modal field $\psi(x, y, z)$ and propagation constant $\beta(z)$ adapt so that they are determined by the local cross-sectional geometry and index profile. Hence at cross-section AA′ in figure A1.5.40 the core radius is, say, $\rho(z_A)$, while at BB′ it will be $\rho(z_B)$. The solutions of the scalar wave equation for the field and propagation constant are then determined for the step profile with radius $\rho(z_A)$ at AA′ and radius $\rho(z_B)$ at BB′. To connect these solutions at each end, consider the local mode phase and amplitude variation separately.

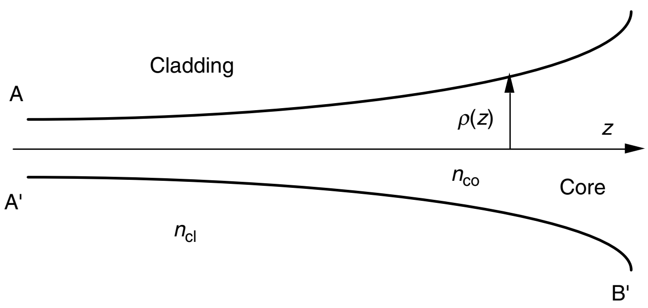

Figure A1.5.40. Schematic of a tapered core.

Local mode phase and power dependence

In a uniform fibre, phase increases linearly with distance as βz. If β now varies continuously with z, i.e. $\beta \rightarrow \beta(z)$, it is intuitive that the linear accumulation of phase is replaced by a continuous summation that can be represented by the integral

$$\int_z \beta(z)\,\mathrm{d}z \tag{A1.5.113}$$

that reduces to βz when $\beta(z)$ is a constant.

In weak guidance the total power P propagating in the fundamental mode along a uniform waveguide or fibre is given in terms of its amplitude a_0 and field ψ_0 by

$$P_0 = \frac{n_{\mathrm{co}}}{2}\left(\frac{\varepsilon_0}{\mu_0}\right)^{1/2} |a_0|^2 \int_{A_\infty} |\psi_0|^2 \mathrm{d}A \tag{A1.5.114}$$

where the integration is over the infinite cross-section. Suppose we assume that this expression is invariant at every position along the taper, i.e. the total power remains fixed for all values of z. The field ψ_0 will then vary with the change in cross-section, i.e. $\psi_0 = \psi_0(z)$, and equation (A1.5.114) determines that the modal amplitude a_0 must also vary as

$$a_0(z) = \left(\frac{P_0}{\dfrac{n_{\mathrm{co}}}{2}\left(\dfrac{\varepsilon_0}{\mu_0}\right)^{1/2} \displaystyle\int_{A_\infty} |\psi_0(z)|^2 \mathrm{d}A \blacksquare} \right)^{1/2} = \left(\frac{P}{N_0}\right)^{1/2}. \tag{A1.5.115}$$

The denominator in the first expression is identical to the definition of the normalization N_0 in equation (A1.5.11), so on recalling the definition of the field of an *orthonormal mode* in equation (A1.5.12) it follows that

$$\hat{\psi}_m = \frac{\psi_m}{N_m^{1/2}}; \quad a_m \psi_m = P \frac{\psi_m}{(N_m)^{1/2}} = P \hat{\psi}_m \tag{A1.5.116}$$

In other words, the orthonormal fundamental mode describes the modal field everywhere along the taper if it is adiabatic but is a good approximation if the taper is approximately adiabatic.

A1.5.9.5 Mode coupling

In situations where there is a loss of power from a mode of a waveguide or fibre due to either an external influence, as is the case with multiple cores in Section A1.5.9.2, or to the longitudinal change in the profile or cross-sectional geometry due to tapering in Section A1.5.9.3, the variation in the power of the mode can be quantified using a set of *coupled-mode equations* [10]. An individual mode of any order propagates without change in its total power, field and propagation constant along a translationally invariant, loss-less waveguide or fibre.

If the waveguide or fibre is now subject to a length-dependent perturbation, then the mode generally will couple its power to all other bound modes and to the radiation field, in a multimode guidance situation, but only to the radiation field in a single-mode guidance situation, assuming an infinite cladding. For a finite-cladding cross-section, the radiation field comprises guided cladding modes together with a radiation field propagating into the medium beyond the cladding (normally air). Accordingly, only coupling between bound (core and cladding) modes will be included from hereon.

Forward and backward-propagating modes

The coupling of a particular mode, say the *j*th forward-propagating mode, is generally to all other forward-propagating modes and to all backward-propagating modes, including the *j*th backward-propagating mode. The *j*th forward-propagating mode in the weak-guidance approximation has a scalar transverse electric field E_j with the complete temporal-spatial dependence

$$E_j(x, y, z, t) = a_j(z)\psi_j(x, y)\exp[i(-\beta_j z - \omega t)] \tag{A1.5.117}$$

where $a_j(z)$ is the z-dependent modal amplitude, which accounts for the coupling of power to or from the *j*th mode. The *k*th backward-propagating mode has the same field as the *k*th forward-propagating mode, and its propagation constant has the same absolute value, but opposite in sign to that of the forward-propagating mode to account for the negative phase velocity, i.e.

$$E_k(x, y, z, t) = a_k(z)\psi_k(x, y)\exp[i(-\beta_k z - \omega t)] \tag{A1.5.118}$$

If $k = j$, this gives the form of the *j*th backward-propagating mode.

Mode normalization

If $\psi_j(x, y)$ is a solution of the scalar wave equation satisfying the usual boundary conditions, then any multiple $p\psi_j$ is also a solution, where p is an arbitrary constant. Thus the ψ_j in the above expressions are not uniquely specified, which in turn affects the value of the amplitude coefficients $a_j(z)$. To remove this potential ambiguity, it is convenient to replace the ψ_j and the ψ_{-k} by their orthonormal forms, i.e. by

$$\psi_j(x, y) \rightarrow \frac{\psi_j(x, y)}{\sqrt{N_j}}; \quad \psi_{-k}(x, y) \rightarrow \frac{\psi_{-k}(x, y)}{\sqrt{N_k}} \tag{A1.5.119}$$

where N_i and N_k are the respective mode normalization defined by equation (A1.5.11). Note that normalization is independent of the direction of propagation.

Coupled-mode equations

The coupled-mode equations comprise a set of linear, first-order differential equations that determine the z-dependence of the modal amplitude of each forward or backward-propagating mode. It is convenient to combine the z-dependent amplitude and phase of each mode by defining new coefficients $b_j(z)$ and $b_{-k}(z)$ such that (see chapter 27 of Ref. [4])

$$b_j(z) = a_j(z)\exp(i\beta_j z); \quad b_{-k} = a_{-k}(z)\exp(i\beta_k z) \tag{A1.5.120}$$

The coupled equations can then be expressed as

$$\frac{\mathrm{d}b_j}{\mathrm{d}z} - i\beta_j b_j = i\sum_k C_{jk} b_k; \quad \frac{\mathrm{d}b_{-j}}{\mathrm{d}z} + i\beta_j b_{-j} = -i\sum_k C_{-jk} b_k \tag{A1.5.121}$$

for the jth forward and backward-propagating modes, respectively, where the summation in k is over all forward and backward-propagating modes. The $C_{jk} = C_{jk}(x,y)$ *coupling coefficients*, defined by

$$C_{jk} = \frac{k}{2n_{\mathrm{co}}} \int_{A_\infty} [\bar{n}^2(x,y,z) - n^2(x,y)]\psi_j \psi_k \, \mathrm{d}A \qquad \text{(A1.5.122)}$$

where A_∞ is the infinite cross-section, $n^2(x,y)$ is the refractive index profile of the unperturbed waveguide or fibre, $n^2(x,y,z)$ is the refractive index profile of the perturbed waveguide or fibre, and the ψ values are orthonormal.

Applications of coupled-mode equations

The set of coupled-mode equations is useful for solving a range of practical propagation problems where there is a significant exchange of power between modes. Such an analysis requires a set of propagation conditions along the fibre, which does not change or only changes very slightly so that the field and propagation constant of each mode remains constant. Examples where coupled-mode equations offer a method of solution include multiple-core fibres and waveguides, as discussed in Section A1.5.9.2, Bragg reflection gratings, and long-period gratings.

Coupled local mode equations

Problems in which the translational invariance of the modes no longer holds, such as well-tapered fibres, waveguides or devices, are not appropriate for a coupled-mode equation analysis. In these cases, an alternative analysis based on an analogous set of coupled local-mode equations can be used (see chapter 28 of Ref. [4]).

In practice, however, problems involving tapered fibres, waveguides and devices, based on single or two-mode propagation, generally have a sufficiently slow rate of taper that coupling between local modes may be negligible so that each local mode propagates approximately adiabatically and almost conserves its power.

A1.6

Introduction to lasers and optical amplifiers

William S Wong, Chien-Jen Chen and Yan Sun

A1.6.1 Introduction

Although Albert Einstein did not invent the laser, his work laid the foundation for its development. In 1917, Einstein was the first to explain how radiation could induce, or stimulate, more radiation when it interacts with an atom or a molecule [14]. A few years later, Richard Tolman discussed stimulated emission and absorption in his paper [65], realizing the important fact that stimulated emission is coherent with the incoming radiation. In other words, the electric dipoles in the atoms oscillate with the incoming photons, which in turn, re-radiate photons that have a fixed phase relationship with incoming photons. If the re-radiated photons are in-phase with the incoming ones, they add constructively to amplify the incoming photons. Thus, the general idea of coherent amplification via stimulated emission was understood since the 1920s. However, it was not until the 1950s when the concept of the 'maser', which is an acronym for microwave amplification by simulated emission of radiation, was developed and demonstrated by Charles Townes and his coworkers at Columbia University [22, 23]. They directed excited ammonia molecules into a cavity whose resonance frequency is tuned to the 24 GHz transition frequency of ammonia [66]. A sufficient number of these excited molecules will initiate an oscillating microwave field in the cavity, part of which will be coupled out of the cavity (see figure A1.6.1). It is interesting to note that maser operation was first demonstrated in the microwave region. Since the spontaneous radiative lifetime is inversely proportional to the third power of the transition frequency, at microwave transition frequencies, the radiative lifetime of the ammonia molecules is about 1×10^{12} longer than it would be at optical frequencies, which allows the system to achieve population inversion easily with a reasonable amount of pump power.

Following the invention of the maser, researchers attempted to create a laser by extending the maser action to optical frequencies, where 'laser' is an acronym for light amplification by simulated emission of radiation. Schawlow and Townes published a paper to explore the possibility of laser action in the infrared and visible spectrum [50]. Although many researchers at the time speculated that a system containing alkali vapours would be the most likely candidate that could be made to oscillate at optical frequencies, they were surprised to learn that a system involving optical pumping of chromium ions in ruby, invented by Maiman [37], was the first to produce coherent optical radiation. His laser consisted of a ruby crystal surrounded by a helicoidal flash tube enclosed within a polished aluminum cylindrical cavity (see figure A1.6.2). When pumped by a very intense pulse of light from a flash lamp, the ruby laser operated in pulsed mode at 694 nm.

Great progress has been made since the 1960s. Today, lasers have become ubiquitous in our lives. They are used in a wide range of applications in communications, medicine, consumer electronics, and military systems. Although it has been fewer than 50 years since the laser was first invented, we have made, and will continue to make, great strides in advancing the state of the art in lasers.

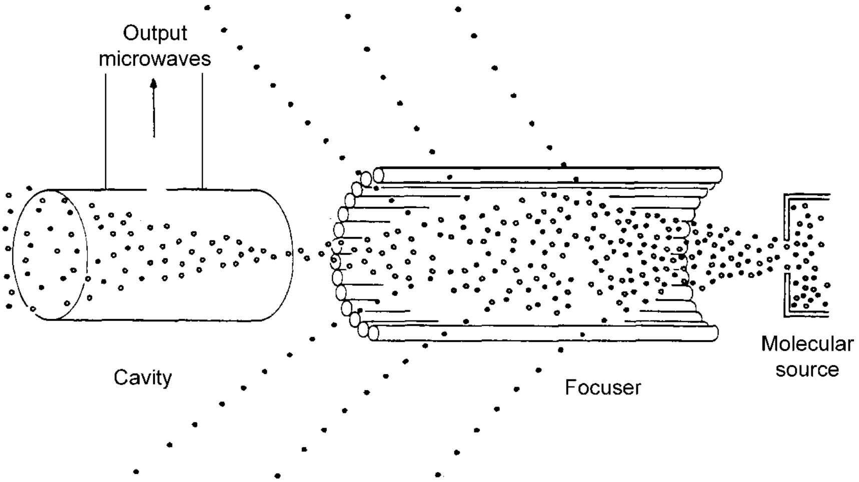

Figure A1.6.1. The ammonia maser. Molecules diffuse from the source into a focuser where the excited molecules (shown as open circles) are focused into a cavity and molecules in the ground state (shown as solid circles) are rejected. A sufficient number of excited molecules will initiate an oscillating electromagnetic field in the cavity, which is emitted as the output microwaves (from [66]).

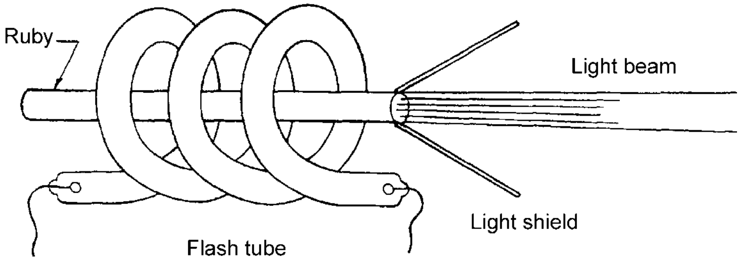

Figure A1.6.2. Schematic diagram of a ruby laser. When the gas flash tube is activated, electromagnetic oscillations occur within the ruby rod. Some of the visible radiation is emitted in a beam through one partially reflecting end of the rod (from [66]).

A1.6.1.1 A two-level atomic system

Before we explain the operation of a laser, we need to understand how radiation interacts with matter. Atoms, molecules, and solids have specific energy levels that are determined by the laws of quantum mechanics. A photon may interact with an atom if its energy matches the difference between two of the energy levels.

Let us focus our attention on two energy levels, E_1 and E_2 of an atom. If we assume that $E_2 > E_1$, we can refer to the levels 1 and 2 as lower and upper levels, respectively. When the energy of the photon $h\nu$ matches the atomic energy-level difference, i.e. $h\nu = E_2 - E_1$, the photon interacts with the atom where processes such as spontaneous emission, absorption, and stimulated emission take place.

Spontaneous emission of a photon takes place when the atom transitions from level 2 to level 1 without any external excitation (figure A1.6.3). The energy difference is released in the form of a photon with energy $h\nu = E_2 - E_1$. The rate of this spontaneous transition, which is independent of the number

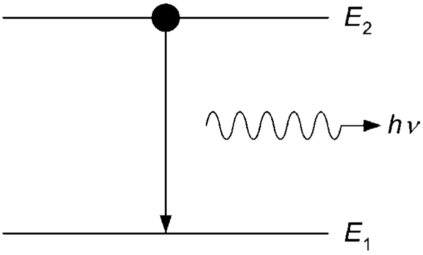

Figure A1.6.3. The process of spontaneous emission.

of photons that is present, is the reciprocal of the spontaneous radiative lifetime of the 2 → 1 transition. Typical values of radiative lifetimes of specific transitions range from picoseconds to several minutes.

In the presence of pumping, the atom will transition from the lower level to the upper level. For example, in the He–Ne laser, the He atoms, initially excited by collisions with electrons, transfer the excitation to the Ne atoms. In addition, in the presence of a photon with energy $h\nu = E_2 - E_1$, the atom in the lower level will also transition to the upper level, while absorbing the photon at the same time (figure A1.6.4). It is an induced transition since the rate of absorption is *proportional* to the intensity of the radiation. As an example, cesium atomic clocks, which utilize the principle of absorption, have the ability to measure time with an accuracy as good as 1 s in over 20 million years. Cesium is the best choice of atom for such a measurement, because all of its 55 electrons, except the outermost one, are confined to orbits in stable shells of electromagnetic force. The energy difference $E_2 - E_1$ is attributed to the cesium atom's outermost electron transitioning from a lower to a higher orbit. After tuning a microwave beam to the resonant absorption frequency (9,192,631,770 Hz) of a collection of cesium atoms, one measures the resulting cycles of oscillations in the microwave signal to establish a time/frequency standard.

If the atom is in the upper level in the presence of radiation, it will make a downward transition to the lower level while emitting a photon of energy $h\nu$ (figure A1.6.5). The emission of the new photon is

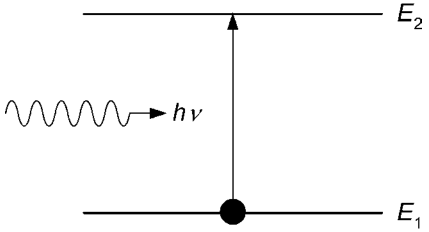

Figure A1.6.4. The process of stimulated absorption.

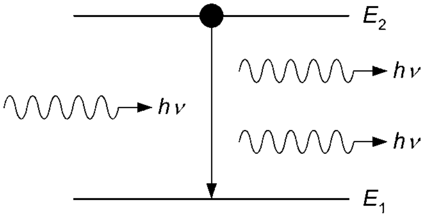

Figure A1.6.5. The process of stimulated emission.

induced, or stimulated, by the incident photon. The new photon also has the same frequency, polarization, and phase as the incident photon. In an optical amplifier, this process of stimulated emission takes place continuously along the length of the gain medium, resulting in a large number of output photons that are replicas of the input photons. In general, in a spontaneous process, such as spontaneous emission, each atom acts independently to produce a noise-like output. On the other hand, in a stimulated process, the atoms in the medium act collectively and oscillate in phase, which makes coherent amplification possible.

Although no photons are involved, nonradiative decays are also an important process for understanding the operation of a laser. If an atom is initially in the upper energy level, it can decay to the lower energy level without emitting a photon. Instead, the energy-level difference $E_2 - E_1$ appears in a phonon, where either the rotational energy or the translational energy of the material system increases, resulting in heating effects.

At thermal equilibrium, the ratio of the atoms in levels 1 and 2 is given by the Boltzmann factor:

$$N_2/N_1 = \exp[-(E_2 - E_1)/k_B T], \tag{A1.6.1}$$

where N_1 and N_2 are the number of atoms in the lower and upper levels, respectively, $k_B \approx 1.38054 \times 10^{-23}\,\mathrm{J\,K^{-1}}$ is the Boltzmann constant, and T is the temperature in kelvin. Since $E_2 > E_1$ by assumption, the above equation tells us that at thermal equilibrium, $N_2 > N_1$; in other words, there are more absorbers than emitters. Therefore, at a normal temperature where $T > 0$, the two-level system always absorbs more incoming radiation with energy $h\nu$ than it will emit. In order to have a net amplification of radiation, it is necessary to achieve a population inversion, where $N_2 > N_1$. Interestingly, the corresponding system is said to have a 'negative temperature' since T will have to be a negative quantity in kelvin in order to satisfy equation (A1.6.1).

A1.6.1.2 Multi-level laser systems

Although, 'laser' is an acronym for 'light amplification by stimulated emission of radiation', lasers are actually optical oscillators (generators or sources of light) and not optical amplifiers (devices for increasing the strength of an input lightwave signal). Despite the variety in the types of lasers, nearly all lasers possess the following three essential elements:

(a) a lasing medium, which can be a solid, liquid, gas, semiconductor, or others;

(b) a pumping process that excites the atoms in the medium into a higher energy level; and

(c) an optical resonator to enable the light to bounce back and forth.

If the amount of coherent amplification inside the resonator exceeds the internal loss, coherent laser oscillation will take place.

It is impossible to achieve continuous laser oscillation in a two-level atomic system. Imagine that we are trying to excite as many atoms into the upper level as possible. While doing so, we are also increasing the rate of stimulated absorption. At best, both upper and lower levels in the two-level system will be populated equally, failing the requirement that we need to have a population inversion ($N_2 > N_1$). To overcome this problem, most laser systems utilize three or more energy levels. A three-level system is shown in figure A1.6.6. Atoms are excited from level 1, the ground state, to level 3, which decay quickly to level 2, also known as a metastable state. Provided that there is a population inversion, stimulated emission, which takes place from level 2 to level 1, will dominate. This condition is met if the nonradiative lifetime from level 3 to level 2 is short, so that it will not give the pumping process a chance to re-populate the ground state. The ruby laser invented by Maiman is an example of a three-level laser system.

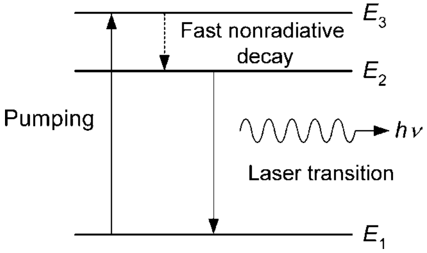

Figure A1.6.6. A typical three-level laser.

A1.6.1.3 Laser cavity

A major element of a laser, in addition to the gain medium, is the laser cavity, which provides optical feedback so that laser oscillation can be achieved. It works like an electronic oscillator where stored energy, amplification, feedback, and output coupling are all engineered for oscillations to take place. It is straightforward to form a laser cavity. In fact, in the simplest form, two parallel mirrors facing each other form the most basic laser cavity—the Fabry–Perot cavity [27, 49, 51, 74]. Lightwave bounces back and forth upon both mirrors, gaining energy each time it passes through the gain medium. Typically, one mirror is highly reflective and the other is partially transmitting to provide output coupling. The gain, loss, and coupling ratios of the mirrors determine the output power of a laser.

Since light is circulating inside the cavity, the phase of the reflected light, after a complete round trip, needs to match that of the original light so that a constructive interference or a standing wave can form. This condition is satisfied only at certain frequencies and these resonant frequencies are referred to as the longitudinal (or axial) modes of the laser cavity. For a cavity with a fixed length, the longitudinal modes are separated by a constant frequency that is equal to the inverse of the cavity round trip time. Within the gain bandwidth of the gain medium of a laser, there may exist multiple longitudinal modes. The lasing threshold is reached when the gain medium is pumped, in which the total round-trip gain of the mode (closest to the gain peak) equals the total round-trip loss. When the threshold is exceeded, the laser oscillation starts in this axial mode. Depending on the property of the gain medium, when the pump power increases, a homogeneously broadened gain medium, which maintains the same gain shape when saturated, can sustain one stable lasing axial mode only, while an inhomogeneous broadened medium can have multiple modes co-existing in a laser.

Similar to a RLC electronic resonator, the quality factor Q of a laser cavity is defined as 2π times the ratio of the stored energy to the energy loss per cycle. Since an optical cycle is very short (a few femtoseconds), energy loss per cycle is relatively small and the quality factor of an optical cavity is normally much greater than that of an electronic resonator.

An important method to generate short laser pulses is to 'switch' the cavity quality factor artificially from very low to normal so that the stored energy in the gain medium can be released in a short time period, otherwise known as the Q-switching method. Lowering the cavity Q can be achieved by increasing the cavity loss or decreasing the feedback from the mirrors. The stored energy, in the form of large inversion in the gain medium, grows as pump power is applied, but the laser oscillation does not happen because of the high cavity loss or the lack of optical feedback. When the cavity Q is restored, the laser threshold is exceeded and the lightwave inside the cavity experiences a large optical gain due to the large inversion and builds up rapidly. The huge optical energy then quickly consumes the large population inversion causing the optical power starts to decrease. In addition, when the cavity Q is lowered at the same time, the optical power diminishes further as the laser is operating below its threshold. The cycle is then repeated for subsequent pulse generation. The Q switching technique is widely applied on all types of lasers, from solid-state lasers, gas lasers, to semiconductor lasers, to produce short pulses.

In addition to the Fabry–Perot cavity, there are different ways to construct a laser cavity. One can replace the planar mirrors with concave or convex spherical mirrors to achieve better confinement of the optical energy inside the cavity [4]. An important consideration of a laser cavity is whether a stable mode exists that corresponds to the mirror geometry. This problem can be approached in a setting of the paraxial wave equation, which describes wave propagation in the paraxial limit, and its eigen solutions, i.e. the Hermit–Gaussian modes. Another approach is ray tracing, which is described by the ABCD matrices. Both methods lead to the same stability criterion written explicitly as $0 \leq g_1 g_2 \leq 1$ [27, 49, 51, 74], where the g parameter of a mirror is defined as $g = 1 - L/R$, where L is the distance between the two mirrors and R is the radius of curvature of the mirror.

As described by the same analysis, higher order Hermit–Gaussian modes, or the transverse modes, can exist in a laser cavity to compete for gain, degrade mode profile, and cause output power fluctuation. Since the higher order transverse modes have larger spatial profiles, they can be eliminated by restricting the active region of the gain media to fit only the fundamental mode. In some high gain lasers, unstable cavities, in which off-axis light diverges, can be used as they have advantages of a larger spatial profile, more efficient gain, ease of alignment, and single modalness.

There are other types of laser cavities, such as a ring cavity consisting of a length of optical fibre. In semiconductor lasers, cleaved facets can be used as mirrors; in addition, linear cavities formed using distributed Bragg reflectors are also common. Depending on the available technology and requirements, laser cavities are chosen to suit their purposes.

A1.6.2 Specific types of lasers

A1.6.2.1 Solid-state lasers

Since the invention of the very first ruby laser in 1960s [37, 38], solid-state lasers, which are composed of gain media in their solid phase by definition, remained as one of the most important and versatile lasers for academia and industry. When pumped to threshold population inversion levels, the three-level or four-level solid-state gain media provide sufficient gain to compensate for losses in the laser cavity. The laser cavity forms a resonator, analogous to the electronic version of an oscillator, which determines the output power, operation modes, and the beam profile of the solid-state laser.

Generally, a solid-state gain medium consists of a crystalline (e.g. YAG) or an amorphous (e.g. glass) host doped with a certain ion (e.g. several percent of Cr^{3+}, Nd^{3+}, Er^{3+}, etc) that acts as the active lasing material. Most commercially available solid-state lasers are pumped by gas discharge flash lamps (e.g. krypton or xenon) or by semiconductor lasers for greater reliability and efficiency. The choice of the gain media depends on lasing wavelength, optical properties (birefringence, dispersion, optical nonlinearity), and mechanical properties (material strength, thermal conductivity). Important solid-state gain media include Nd^{3+}-doped YAG (Nd^{3+}:YAG), Nd^{3+}:glass, Ti^{3+}:sapphire, and colour-centre lasers, etc.

The Nd^{3+}:YAG laser is a four-level laser and is typically operating at the 1.064 μm wavelength range with a narrow linewidth of a few nanometers [18, 35]. Its good thermal conductivity and temperature-insensitive threshold make it suitable for both pulsed and continuous-wave operations. Typically, it is pumped optically with flash lamps or laser diodes, and water-cooled in high output power applications. It is popular for various laboratory applications such as pumping another laser or being frequency-doubled to provide green light. The energy-level diagram of the Nd^{3+}:YAG laser and its emission spectrum are shown in figure A1.6.7.

Compared with Nd^{3+}:YAG, the Nd^{3+}: glass is easier to manufacture and process. It can be made into a larger size gain medium to achieve higher output powers. Depending on the host glass types, it

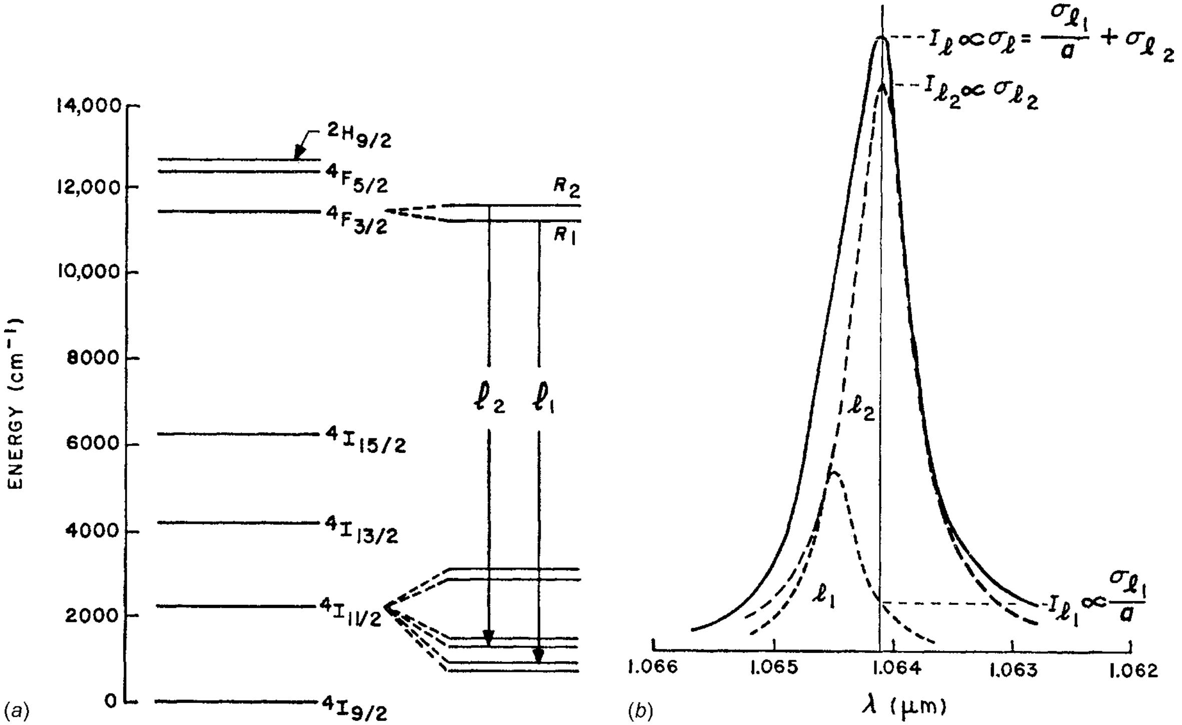

Figure A1.6.7. (*a*) Energy-level diagram of Nd^{3+}:YAG (from [35]), (*b*) Spontaneous-emission spectrum of Nd^{3+}:YAG near 1.064 μm at room temperature. The two Lorentzian lines contributing to the laser transition are shown by dashed lines (from [35]).

typically operates at around 1.06 μm with a wider linewidth of tens of nanometres [34, 54]. Using a large size Nd^{3+}:glass gain medium and the *Q*-switch technique, one can generate pulses with terawatt peak power. However, due to its low thermal conductivity, the Nd^{3+}:glass laser operates at a low repetition rate (10 pulses per second). For comparison, we show the fluorescent emission spectra of Nd^{3+} in various glass hosts in figure A1.6.8.

Among the solid-state gain media, Ti^{3+}:sapphire is characterized by its broad gain bandwidth from 0.66 μm to greater than 1.0 μm (more than 100 THz of bandwidth when modelocked) [43]. It is used in tunable continuous wave (CW) lasers for broad tuning ranges or in mode-locked configuration to produce ultra-short pulses (down to several femtoseconds). The Ti^{3+}:sapphire lasers are often pumped by other lasers such as laser diodes or argon ion gas lasers due to its short excited state lifetime (3.2 μs).

Two common operation modes of solid-state lasers are the CW mode and the pulsed mode. In the CW operation, solid-state lasers generate monochromatic, highly coherent, and high-intensity light. A widely used mechanism to produce pulses in solid-state and other lasers is the *Q*-switching method [68, 69]. By changing the cavity *Q* mechanically, electrically, or optically, the stored energy in the laser gain medium can be released with a short time period to generate a pulse (in the order of nanoseconds) with a high peak intensity [51, 67, 74] (see also A1.6.1.3 for a description of *Q* switching). Short pulses provide advantages in manufacturing and in medical applications such as micro-machining/micro-fabrication and laser ablation since the size of the heat-affected zone can be reduced. As the demand on shorter pulse duration and higher peak intensity increases, different techniques such as mode-locking techniques [26, 53] and chirped pulse amplification (CPA) techniques [60] were applied on solid-state

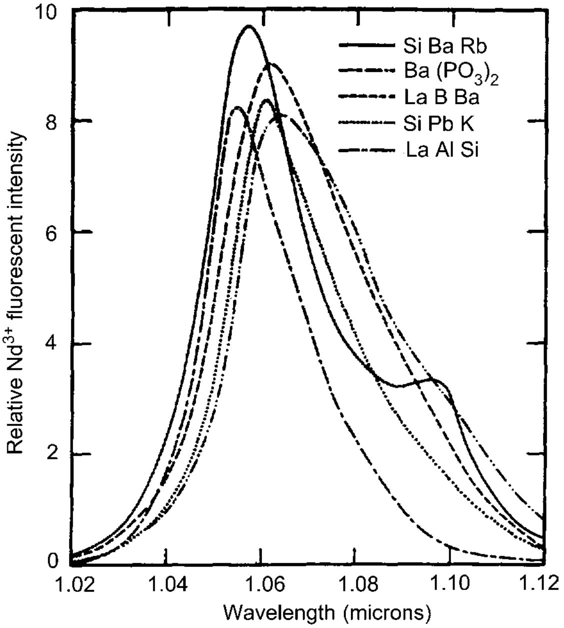

Figure A1.6.8. Spontaneous-emission spectrum of Nd^{3+} in various glass hosts near 1.06 μm (from [54]).

lasers to generate ultra-short pulses (down to sub-picosecond ranges). In fact, solid-state lasers, due to their wide bandwidth and excellent optical properties, generated many of the record-breaking short pulses. These ultra-short pulses are suitable for applications in the study of ultra-fast phenomena, spectroscopy, and telecommunication.

A1.6.2.2 Gas lasers

As another important family of lasers, gas lasers were fast growing in the laser industry due to their simple pumping schemes and the wide availability of gain media. In gas lasers, the population inversion is typically created by electric discharge, which is relatively simple to construct and operate. Although the gain media are in the gaseous phase, they can be made up of neutral atoms, ions, or gas molecules. As examples, we will briefly introduce the three most popular gas lasers: the He–Ne laser, the Argon ion laser (Ar$^+$), and the CO$_2$ laser.

The He–Ne laser, one of the best known lasers, operates at the famous 632.8 nm wavelength [5, 31]. The gain medium consists of a mixture of two noble gases, He and Ne, with a population ratio of about 10 to 1. The He atoms are first excited to higher energy levels by the electrical discharge and then pass energy to the Ne atoms through inelastic collisions. This is possible due to similar energy levels between the He and the Ne atoms (see figure A1.6.9). The excited Ne atoms provide gain for the laser operation in the He–Ne lasers, which also radiate at wavelengths of 1.15 μm and of 3.39 μm, in addition to the 632.8 nm. In fact, optical filtering in the laser cavity is often applied in the He–Ne lasers to reduce the internal gain in the infrared since the optical gain at 632.8 nm is relatively low. The He–Ne lasers were widely used in optical alignment, survey, and bar-code scanning, etc, before the advent of inexpensive laser diodes.

The Ar$^+$ lasers are capable of producing high power in the visible wavelength range. Hundreds of wavelengths could exist in an Ar$^+$ laser cavity; however, the 488.0 and 514.5 nm are two of the most

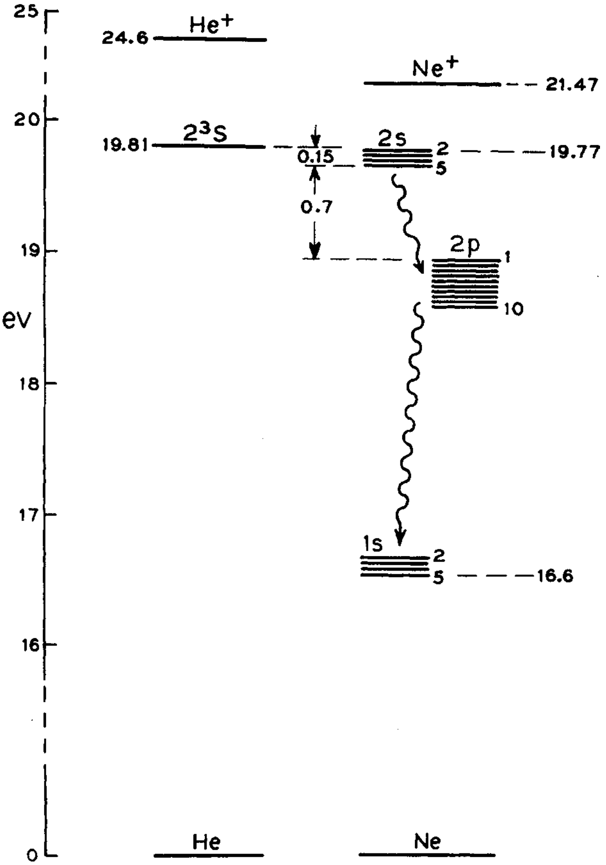

Figure A1.6.9. Energy level diagram of the He and Ne atoms (from [31]).

prominent wavelengths [6, 21]. The pumping mechanism in Ar^+ lasers is complicated, including multiple collisions between electrons, between Ar atoms, and between Ar^+ ions. Since the active laser medium consists of Ar^+ ions, whose ground state level is 16 eV higher than that of the Ar atoms, much of the pump power is wasted in providing ionization of the Ar atoms. Because of the ground level difference, which does not contribute to the laser oscillation, the Ar^+ laser threshold current density is typically high and the efficiency of the laser is low. Due to the low efficiency, bulky water-cooling subsystems are used to cool high-power Ar^+ lasers.

The CO_2 lasers are gas lasers and are well known for their high efficiency and high output powers [45, 46]. In contrast with the He–Ne laser and the Ar^+ laser, in which transitions in electron energy levels provide laser gain in the cavity, CO_2 lasers operate on molecular vibration modes. The vibration modes are represented by three quantum numbers (n_1, n_2, n_3) where the ground state is at (0, 0, 0). Typically, N_2 molecules and He atoms are also present in the CO_2 laser cavity. The N_2 molecules store the energy from the electrical discharge in the fundamental vibration mode and then transfer the energy to the asymmetric vibration (0 0 1) mode through collision since both vibration modes have similar energy levels. The CO_2 laser gain is then produced from the transition of the asymmetric vibration mode to lower level vibration modes, including wavelengths of 10.6 and 9.6 μm. The He atoms, moving at higher speed, effectively reduce the lifetime of the vibration modes at lower levels of the laser and remove heat. This process makes population inversion possible and increases the overall efficiency. Due to its high output power, the CO_2 laser is used in industries such as metal processing and machining.

A1.6.2.3 Semiconductor lasers

A semiconductor (e.g. silicon, germanium, gallium arsenide) is a material whose electrical properties are between those of a conductor and an insulator. The electrons in a semiconductor are found in bands that are separated by a band gap—the lower band is the valence band while the upper band is called the conduction band. For example, GaAs has a bandgap of 1.424 eV. Furthermore, by doping intrinsic semiconductor materials with impurities, one can make n-type or p-type materials that have more or fewer negative current carriers.

Shortly after the invention of the first laser, the first semiconductor laser was demonstrated independently in 1962 by four research groups in the United States [25, 30, 44, 47]. These early devices are homojunctions operated at liquid nitrogen temperatures. When a current (defined as the flow of *positive* charges) is injected so that it flows through the junction from a p-type material into an n-type material, electrons from the n-type material will recombine with the holes from the p-type material, releasing a form of energy known as recombination energy. In an indirect-bandgap material such as silicon, this energy is released as vibrational energy and heat; on the other hand, in a direct-bandgap material such as gallium arsenide, radiation is emitted whose frequency is a function of the bandgap energy. In the absence of optical feedback, this device functions as a light-emitting diode (LED) where its output consists of incoherent spontaneous emission. However, feedback from reflective surfaces is made possible using the cleaved facets. Since the refractive index of a semiconductor is usually greater than 3.0, the reflectivity of each cleaved facet can be as high as 25% without any coatings.

By the late 1970s, semiconductor lasers are able to operate in CW mode at room temperature. These lasers utilize a double heterostructure (figure A1.6.10) to improve the confinement of light in the active region, resulting in lower threshold currents [2, 28]. Later, the incorporation of thin quantum wells into the heterostructure offers additional advantages such as low threshold current density, high efficiency, and high differential gain. Figure A1.6.11 shows that the threshold current density has been dramatically reduced by a factor of 10,000 since the early 1960s.

The technology of semiconductor lasers has been advanced to a point where, without realizing it, an average person owns at least a few of them. Examples are lasers used in CD or DVD players, in laser printers, and in laser pointers. In addition, in fibre optics communications, semiconductor lasers are used as transmitters and as EDFA and Raman pump lasers.

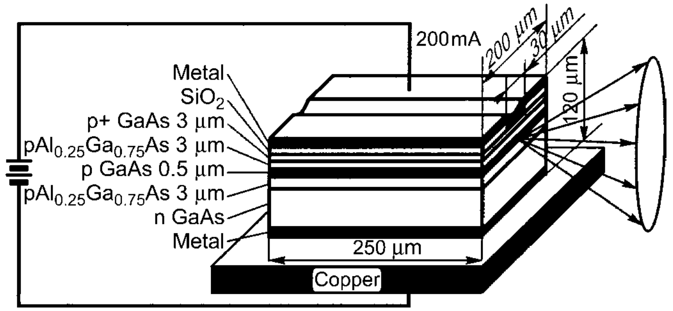

Figure A1.6.10. Schematic view of the structure of the first injection double-heterostructure laser operating in the CW regime at room temperature (from [2]).

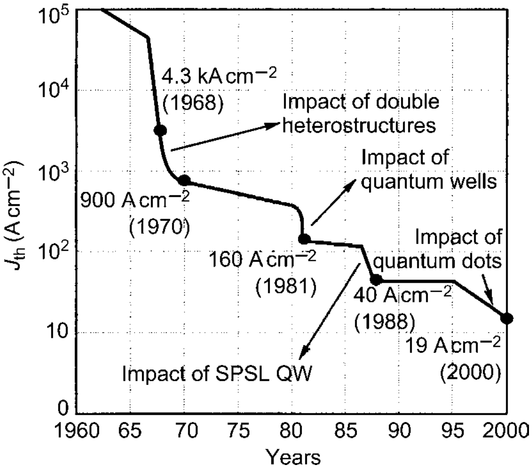

Figure A1.6.11. Improvements of the threshold current of semiconductor lasers over the last 40 years (from [3]).

A1.6.2.4 Short-pulse lasers

When the gain medium of a Fabry–Perot laser is homogenously broadened, only one single longitudinal mode oscillates. On the other hand, if the gain medium is inhomogenously broadened, for example, via spatial hole burning or spectral hole burning, a few longitudinal modes will oscillate, provided that their round-trip gain is greater than unity. These longitudinal modes are spaced evenly in the frequency domain with frequency spacing $\Delta v = c/2nL$, where n is the average refractive index inside the Fabry–Perot cavity, and c is the speed of light in vacuum. If we are able to lock these modes together such that their phases are fixed relative to one another, we can create a train of laser pulses at the output of a laser. This technique, known as modelocking, can be initiated actively using a time-varying amplitude modulation, or it can be triggered using a saturable absorber in the cavity whose transmissivity decreases with increasing optical intensity. Very short optical pulses can be generated from modelocked lasers because the electric field from the various longitudinal modes are coherent—they interfere constructively at the peak of the pulse while cancelling one another at the wings of the pulse.

To capture fast-moving images on film, a photographer uses a fast shutter setting. Since the speed of mechanical shutters is limited to milliseconds, improvement is made to capture faster events by illuminating the object with a stroboscope. As one of the pioneers in strobe-light photography, Edgerton captures the dramatic image of a rifle bullet piercing an apple in one of his high-speed photographs (figure A1.6.12). The photos are taken in a room with the lights turned off. When the bullet is fired, its shock wave is detected by a crystal microphone, which then triggers the strobe light. Edgerton's technique enables him to freeze a microsecond event onto a photographic negative. With the advancement of ultrafast laser research, nanosecond, picosecond, and subsequently, femtosecond laser pulses are available for scientists to 'freeze' and study physical and chemical processes in a very short time scale. In fact, some used to believe that the various chemical and biological processes, such as the breaking of chemical bonds and vision, were slow processes and did not occur in the femtosecond time scale, until photochemistry experiments using short laser pulses proved otherwise. These results can be explained by the fact that, since molecular motions occur over very short distances, they can be very fast.

Given the existence of the various techniques to produce femtosecond pulses, how does one measure the duration of these pulses? In general, to measure a fast event, one needs an even faster event in order to capture it, which is not often possible since the laser pulse in interest might be the

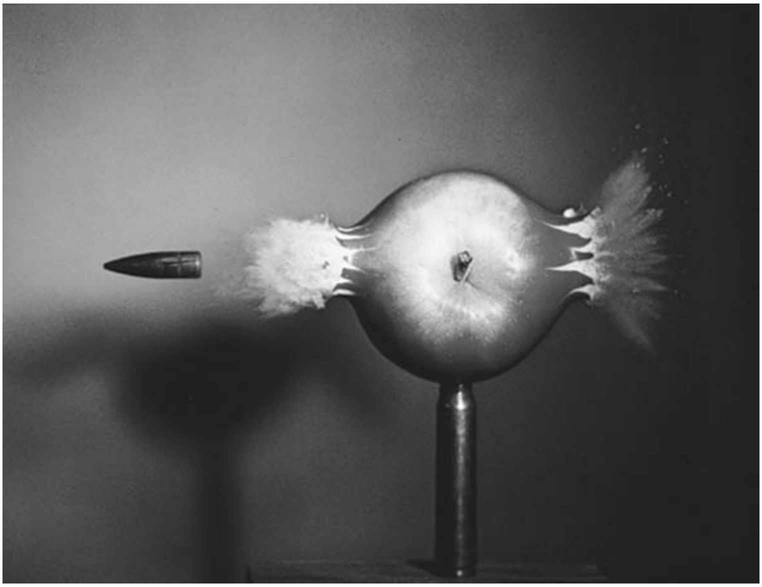

Figure A1.6.12. A microsecond exposure of a bullet travelling 2800 ft s^{-1} while piercing an apple (from http://www.geh.org/taschen/htmlsrc4/m199603470007_ful.html).

shortest event available. Likewise, researchers working in scanning-tunneling microscopy face a similar problem when they want to establish the spatial resolution of their system—the fine tip they use to probe the sample is often the finest man-made object that is available to them. In 1967, Weber found a partial solution; he suggested measuring the laser pulse width with the pulse itself by performing an intensity autocorrelation [71]. The optical pulse is split into two identical pulses using a beam splitter. The two pulses are then focused onto a nonlinear crystal that is capable of generating a second harmonic. The second harmonic generated will be collected in a photomultiplier tube while the temporal delay between the two pulses is varied. For example, the largest amount of signal is obtained when the two pulses overlap temporally. This operation is identical to performing an autocorrelation function mathematically, from which the approximate pulse duration can be deduced. Although it is a clever technique, the autocorrelation method does not yield complete details about the intensity profile of the pulse. Nor does it provide any information regarding the phase or the chirp of the optical pulse.

Ideally, one would like to get pulse information in both time and frequency domains, which is usually referred to as a spectrogram. It is analogous to the musical score for a symphony, informing musicians which notes to play at a given time. It was not until 1993 that researchers developed a novel method to retrieve to obtain the spectrogram of an optical pulse. Using a technique called frequency-resolved optical gating [32], or FROG, they measured the optical spectrum of the autocorrelation and then applied a phase retrieval algorithm to obtain the final spectrogram. Their algorithm works because knowledge of only the magnitude of a two-dimensional Fourier transform of a function of two variables uniquely determines the function (both phase and magnitude), provided that the function is well behaved. Figure A1.6.13 shows that both the intensity autocorrelation and the interferometric autocorrelation cannot distinguish positively chirped pulses from negatively chirped ones. On the other hand, the spectrogram extracted using FROG resolves this ambiguity as it contains complete amplitude and phase information about the optical pulse.

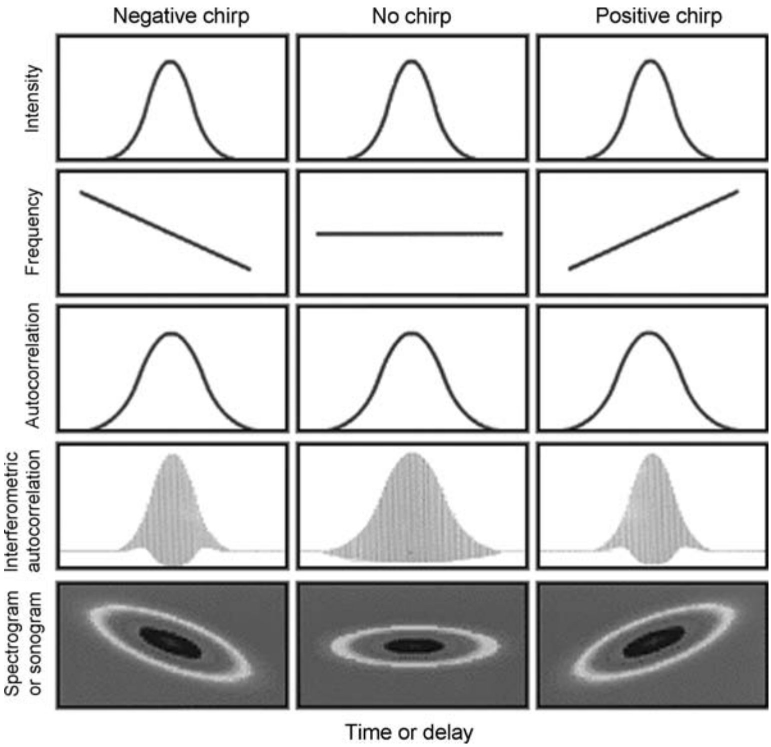

Figure A1.6.13. The intensity versus time, the frequency versus time, the intensity autocorrelation versus delay, the interferometric autocorrelation versus delay, and spectrograms (or sonograms) of negatively chirped, unchirped and positively chirped Gaussian-intensity pulses. In the spectrograms, the vertical axis is frequency and the intensity is colour-coded. Note that the autocorrelation and interferometric autocorrelation cannot distinguish positive from negative chirp, while the spectrogram and sonogram can (from [70]).

A1.6.3 Optical amplifiers

A1.6.3.1 Basics of optical amplifiers

Optical amplifiers are used to boost the optical power of the input optical wave. Optical amplifiers are essentially 'single-pass' lasers, or 'lasers' without the two (reflective) mirrors. Just as in the case of lasers, the gain medium is 'inverted' and provides stimulated emission when there is an input optical wave. In principle, all types of lasers can be converted into optical amplifiers. For simplicity, we will use optically pumped amplifiers in the following discussions. In such amplifiers, three optical waves are present, the pump wave that provides the inversion in the gain medium, the input optical wave that is the input signal to be amplified, and the output wave that has been amplified in the amplifier.

There are different applications for various types of optical amplifiers. Accordingly, the parameters of interest also vary. For example, the gain is an important parameter for laser fusion, while noise is essential for telecom applications. In general, the three commonly used parameters are gain, output power, and noise figure.

Gain is defined to be the ratio between the output power and input power, where it is usually measured in decibels. Unity gain, or 0 dB, means no gain or loss. On the other hand, most practical optical amplifiers operate in gain regions much higher than 1. A typical gain curve is shown in

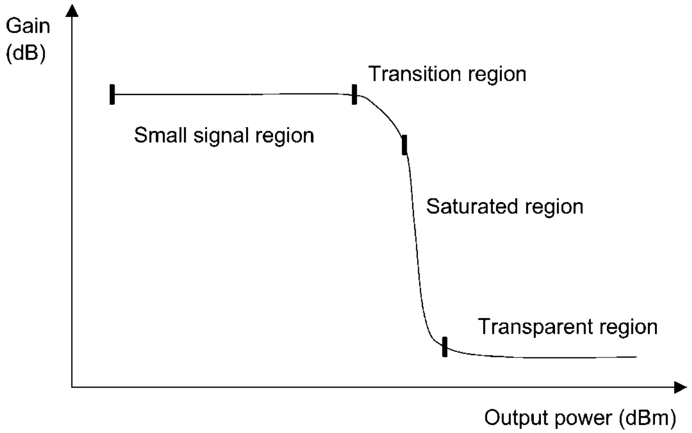

Figure A1.6.14. Gain versus output power for a fixed pump power.

figure A1.6.14 as a function of output power for a fixed pump power. The gain is also commonly plotted as a function of input power. There are four regions in this saturation curve: the small signal region, the transition region, the saturated region, and the transparent region.

In the small signal region, the input power is low, and the gain remains constant when input power changes. The inversion in the gain medium is determined only by the amount of pump power and is independent of the weak input optical power. An advantage for this operation region is that the amplifier's gain value remains constant. However, the photon conversion efficiency from pumps to signals is low. Most of the pump photons are not converted into signal photons, but into spontaneous emission or heat or other forms of energy.

As input power increases into the transition region, the interaction between the signal and the gain medium gets stronger. In this region, the signal starts to deplete the gain medium and the inversion level starts to drop. This causes the gain to decrease when input power increases.

When the input power is high, the amplifier works in the saturated region where the gain drops sharply with increased input power. The inversion level is low and the photon conversion efficiency from the pump wave to the signal wave is high. This is a common operation region for amplifier design in order to make efficient use of the pump power. In this highly saturated region, the output power changes very little as input power varies, as shown in figure A1.6.14.

In the limit of high input power, the amplifier moves into the transparent region where the pump is relatively weak and the input optical wave essentially bleaches through the medium. There are approximately equal number of atoms in the upper level and in the lower level. No practical amplifiers are designed to work in this region.

During the amplification process, spontaneous emission from the gain medium may add to the optical signal wave. Noise figure is the parameter to measure how much noise is added in the amplifier. A low noise figure is important for telecom applications, as we desire to minimize the degradation of the signal-to-noise ratio when a signal is amplified. The quantum limit for a practical optical amplifier is 3 dB [1]. Under the assumption of high-gain operation for the amplifier, high inversion level allows for low noise figure while low inversion level yields high noise figure.

There are other parameters that need to be considered when designing an amplifier, such as reliability, size, cost, etc. We will not discuss the details here as they are beyond the scope of this chapter. In the following sections, we will cover four types of amplifiers—erbium-doped fibre amplifiers

(EDFAs), Raman optical amplifiers (ROAs), semiconductor optical amplifiers (SOAs), and amplifiers that are built to amplifier short pulses.

A1.6.3.2 Erbium-doped fibre amplifiers (EDFAs)

Perhaps the most well-known optical amplifier is the EDFA that was first reported in 1987 [12, 40]. Traditionally, the so-called O–E–O signal regeneration was used in optical communication systems, where optoelectronic regenerators are installed between terminals to convert signals from the optical domain to the electrical domain, and then back to the optical domain. Since its invention, EDFA has revolutionized optical communications. Unlike optoelectronic regenerators, this optical amplifier does not require high-speed electronic circuitry and is transparent to data rate and format, which dramatically reduces system cost. EDFAs also provide high gain, high output power, and low noise figure. We will introduce several new important EDFA features and parameters below.

(a) *Energy levels*. The energy levels of the erbium ion and the associated spontaneous lifetime in the fibre glass host are shown in figure A1.6.15. The energy difference between the upper level and the lower level is such that the photons generated are in the 1.5 μm transmission window of an optical fibre. The gain spectra at different inversion levels are shown in figure A1.6.16. Erbium-doped fibre can be pumped by semiconductor lasers at either 980 or 1480 nm. The rapid improvements in semiconductor pump lasers have made the EDFA possible for practical applications. A three-level model can be used for 980 nm pumps while a two-level model usually suffices for 1480 nm pumps [20, 61]. Complete inversion can be achieved with 980 nm pumping but not with 1480 nm pumping [61]. Because of the photon energy difference, the quantum efficiency is higher with 1480 pumping.

(b) *Dynamics*. The spontaneous lifetime of the excited energy level is about 10 ms, which is much slower than the signal bit rates of practical interest. Because of the slow dynamics, an EDFA only experiences the averaged optical power for the practical date rates. As a result of the slow dynamics, inter-symbol distortion and inter-channel crosstalk are negligible even when the EDFAs are working in the saturated region. Besides, since all of the optical signal channels can be amplified simultaneously in one erbium-doped fibre, the EDFA has become a key enabler for the widely used wavelength-division multiplexing (WDM) technology. This is a significant advantage for EDFAs.

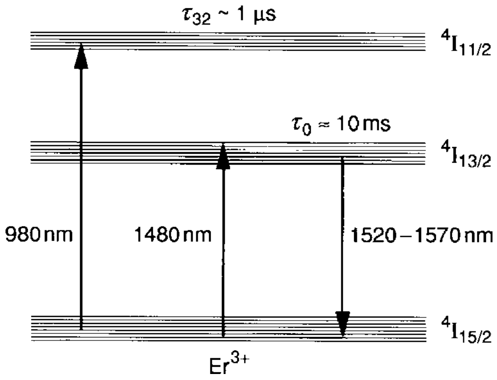

Figure A1.6.15. The energy levels of erbium ion in optical fibre (from [61]).

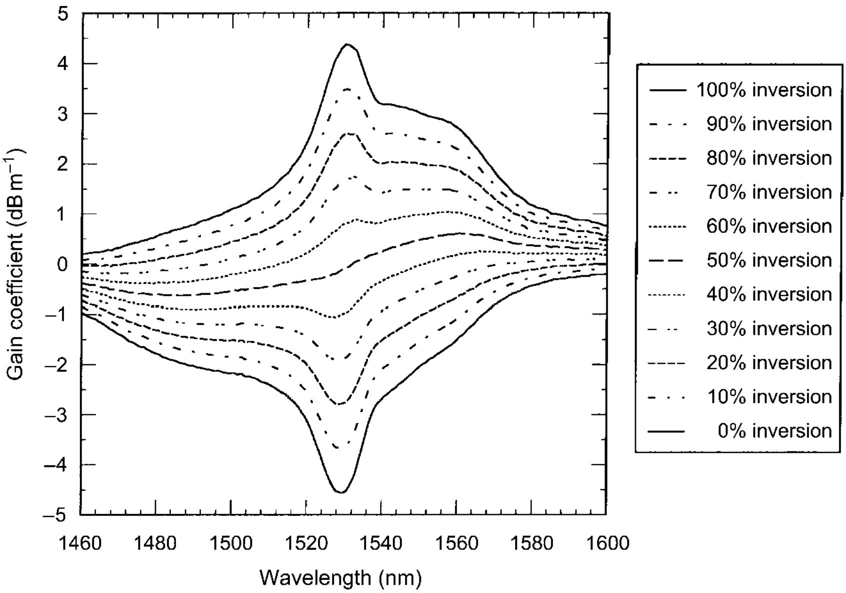

Figure A1.6.16. Gain spectra of erbium-doped fibre (from [61]).

(c) *Bandwidth.* For WDM applications, since uniform gain is desired for all the signal channels, bandwidth is another important parameter for EDFAs. From figure A1.6.16, we can see that the gain is flat somewhere between 1540 and 1560 nm for an inversion level of approximately 50%. Actually, it is this generic flat gain band that was used in initial WDM systems.

Significant progress has been made in amplifier design to achieve excellent performance. Several key techniques are discussed below:

(a) *Multi-stage design.* In order to achieve both low noise figure and high output power, two or more gain stages are usually used where the input stage is kept at a high inversion level and the output stage is kept at a low inversion level [11, 52]. For optical amplifiers with two or more gain stages, the overall noise figure is mainly decided by the high gain input stage and the output power is basically determined by the strongly saturated output stage. The passive components have minimal impact on the noise figure and the output power when they are in the middle stage.

(b) *Gain equalization filter.* A wide bandwidth is desired to accommodate a large number of optical channels. To fully utilize the gain band between 1530 and 1565 nm, gain equalization filters (GEFs) can be used to flatten the gain spectrum. Several technologies have been investigated to fabricate GEFs, including thin film filters, long period gratings, short period gratings, silica waveguide structure, fused fibres, and acoustic filters. Depending on the design, a bandwidth of 35–40 nm can be obtained in the C-band [73]. This kind of amplifier with 35 nm of flat bandwidth was used in the long distance transmission of 32 and 64 channels at 10 Gb s^{-1} [62], and has since become the commonly used bandwidth for C-band communication systems.

(c) *L-band operation.* Because the gain drops sharply on both sides of C-band at the inversion level discussed above, it is not practical to further increase the bandwidth with a GEF. On the other hand, a flat gain region between 1565 and 1615 (L-band) can be obtained at a much lower inversion level [39]. To achieve comparable gain as the C-band, a longer piece of erbium-doped fibre or higher erbium doping would be needed. By combining C-band and L-band, a much wider bandwidth can be realized [63]. Such ultra-wide-band optical amplifiers have made possible high-capacity communication systems at terabits/second or higher [57].

(d) *Large dynamic range.* For commercial systems deployed in the field, the fibre span length and loss varies from location to location. A large dynamic range in the amplifier gain is required for in-line optical amplifiers. Optical attenuators can be used in the middle stage to increase the dynamic range of EDFAs. Such amplifiers can provide flat spectrum and good noise figure when span loss varies.

(e) *Dispersion compensation.* Dispersion compensation is needed for high-speed optical channels and can be done with dispersion compensating fibre. Such compensation is best done on a span-by-span basis. The dispersion compensation modules (DCM) are usually inserted in a middle stage in the EDFAs to optimize the overall optical performance. Typically a middle-stage loss of about 10 dB is reserved for the plug-in of DCM.

In the above discussion, we mainly dealt with the static features of EDFA. In the event of either a network reconfiguration or a failure, the number of WDM signals traversing the amplifiers would change. As a result, the power of the surviving channels would increase or decrease due to the cross-saturation effect in amplifiers. Dropping channels can give rise to surviving channel errors since the power of these channels may surpass the threshold for nonlinear effects such as Brillouin scattering. The addition of channels can cause bit errors by depressing the power of the surviving channels to below the receiver sensitivity. To overcome such error bursts in surviving channels in the network, the signal power transients have to be controlled. Because of the saturation effect, the speed of the gain dynamics in a single EDFA is in general much faster than the spontaneous lifetime of about 10 ms [61]. The time constant of gain dynamics is a function of the saturation caused by the pump power and the signal power. The time constant of gain recovery on single-stage amplifiers was reported to be between 110 and 340 μs [19].

In a recent work, the phenomena of fast power transients in an EDFA chain was reported [76]. Even though the gain dynamics of an individual EDFA is unchanged, the rate of change of the channel power at the end of the system becomes faster for longer amplifier chains. This fast gain dynamics results from the effects of the collective behaviour in a chain of amplifiers. The output of the first EDFA attenuated by the fibre span loss acts as the input to the second EDFA. Since both the output of the first EDFA and the gain of the second EDFA increase with time, the output power of the second amplifier increases at a faster rate. This cascading effect results in faster and faster transients as the number of amplifiers increase in the chain. To prevent performance penalties in a large scale WDM optical network, surviving channel power excursions must be limited to certain values depending on the system margin. Several control schemes have been studied, including pump control [13], link control [56], and laser control [75].

Considerable progress has been made in optical amplifiers in recent years. The bandwidth of amplifiers has increased nearly seven times and flat gain amplifiers with 84 nm bandwidth have been demonstrated. This has been made possible by the addition of the L-band branch. With the advent of these amplifiers, commercial terabits/second lightwave systems will be realizable. Research is underway to develop amplifiers outside the erbium fibre band. Raman amplifiers and semiconductor amplifiers are also potential candidates for amplification across the entire silica fibre transmission band. Progress has also been made in the understanding of gain dynamics of amplifiers. Several control schemes have been successfully demonstrated to mitigate the signal impairments due to fast power transients in a chain of amplifiers and will be implemented in lightwave networks. The terrestrial lightwave systems have been increasing in transmission capacity. To meet the enormous capacity demand the currently available

$400\,\mathrm{Gb\,s^{-1}}$ capacity system with 40 channels will soon be followed by systems having terabits/second and higher capacity on a single fibre.

A1.6.3.3 Raman optical amplifiers

Distributed Raman amplification using optical fibres is an old and yet emerging technology that can supplement the functionality of EDFAs in high-speed ($\geq 10\,\mathrm{Gb\,s^{-1}}$) long-haul transmission systems. Before the advent of the EDFAs, ROAs were used to re-amplify solitons in a re-circulating loop (figure A1.6.17) in order to demonstrate the feasibility of long-haul soliton transmission [42]. Major advantages of using ROAs include low-noise characteristics in distributed mode operation, flexible gain allocation, wide gain bandwidth, and simple construction.

The amount of Raman scattering and its spectrum depend on the material. For silica, which is an amorphous material, the peak Raman gain is at 13.2 THz lower than the pump frequency, which corresponds to a wavelength of about 100 nm longer than the pump at 1450 nm [15, 59]. One can modify the operating gain shape and flatness of the Raman optical amplifier by choosing pump wavelengths and pump powers. For example, one can readily make Raman amplifiers to operate in the S-band (1485–1525 nm) or in the L+ (1604–1640 nm) band. The pump scheme is relatively simple because one only needs to launch the pump light into the fibre via a wavelength-dependent coupler (WDC) or an optical circulator.

The process of Raman scattering can be viewed as the modulation of light (the pump) by molecular vibrations in a material, which are referred to as optical phonons [29]. Upper and lower sidebands appear in the scattered light spectrum because the frequency of the pump is both up-shifted and down-shifted by the optical phonon. At high temperatures, the two sidebands are of equal intensity; however, at room temperature, the lower frequency sideband is favoured. So far we have described the process of

Figure A1.6.17. The first optical transmission system using Raman optical amplifiers (from [42]).

spontaneous Raman scattering, which was discovered by Sir Raman in 1928 [48]. One can stimulate the process by injecting both the pump and the down-shifted signal into the medium. In this case, the two optical waves will beat together to stimulate the optical phonon, which in turn, will cause more pump to convert into the signal. This is known as stimulated Raman scattering, which was observed 34 years later by Woodbury and Ng [72]. One direct consequence is that the input is amplified coherently and the medium acts like a distributed optical amplifier.

The distributed nature of the Raman amplification provides an advantage to the overall noise performance. As much as 5 dB of improvement in the optical signal-to-noise ratio (OSNR) can be achieved with 10–15 dB of distributed Raman gain. Signal is amplified along the fibre length such that the amount of noise generated in the amplification process is less than that of a lumped amplifier placed at the end of the same fibre span, where signal strength is the weakest. The Raman on–off gain (in decibels), defined as the signal gain with, and without pumps, is proportional to the Raman gain coefficient, the effective length, and the pump intensity. It is also inversely proportional to the fibre effective area (see figure A1.6.18).

Although ROAs hold promise for telecommunication applications, they also have some drawbacks in certain applications compared with those of EDFAs. First, the low efficiency in converting pump power to signal power implies that there is a need for high pump powers. Note that high-power semiconductor pump lasers, which were only available recently, was the main driver for the re-emerging of ROAs. The high-pump-power requirement is generally not desirable for several reasons, such as personnel safety concerns and components reliability concerns. Secondly, the relatively long length of fibre in a ROA allows Rayleigh-related reflection to degrade the performance of a telecommunication system. Typically, the fibre lengths of ROAs are of the order of several kilometres. These Rayleigh-related effects include multiple-path interference (MPI), double-Rayleigh backscattering noise (DRS), and ROA instability, all of which become more severe when pump power is increased [36]. In addition, the fast Raman response time causes time-dependent deleterious effects such as inter-channel cross-talk and the transfer of pump noise to the signal [10]. This is an important constraint for ROAs where the pumps are co-travelling in the same direction as that of the signals. Lastly, similar to EDFAs, ROAs also exhibit transient effects when the input signal power fluctuates [9].

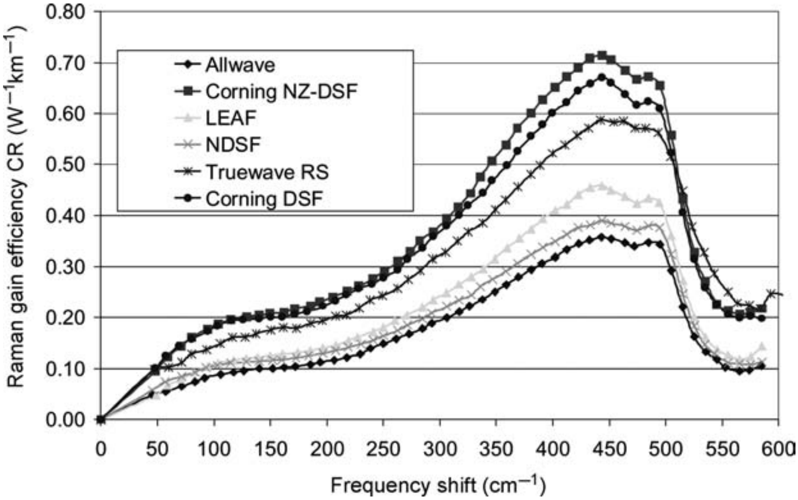

Figure A1.6.18. Raman gain as a function of fibre type (from [15]).

Through careful amplifier and system design, we can overcome some of the problems in ROAs. Nowadays, it is common, especially in laboratories, to combine ROAs and EDFAs to achieve the optimal performance in optical transmission. Several recent $40\,\mathrm{Gb\,s^{-1}}$ transmission experiments rely on distributed Raman gain in order to achieve record-breaking performance. For example, multi-terabits/second transmission experiments over several thousand kilometers were carried out [8, 16, 17, 24].

The quest for higher capacity is, and will still be the focus of transmission research since higher capacity transmission may provide an economic advantage. Increasing the signal-to-noise-ratio using Raman amplifiers is one effective approach. Together with other technologies such as sophisticated coding schemes (forward-error correction, etc), new modulation format, new multiplexing schemes, and higher-quality fibres, the transmission capacity is constantly increasing. Recently, research teams demonstrated $40\,\mathrm{Gb\,s^{-1}}$ transmission using a 100 GHz channel spacing for ultra-long-haul (>3000 km) systems, yielding a high spectral efficiency of $40\,\mathrm{Gb\,s^{-1}}/100\,\mathrm{GHz} = 0.4\,\mathrm{b\,s^{-1}\,Hz^{-1}}$. In the years to come, even more efficient use of available fibre spectrum and higher spectral efficiency are likely to take place. Transmission of multi-terabits/second over long distances will be achieved.

A1.6.3.4 Semiconductor optical amplifiers

SOAs, because of their small physical size, low-cost, and electrical pumping, are ideal amplifiers to be used in low-cost telecommunication systems. To achieve gain in the medium, the semiconductor material is excited to achieve population inversion. There exists two types of SOAs—travelling-wave amplifiers, and Fabry–Perot amplifiers. In the former, the input signal travels from the input port to the output port in the forward direction only, which is made possible by minimizing the reflectivity at the cleaved facets via an antireflection coating. The reflectivity can be reduced further by using angled facets. For Fabry–Perot amplifiers, the input signal is partially reflected at each facet as naturally cleaved facets are used. Because of its resonant nature, the output power of Fabry–Perot SOAs is limited to -10 dBm, while the output power of travelling-wave SOAs can exceed $+13$ dBm.

The gain spectrum of SOAs can be engineered to be as broad as 100 nm. Moreover, through the choice of the material composition (GaAlAs, InGaAlP, InGaAsP, etc), they can operate in the visible or in the near-infrared (1.3–1.6 μm). Since the typical noise figures of SOAs are in the range of 7–9 dB, the use of SOAs has been limited to short-haul (100–200 km) transmission experiments [55, 64].

In a quest to boost output power of a laser, a master-oscillator power-amplifier (MOPA) design is used, where the output of a laser, acting as an oscillator, is amplified subsequently in a booster section. Greater than 1 W of output power is achievable in monolithically integrated MOPAs [41].

SOAs possess undesirable characteristics that must be overcome with clever engineering solutions. For example, the polarization-dependent gain (PDG) of an SOA can be as high as 6 dB. One method to mitigate the polarization effect is to use polarization diversity, where the input optical signal traverses an SOA twice, one in each orthogonal polarization. Another method of growing strained multiple quantum wells in the active region reduces the amount of PDG to below 1 dB [7].

Because the carrier lifetime in SOAs is as short as 500 ps, its fast gain dynamics, together with its relatively low saturation power, induce cross-gain saturation, when the input signal consists of multiple wavelength channels. In other words, if the SOA is used in a WDM system, the instantaneous gain of a given wavelength channel is saturated not only by its channel power, but also by the combined instantaneous power (bit pattern) of the remaining channels. This deleterious effect can be counteracted by (i) operating the SOA in the quasi-linear regime, hence reducing the output power per channel [55], (ii) adding a strong saturating tone to the input signal to act as a reservoir [64], (iii) using polarization multiplexing [58], and (iv) not using intensity modulation on the optical carrier, but using frequency or phase modulation instead [33].

A1.6.3.5 Short-pulse amplification

Although the intensity of a moderate laser beam can be high when it is focused to a spot, on-going work has never stopped in building laser amplifiers to generate higher power laser beams. One limiting factor in amplifying short pulses is the excessive nonlinearity generated when the short pulse passes through the gain medium. Nonlinear effects encountered include (i) self-focusing, which causes the laser beam to collapse to a focal point with catastrophic results; (ii) spatial filamentation of the input beam; (iii) excessive self-phase modulation, where the intensity-dependent phase shift degrades the temporal quality of the output pulse. In other words, in typical high-power short-pulse laser systems, it is the peak intensity, rather than the energy or the fluence, that causes pulse distortion or laser damage. Previously, large laboratories, such as the Lawrence Livermore National Laboratory, construct lasers and amplifiers with large beam diameters as an expensive way to increase the laser power while keeping the intensity below nonlinear effects. CPA overcomes the problem by pre-stretching the input pulse using a dispersive diffraction grating pair and then compressing the output pulse using another pair of diffraction gratings (figure A1.6.19) [60]. Since the optical pulse remains dispersed as it traverses the amplifying medium, the amount of nonlinearity experienced by the optical pulse is minimized. By 1990, this technique has been used to boost the peak power of an incoming laser pulse to over 10 TW (10×10^{12} W) levels (figure A1.6.20). Since the maximum intensity is limited to $10^{12}\,\mathrm{W\,m^{-2}}$ without using CPA, the pulse energy is therefore boosted 10 billion-fold. Although this optical pulse lasts a few tens of femtoseconds only, its instantaneous peak power is equal to the power output from the entire electrical grid in the world. When focused onto a small spot, one can create high-energy pulses with intensities as high as $10^{22}\,\mathrm{W\,m^{-2}}$, thus opening up new and exciting areas in nonlinear optics. For example, electrons are accelerated to relativistic velocities in the so called 'table-top accelerators'. To avoid excessive gain saturation in the amplifier, the repetition rate of the incoming pulse train is often reduced using a pulse-selecting Pockels cell. Incidentally, the concept of CPA is also used in chirped

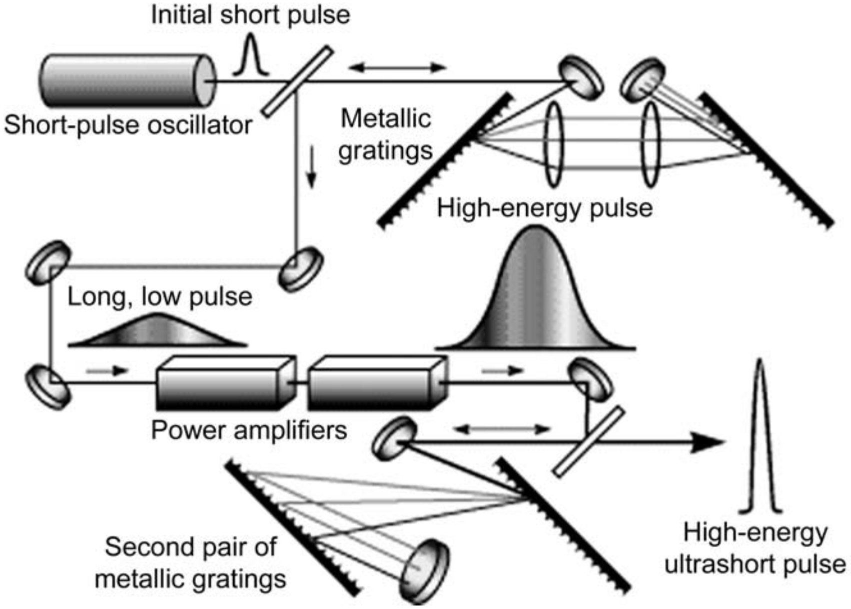

Figure A1.6.19. The concept of chirped pulse amplification (from http://www.llnl.gov/str/Petawatt.html).

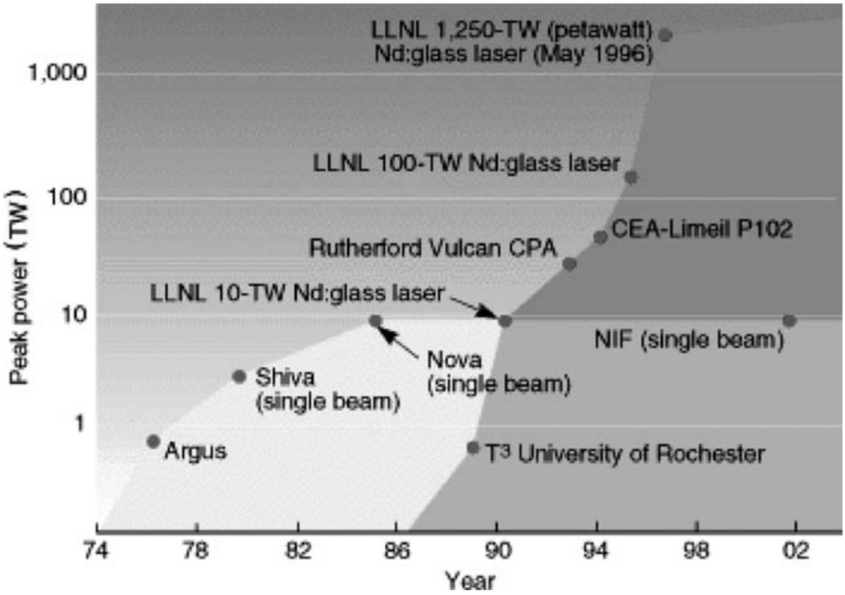

Figure A1.6.20. Milestones in the advancement of laser peak power. The darkest shaded region at upper right indicates that the laser pulses are amplified using chirped pulse amplification (from http://www.llnl.gov/str/Petawatt.html).

radar systems—in order to avoid saturating the power amplifier in the transmitter, the millimetre radar pulse is stretched in time (linearly chirped) by a surface acoustic wave (SAW) acting as a dispersive delay line, before it is amplified and emitted. A pulse-compression filter is then used in the receiver to demodulate and compress the return signal into a shorter pulse, which results in a higher range resolution than radar systems not using chirped pulses.

FCPA-2
FCPA-2

Figure A1.6.21. IMRA America, Inc.'s turn-key oscillator-amplifier laser system (from www.imra.com).

Using the latest technological advances in pump laser, rare-earth-doped fibre, control electronics, and packaging, vendors are now offering turn-key table-top systems utilizing CPA. For example, IMRA's oscillator-amplifier laser system can produce high-energy femtosecond pulses with peak powers as much as 10 MW (figure A1.6.21). The diode-pumped system uses CPA in a large-core Yb-doped fibre amplifier. Since optical fibre is an excellent medium to be used as a temperature sensor, the entire system is packaged athermally to achieve good frequency stability and low pulse-timing jitter.

A2.1
Advanced optics

Alan Rogers

A2.1.1 Introduction

The practice of optoelectronics at the level of device and system design necessitates a familiarity with some quite advanced, and sometimes quite subtle, optical physics. This chapter will deal, at a fairly fundamental level, with those topics which the author considers most important for an appreciation of present-day optoelectronics.

The topics chosen naturally are concerned with the properties of light and its control by waveguides, and with those properties of solid materials relevant to their interactions with light radiation.

Many of the basic ideas which are needed to understand these processes have already been introduced in earlier chapters; in this chapter, however, we shall need to extend and refine the coverage to the point where we can understand the structure and operation of specific optoelectronic devices. These devices depend, in most cases, on the physics of optical radiation and of the solid state, in a fairly detailed way.

It is thus necessary to gain a more detailed familiarity with this physics, since it lies at the heart of the subject, and without this knowledge it would be impossible either to understand properly existing optoelectronics or to progress to new devices and new systems beyond our present-day thinking.

We shall begin by looking at the physics of radiation.

A2.1.2 The physics of radiation

A2.1.2.1 Black-body radiation

All matter, provided that it has a temperature other than absolute zero, emits radiation. This is a consequence of the fact that a temperature above absolute zero implies that the atoms or molecules are in motion, and are thus colliding with each other constantly. These collisions transfer kinetic energy of motion, but also sometimes excite the atomic system to a higher state, from which it may relax by emitting a photon. This is a consequence of a very basic principle in physics, the ‘law of equipartition of energy’, which states that the energy of a system, in equilibrium, will be distributed equally among all possible degrees of freedom: the kinetic energy of a material is one such degree, excited states represent another. By assigning a temperature to a body, we require it to be in thermal equilibrium with its surroundings (i.e. there is no net heat gain from, or loss to, the surroundings over time), so equipartition must apply.

The first question which naturally arises now is: how much radiation is emitted by a body at a given temperature? And the second (perhaps not quite as naturally!) is: what is the distribution of this emitted radiation over the wavelength spectrum?

In answering these questions, we shall explore ideas which are valuable for a whole range of topics in optoelectronics, and more general physics, so it is worth while taking some time over them.

Classical thermodynamics assumed that atoms emitted light as a result of radiation by electrons which were oscillating at natural resonant frequencies within the atoms. It further assumed (it had no reason to assume otherwise) that these oscillations could occur with any amount of energy, depending on the strength of the stimulus.

The other piece of information which the classical thermodynamicists needed before they could proceed was the Boltzmann factor. This tells us the ratio of the number of atoms which have energy E_1 compared to those with energy E_2 in a system in equilibrium at absolute temperature T, and takes the form [1]:

$$\frac{N_1}{N_2} = \exp\left(-\frac{E_1 - E_2}{kT}\right)$$

where k is Boltzmann's constant, with value $1.38 \times 10^{-23}\,\mathrm{J\,K^{-1}}$. This factor had already been derived, using classical statistical thermodynamics, by means of an exquisite argument (which we do not have space to develop, but see any text on statistical mechanics).

Let us now derive the classical result for the radiation emitted by a 'perfect' body, i.e. a body capable of emitting or absorbing radiation of any wavelength and thus containing oscillators (atoms or molecules) capable of oscillating at any frequency. Such a body is called a 'black' body since it absorbs, rather than reflects, all light falling upon it, and therefore looks 'black' (until it emits!). Such a body is a valuable idealization, since we can categorize 'real' bodies according to how closely they approximate to it.

Let us suppose that within this black body the oscillators can have any energy and (for reasons which will become clear later) these energies will be described as a set distributed as:

$$0, \mathrm{d}E, 2\mathrm{d}E, \cdots, n\mathrm{d}E, \cdots$$

where dE is infinitesimally small, so that the distribution is continuous. The ratios of numbers of oscillators with each of these energy bands will comprise the set (according to the Boltzmann factor):

$$1 : \exp\left(-\frac{\mathrm{d}E}{kT}\right) : \exp\left(-\frac{2\mathrm{d}E}{kT}\right) : \cdots : \exp\left(-\frac{n\mathrm{d}E}{kT}\right) : \cdots.$$

Thus if there are N oscillators with zero energy, the total number of oscillators will be:

$$N_\mathrm{T} = N\left[1 + \exp\left(-\frac{\mathrm{d}E}{kT}\right) + \exp\left(-\frac{2\mathrm{d}E}{kT}\right) + \cdots + \exp\left(-\frac{n\mathrm{d}E}{kT}\right) + \cdots\right].$$

This is a geometrical progression which is easily summed to give:

$$N_\mathrm{T} = \frac{N}{1 - \exp\left(-\dfrac{\mathrm{d}E}{kT}\right)}. \tag{A2.1.1}$$

Also, the total energy of all the oscillators is given by multiplying each term by its energy allocation:

$$E_\mathrm{T} = N\left[\mathrm{d}E\exp\left(-\frac{\mathrm{d}E}{kT}\right) + 2\mathrm{d}E\exp\left(-\frac{2\mathrm{d}E}{kT}\right) + \cdots\right.$$
$$\left. + n\mathrm{d}E\exp\left(-\frac{n\mathrm{d}E}{kT}\right) + \cdots\right]$$

giving, on summation,

$$E_{\mathrm{T}} = \frac{N\mathrm{d}E}{\exp\left(\frac{\mathrm{d}E}{kT}\right)\left[1 - \exp\left(-\frac{\mathrm{d}E}{kT}\right)\right]^2}. \tag{A2.1.2}$$

On dividing equation (A2.1.2) by equation (A2.1.1) we obtain the mean energy per oscillator as:

$$\bar{E} = \frac{\mathrm{d}E}{\exp\left(\frac{\mathrm{d}E}{kT}\right) - 1}. \tag{A2.1.3}$$

We may now let $\mathrm{d}E \rightarrow 0$ to discover the physical value for this mean energy, whereupon we find (expanding the exponential in the denominator):

$$\bar{E} = \lim_{\mathrm{d}E\rightarrow 0} \frac{\mathrm{d}E}{1 + \frac{\mathrm{d}E}{kT} + \frac{1}{2}\left(\frac{\mathrm{d}E}{kT}\right)^2 + \cdots - 1}$$

or

$$\bar{E} = kT. \tag{A2.1.4}$$

(This is entirely in accordance with other 'equipartitional' approaches which allow $kT/2$ of energy per degree of freedom. In our case there are two degrees of freedom per oscillator, one for kinetic energy, the other for potential energy, giving kT in all.)

The final piece of information we need is the number of independent oscillations which can occur within a given volume of material. Clearly, the fact that the volume is finite means that there are boundaries and these impose boundary conditions on the oscillations, just as a string stretched between two fixed points is bounded by the fact that any oscillation of the string must have zero amplitude at the points of fixation.

Let us simplify things by taking the volume to be a cube of side l (figure A2.1.1(*a*)): suppose now that oscillations occur within the cube and that the velocity with which these propagate is c. The walls of the cube impose a zero-amplitude boundary condition for these oscillations, so the resonant oscillations can only occur parallel with the sides of the cube with frequencies $nc/2l$, n being a positive integer and $c/2l$ the fundamental.

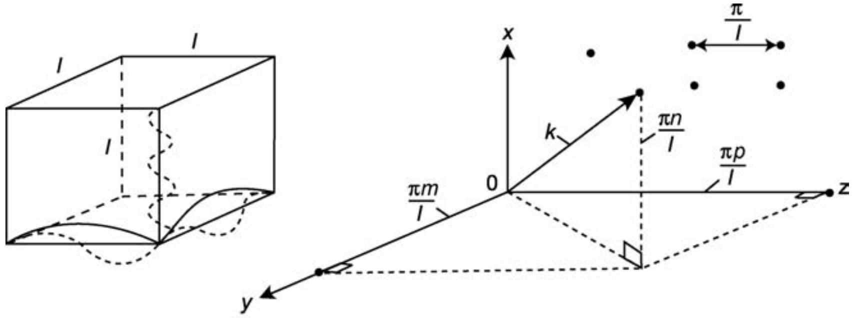
Now waves can, of course, travel in many directions and we can best represent any given wave by its wave vector $\boldsymbol{k}$, which has the same direction of the wave and an amplitude $2\pi/\lambda$, where λ is the wavelength. We may now write the frequencies of the waves travelling parallel to the sides of the cube as:

$$f_n = \frac{nc}{2l}$$

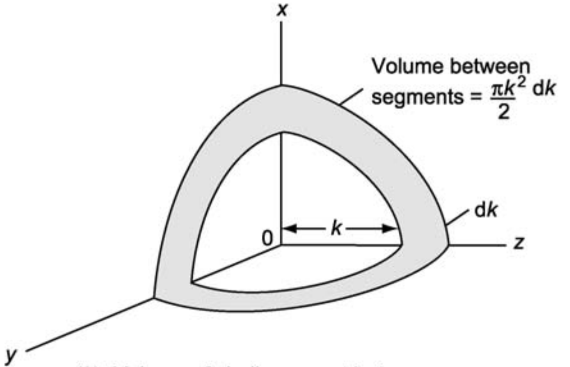
and the wavenumbers as:

$$k_n = \frac{2\pi}{c} f_n = \frac{\pi n}{l}. \tag{A2.1.5}$$

Let us now take axes Ox, Oy, Oz parallel with the sides of the cube and plot in three dimensions a lattice of points corresponding to all the k_n in equation (A2.1.5). It is easily seen that *any* oscillation for the cube can be represented by its wave vector from the origin of axes to one of the points we have plotted. The plot is often called 'k-space', for obvious reasons.



(*a*) Waves in a bounded cube, and '*k*-space'



(*b*) Volume of shell segment in *k*-space

Figure A2.1.1. *k*-space diagram.

We now ask the question: how many oscillations can the cube support with wavelengths between k and $k + \mathrm{d}k$? This, we can see, will correspond to the number of points on our plot which lie in the volume between spheres of radius k and $k + \mathrm{d}k$, respectively. This volume in k-space is, $4\pi k^2 \mathrm{d}k$ (figure A2.1.1(*b*)). However, since only positive values of n are valid we only need that octant of the spherical shell where all the axes are positive, which is one-eighth of the total, i.e. $\pi k^2 \mathrm{d}k/2$. To find the number of points in this volume we divide by one elementary volume in our lattice, defined by the interval between points, i.e. a cube of side π/l, volume π^3/l^3.

Hence the number of oscillations between k and $k + \mathrm{d}k$ is

$$N_0' = \frac{\frac{1}{2}\pi k^2 \mathrm{d}k}{\pi^3/l^3} = \frac{k^2 l^3 \mathrm{d}k}{2\pi^2}$$

and if we allow two orthogonal linear polarizations per oscillation (any electromagnetic wave can always be resolved into two such components) this becomes:

$$N_0 = \frac{k^2 l^3 \mathrm{d}k}{\pi^2}.$$

Since the volume of our original cube is l^3 we can express this in the form of a number of oscillations per unit volume:

$$N_{\mathrm{v}} = \frac{k^2 \mathrm{d}k}{\pi^2}. \tag{A2.1.6a}$$

It is now more convenient to write N_{v} in terms of frequency (since frequency is more directly related with energy). We have

$$k = \frac{2\pi}{\lambda} = \frac{2\pi f}{c}.$$

Hence

$$N_{\mathrm{v}} = \frac{8\pi f^2}{c^3} \mathrm{d}f. \tag{A2.1.6b}$$

This is an important result in itself and appears in many aspects of laser theory; it should be noted carefully.

We may use it immediately for our present purposes to derive the classical result for the energy spectrum of a black-body radiator. From equation (A2.1.4) we saw that each oscillation has mean energy kT. Hence the energy density (i.e. energy per unit volume) lying between frequencies f and $f + \mathrm{d}f$ is given by:

$$\rho_{\mathrm{f}} \mathrm{d}f = \frac{8\pi f^2}{c^3} kT \mathrm{d}f. \tag{A2.1.7}$$

This is the classical result, the so-called Rayleigh–Jeans equation. *It is wrong!* It has to be. We can see this immediately by calculating the total energy density emitted over all wavelengths of the spectrum:

$$\rho_{\mathrm{T}} = \int_0^\infty \frac{8\pi f^2}{c^3} kT \mathrm{d}f$$

$$= \frac{8\pi kT}{c^3} \left[\frac{f^3}{3} \right]_0^\infty \rightarrow \infty!$$

The answer is thus that an infinite amount of total energy is emitted by any black body; this is, of course, quite impossible. This result caused much head scratching amongst classical physicists around the turn of the century. When the spectrum of a black body (or as close to one as could be realized in practice) was measured, the shape was as shown in figure A2.1.2. The agreement with the Rayleigh–Jeans expression (equation (A2.1.7)) was good at low frequencies, but the two diverged wildly at the higher frequencies: the problem was thus dubbed the 'ultra-violet (i.e. high frequency) catastrophe'.

A2.1.2.2 The quantum result

Max Planck, in 1900, saw a very simple way to avoid the above problem. He suggested that an oscillator could not possess *any* value of energy but only a value which was an integer times a certain minimum value. If this latter was ε, then the only possible values for the energy of the oscillation were ε, 2ε, $3\varepsilon \cdots n\varepsilon$. This changed things completely, as we shall now show.

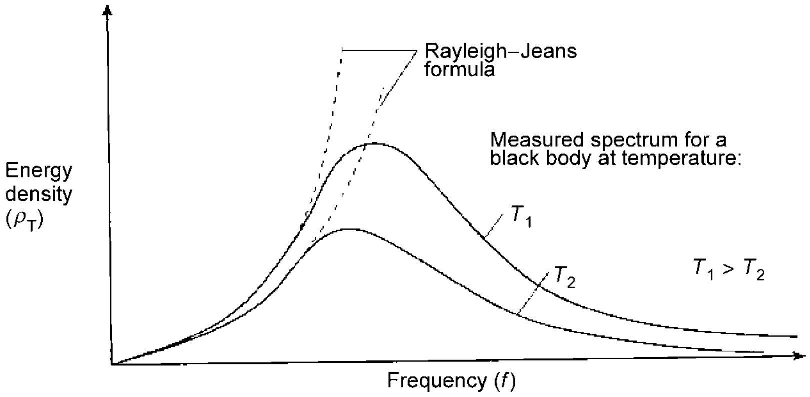


Figure A2.1.2. The black-body spectrum.

We can now, very conveniently, return to equation (A2.1.3) for the mean energy of an oscillator:

$$\bar{E} = \frac{\mathrm{d}E}{\exp\left(\dfrac{\mathrm{d}E}{kT}\right) - 1}$$

dE can now be identified with ε, and now it does *not* tend to zero, but always remains nonzero.

Now ε is the minimum energy of the oscillator which emits radiation and thus can be identified, in turn, with the quantity $h\nu$, where ν is the lowest frequency of radiation it emits, remembering that the oscillator can have any of the energies $nh\nu$, where n is any positive integer. (We now use ν for frequency, rather than f, to remind ourselves that we are dealing with quantum phenomena rather than continuous events, h is the quantum constant (Planck's constant) with value 6.626×10^{-34} J s.)

Thus we have, in the quantum case:

$$\bar{E} = \frac{h\nu}{\exp\left(\dfrac{h\nu}{kT}\right) - 1}$$

rather than kT, and the energy density lying between ν and $\nu + \mathrm{d}\nu$ now will be, using equation (A2.1.7):

$$\rho_\nu \mathrm{d}\nu = \frac{8\pi\nu^2}{c^3} \frac{h\nu}{\exp\left(\dfrac{h\nu}{kT}\right) - 1} \mathrm{d}\nu. \tag{A2.1.8}$$

This is the celebrated Planck radiation formula, and it solves all our problems, for it agrees with the experimental spectrum (figure A2.1.2).

If integrated over all frequencies it remains finite, and gives the result:

$$E_\mathrm{T} = \frac{2\pi^5 k^4}{15 c^2 h^3} T^4. \tag{A2.1.9}$$

Equation (A2.1.9) represents the Stefan–Boltzmann law for the total energy emitted by a black body; classical thermodynamics was able to show that this quantity should be proportional to the fourth power of the absolute temperature, but was unable to predict the value of the constant of proportionality; quantum physics has provided the answer to this.

Similarly, classical thermodynamics was able to prove Wien's displacement law, which states that the value of the wavelength associated with the energy maximum in the spectrum (figure A2.1.2) is inversely proportional to the absolute temperature, i.e.

$$\lambda_{\mathrm{m}} = \frac{\Omega}{T}$$

but was unable to determine the value of the constant Ω. By differentiating equation (A2.1.8) we easily find that:

$$\Omega = \frac{ch}{4.9651k}.$$

The above results had a profound effect. Although Planck at first felt that his quantum hypothesis was no more than a mathematical trick to avoid the ultra-violet catastrophe, it soon became clear that it was fundamentally how the universe did, in fact, behave: quantum theory was born.

A2.1.2.3 'Black-body' sources

The concept of a black body is that of a body which emits and absorbs all frequencies of radiation. We know now that the quantum theory requires us to limit the frequency to multiples of a certain fundamental frequency, but, in practice, owing to the particular molecular structure of any given body, the quantum (and classical) 'black body' remains an idealization, and real bodies, when hot, will not yield a spectrum in strict accordance with Planck's radiation law but only an approximation to it (sometimes a very close approximation, however).

Nevertheless, we can very conveniently measure the temperature of a radiating body by measuring the wavelength at which the spectrum peaks, using Wien's law, or, if the peak is not at a convenient (for our detector) position in the spectrum, by measuring the total energy emitted (using a bolometer) and applying the Stefan–Boltzmann law. Very often we require a source which emits over a broad range of frequencies, and a convenient way to obtain this is to create a discharge in a gas. An electrical discharge creates a large number of free, energetic electrons which cause a large range of atomic excitations, thus giving rise to radiation over a broad frequency range. Intensities can be quite high, so that the experimenter or designer can then pick out those frequencies that are needed, with frequency-selective optical components such as prisms or diffraction gratings.

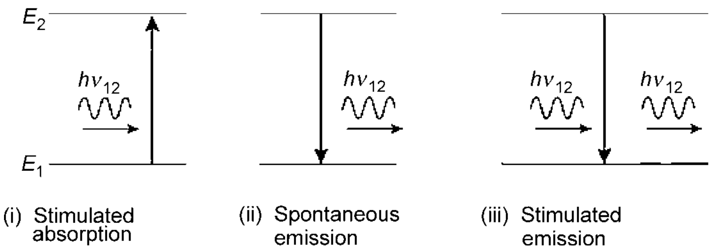
However, the importance of the idealization known as a black body lies primarily in the fact that it allows an insight into the fundamental nature of electromagnetic radiation and the quantum laws which it obeys. This is crucial to our understanding of its role in optoelectronics, and especially to our understanding of laser radiation, which is the next topic for consideration.

A2.1.2.4 The theory of laser action

The rate equations and the gain mechanism

The elements of laser action were introduced in chapter A.1. Lasers are extremely important in optoelectronics, as has been stressed, and it is necessary now to deal with laser action in more quantitative detail.

Let us consider two energy levels of an atomic system E_1 and E_2, with $E_2 > E_1$ (figure A2.1.3).



E_2
E_1
$h\nu_{12}$
$h\nu_{12}$
$h\nu_{12}$
$h\nu_{12}$
(i) Stimulated absorption
(ii) Spontaneous emission
(iii) Stimulated emission

Figure A2.1.3. Two-level photon transitions.

We know that the system can be raised from E_1 to E_2 by absorption of a photon with frequency ν_{12}, where:

$$h\nu_{12} = E_2 - E_1$$

and we also know that the system, after having been excited, will eventually, spontaneously, revert to its ground state E_1 by emitting a photon of energy $h\nu_{12}$.

However, the excited state E_2 can also be stimulated to decay to the state E_1 by the action of another photon of energy $h\nu_{12}$. This process is called stimulated emission. Thus now we are considering three distinct processes:

(a) stimulated absorption ($E_1 \rightarrow E_2$);

(b) spontaneous emission ($E_2 \rightarrow E_1$);

(c) stimulated emission ($E_2 \rightarrow E_1$).

There can be no spontaneous 'absorption' since this would violate the law of conservation of energy.

In order to calculate the relationships between atoms and radiation in equilibrium (i.e. black-body radiation), Einstein used a very simple argument: consider the atoms to be in equilibrium with each other and with the radiation in a closed system. The rate (per unit volume) at which atoms are raised to the upper state is proportional to the density of photons, ρ_ν, at energy $h\nu_{12}$ and to the density of atoms N_1 (number per unit volume) in state E_1, i.e.

$$R_{12} = N_1 \rho_\nu B_{12} \quad \text{(stimulated absorption)}$$

where B_{12} is a constant.

Similarly, the rate at which atoms in state E_2 are stimulated to return to state E_1 is given by:

$$R_{21} = N_2 \rho_\nu B_{21} \quad \text{(stimulated emission)}$$

where N_2 is the density of atoms in state E_2. Now spontaneous emission from state E_2 to E_1 occurs after a characteristic delay determined by the detailed atomic characteristics, and is governed by quantum rules. Its rate therefore is proportional to N_2, the constant of proportionality, comprising, essentially, the reciprocal of the decay time. Thus we have

$$S_{21} = N_2 A_{21} \quad \text{(spontaneous emission).}$$

The constants A_{21}, B_{12}, B_{21} are called the Einstein coefficients.

Clearly, in equilibrium, we must have:

$$N_1\rho_\nu B_{12} = N_2\rho_\nu B_{21} + N_2 A_{12} \tag{A2.1.10}$$

since the total upward and downward transition rates must be equal.

Hence from equation (A2.1.10):

$$\rho_\nu = \frac{(A_{21}/B_{21})}{(B_{12}N_1/B_{21}N_2) - 1}.$$

But we know from the Boltzmann relation that:

$$\frac{N_1}{N_2} = \exp\left(-\frac{E_1 - E_2}{kT}\right)$$

and also that $E_2 - E_1 = h\nu_{12}$.

Hence, generalizing from ν_{12} to ν:

$$\rho_\nu = \frac{(A_{21}/B_{21})}{(B_{12}/B_{21})\exp\left(\dfrac{h\nu}{kT}\right) - 1}. \tag{A2.1.11}$$

Now it was shown in section A2.1.2.2 that for equilibrium (black-body) radiation (equation A2.1.8):

$$\rho_\nu = \frac{8\pi h\nu^3}{c^3}\frac{1}{\exp\left(\dfrac{h\nu}{kT}\right) - 1}.$$

Hence it follows, by comparing this with (A2.1.11):

$$B_{12} = B_{21} \tag{A2.1.12a}$$

$$A_{21} = B_{21}\frac{8\pi h\nu^3}{c^3}. \tag{A2.1.12b}$$

Relations (A2.1.12*a*) and (A2.1.12*b*) are known as the Einstein relations, and are very important determinants in the relationships between atoms and radiation. For example, it is clear that, under these conditions, the ratio of stimulated to spontaneous emission from E_2 to E_1 is given by:

$$S = \frac{R_{21}}{S_{21}} = \frac{\rho_\nu N_2 B_{21}}{N_2 A_{21}} = \frac{\rho_\nu c^3}{8\pi h\nu^3}$$

and using the expression for ρ_ν from equation (A2.1.8):

$$S = \frac{1}{\exp\left(\dfrac{h\nu}{kT}\right) - 1}.$$

If, for example, we consider the specific case of the He–Ne discharge at a temperature of 370 K with $\lambda = 632.8$ nm ($\nu = 4.74 \times 10^{14}$ Hz) then we find

$$S \approx 2 \times 10^{-27}.$$

Stimulated emission is thus very unlikely for equilibrium systems.

Another point worthy of note is that, for given values of N_2 (density of atoms in upper state E_2) and ρ_ν (density of photons) the rate of stimulated emission (B_{21}) is proportional to $1/\nu^3$. This follows from equation (A2.1.12*b*) since

$$B_{21} = \frac{A_{21}c^3}{8\pi h\nu^3}$$

and A_{21} is an atomic constant, representing the reciprocal of the spontaneous decay time.

This means that the higher the frequency the more difficult is laser action, for this depends upon stimulated emission. Ultraviolet, x-ray and γ-ray lasers present very special problems which, hopefully, will preclude the possibility of 'death-ray' weapons (x-rays and γ-rays are very damaging to living tissues).

However, we do wish to use lasers at lower frequencies, visible and infrared for example, for purposes of communication, display and measurement, and the equation for R_{21} tells us that the way to increase the stimulated emission is to increase the values of N_2 and ρ_ν.

We know that, in equilibrium, $N_2 < N_1$, from the form of the Boltzmann factor, and ρ_ν is given by equation (A2.1.8). Hence, we shall have to disturb the equilibrium to achieve significant levels of stimulated emission.

One way in which this can be done is to inject radiation at frequency ν, so that ρ_ν is increased above its equilibrium value. Suppose that this is done until the stimulated emission greatly exceeds the spontaneous emission (which does not, of course, depend upon ρ_ν), i.e. until:

$$N_2\rho_\nu B_{21} \gg N_2A_{21}.$$

The condition for this, clearly, is that

$$\rho_\nu \gg \frac{A_{21}}{B_{21}}$$

which, from equation (A2.1.12*b*), means that:

$$\rho_\nu \gg \frac{8\pi h\nu^3}{c^3}.$$

However, increasing ρ_ν does also increase the stimulated absorption. In fact, equation (A2.1.10) becomes, when ρ_ν is large:

$$N_1\rho_\nu B_{12} = N_2\rho_\nu B_{21}.$$

But we also know from equations (A2.1.12*a*) and (A2.1.12*b*) that $B_{12} = B_{21}$; hence $N_1 = N_2$ under these conditions. In other words, an incoming photon at frequency ν is just as likely to cause a downward transition (stimulated emission) as it is an upward one (stimulated absorption). Hence we cannot increase the population N_2 above that of N_1 simply by pumping more radiation, at frequency ν, into the system. Clearly, we must change tack if we are to enhance the stimulated emission and produce a laser.

Consider a three-level rather than a two-level system (figure A2.1.4(*a*)). Suppose that light at frequency ν_{13} is injected into this system, so that there is a large amount of stimulated absorption from E_1 to E_3. Spontaneous decays will occur from E_3 to E_2 and then $E_2 \rightarrow E_1$ with also $E_3 \rightarrow E_1$; but if the levels are chosen appropriately according to the quantum rules, the $E_3 \rightarrow E_2$ decay can be fast and the $E_2 \rightarrow E_1$ relatively much slower. Clearly, the result of this will be that atoms will accumulate in level E_2. Now the really important point is that, unlike the previous two-level case, atoms in level E_2 are immune from stimulated emission by photons at frequency ν_{13}. Hence we can now increase the number of atoms in level E_2, at the expense of those in E_1, by increasing the intensity of the radiation at frequency ν_{13}.

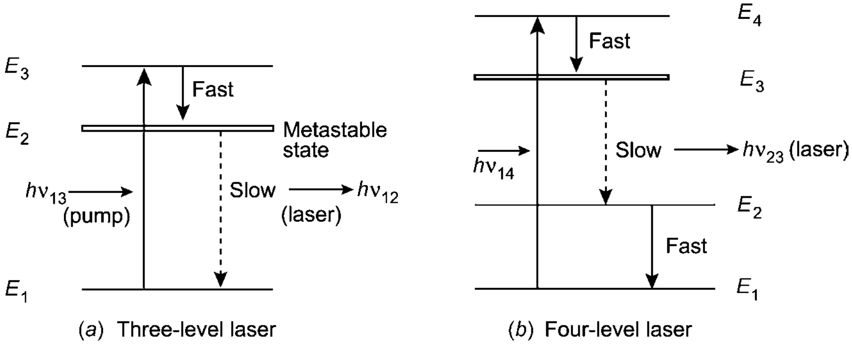


Figure A2.1.4. Energy-level diagrams for laser action.

We can thus soon ensure that:

$$N_2 > N_1$$

and we have an 'inverted population' (i.e. more atoms in a higher energy state than a lower one) as a result of the 'pump' at frequency ν_{13}. This inverted population can now be exploited to give optical amplification at frequency ν_{12}.

Let us quantify this amplification via the rate equations we have developed. Suppose that photons at frequency ν_{12} are injected into the medium in a certain direction. These will meet the inverted population in energy state E_2 and will stimulate the downward transition $E_2 \rightarrow E_1$, producing more photons at frequency ν_{12} in so doing (this is, of course, the origin of the amplification). We assume, quite confidently, that the medium is being sufficiently strongly pumped for the stimulated photons to be well in excess of any spontaneous emission from E_2 to E_1. Now suppose that, under these conditions, the number of photons per unit volume when the injected radiation enters the system is p_{12}. Then the rate at which p_{12} increases will depend upon the difference between upward and downward transition rates between levels 1 and 2, and hence we write:

$$\frac{\mathrm{d}p_{12}}{\mathrm{d}t} = N_2 \rho_{\nu_{12}} B_{21} - N_1 \rho_{\nu_{12}} \mathrm{B}_{12}.$$

Now $\rho_{\nu_{12}}$ is the energy density of photons, hence

$$\rho_{\nu_{12}} = p_{12} h\nu_{12}.$$

Also we know that $B_{12} = B_{21}$ (from equations (A2.1.12*a*) and (A2.1.13) and thus:

$$\frac{1}{h\nu_{12}} \frac{\mathrm{d}\rho_{\nu_{12}}}{\mathrm{d}t} = B_{12} \rho_{\nu_{12}} (N_2 - N_1). \tag{A2.1.13}$$

We shall now write $\rho_{\nu_{12}}$ as ρ_ν to avoid cluttered equations and, integrating equation (A2.1.13):

$$\rho_\nu = \rho_{\nu,0} \exp[(N_2 - N_1)t]$$

where $\rho_{\nu,0} = \rho_\nu$ at $t = 0$.

If the injected wave is travelling at velocity c in the medium we can transfer to a distance parameter via $s = ct$ and obtain:

$$\rho_\nu = \rho_{\nu,0} \exp\left[\frac{h\nu}{c} B_{12} (N_2 - N_1) s\right].$$

This is to be compared with the standard loss/gain relation for propagation in an interactive medium, i.e.

$$I = I_0 \exp(gx)$$

and it is clear that the gain coefficient g can be identified as:

$$g = \frac{h\nu}{c} B_{12}(N_2 - N_1) \tag{A2.1.14a}$$

which is the gain coefficient for the medium (fractional increase in intensity level per unit length) and will be positive (i.e. gain rather than loss) provided that $N_2 > N_1$, as will be the case for an inverted population. Hence, this medium is an optical amplifier. The injected radiation at frequency ν_{12} receives gain from the optical pump of amount:

$$G = \frac{I}{I_0} = \exp(gs)$$

so that it increases exponentially with distance into the medium. Clearly g in equation (A2.1.14*a*) is proportional to $(N_2 - N_1)$. In a three-level system such as we are considering the lower level of the amplifying transition is the ground state, which is initially heavily populated. It follows that more than half the atoms must be excited by the pump before population inversion can be achieved $(N_2 > N_1)$. It is quite hard work for the pump to excite all these atoms. Consider, however, the *four*-level system shown in figure A2.1.4(*b*). Here the pump is at ν_{14}, there is a quick decay to level 3 and a slow one to levels 2 and 1. The decay from 2 to 1 is again fast. Clearly, the consequence of this is that it is relatively easy to provide level 3 with an inverted population over level 2, since level 2 was not well populated in the first place (being above the ground state), and atoms do not accumulate there since it decays quickly to ground. Hence we can ensure that:

$$N_3 \gg N_2$$

with much less pump power than for $N_2 > N_1$ in the three-level case. The amplification at ν_{32} is thus much more efficient, and the four-level system makes for a more efficient amplifier.

The laser structure

Having arranged for efficient amplification to take place in a medium it is a relatively straightforward matter to turn it into an oscillator, i.e. a laser source. To do this for any amplifier it is necessary to provide positive feedback, i.e. to feed some of the amplified output back into the amplifier in reinforcing phase. This is done by placing parallel mirrors at each end of a box containing the medium, to form a Fabry–Perot cavity. The essential physics of this process is that any given photon at ν_{12} will be bounced back and forth between the mirrors, stimulating the emission of other such photons as it does so, whereas without the mirrors it would make only one such pass.

An important condition for any system to oscillate under these circumstances is that the gain should be in excess of the loss for each cycle of oscillation. The total loss for a photon executing a double passage of the cavity (figure A2.1.5) will depend not only on the loss per unit length in the medium (due to scattering, excitations to other states, wall losses, etc) but also on the losses at the mirrors and, it must be remembered that one of the mirrors has to be a partial mirror in order to let some of the light out otherwise we could not use the laser oscillator as a source! Hence the condition for oscillation is:

$$\frac{I_f}{I_i} = R_1 R_2 \exp[(g - \alpha)2l] > 1 \tag{A2.1.14b}$$

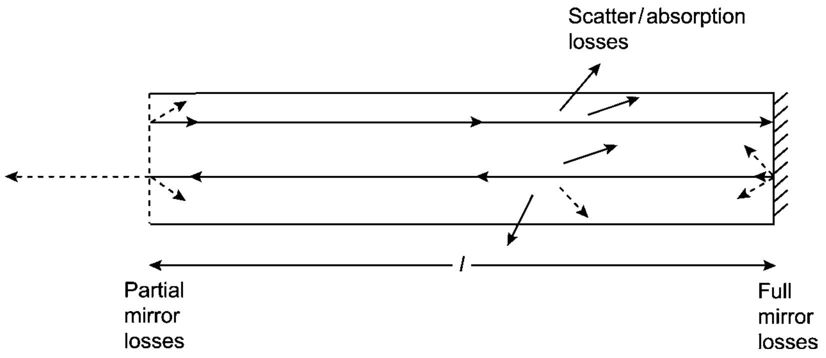

Figure A2.1.5. Loss mechanisms in laser cavity.

where I_f and I_i refer to the final and initial intensities for the double passage of the cavity, R_1 and R_2 are the reflectivities for the two mirrors, respectively, α is the loss per unit length in the medium and l is the cavity length. (The factor 2 in the exponential refers to the double passage of the photon.)

One further word of warning: the value of g must correspond to the population inversion whilst oscillation is taking place, not the value before the feedback is applied. Clearly the value of N_2/N_1 will be very different, once stimulated emission starts to occur, from its value when the system is simply being pumped into its inverted state. This has implications for pumping rates and the balancing of rate equations which we shall not pursue: the principles, hopefully, are clear, however.

The simple arrangement of a pumped medium lying between two parallel mirrors (one partial) will, under the correct pump conditions, therefore lead to radiation emerging with the following properties:

(a) Narrow linewidth, since only one energy of transition is involved in the laser action; and the mirrors, if wavelength selective, will block any spontaneous light which is emitted in addition.

(b) The output direction of the light will be exactly normal to the (accurately parallel) planes of the mirrors and thus will be highly collimated in one direction.

(c) When a photon is emitted via stimulated emission by another photon, it is emitted with the same phase as the original photon (remember the driving force/resonating system analogy), thus all the laser photons are locked in phase: we have coherent light (within the limitations only of the linewidth of the transition).

(d) The light can be very intense since all the 'light amplification by stimulated emission of radiation' from a long length of medium with small cross-sectional area can be collimated into one direction.

The above important features summarize the basic properties of laser light: it is pure (in wavelength and phase), intense, well-collimated light. It is thus easy to control and modulate; it is a powerful tool.

In order to enhance its usefulness as a tool there are two quite simple additions which can be made to the basic design: The Fabry–Perot cavity formed by the two parallel mirrors will possess defined longitudinal 'modes'. Waves propagating in opposite directions within the cavity, normal to the mirrors, will interfere and reinforce to give rise to an allowable stable mode only when

$$2L = m\lambda$$

where L is the length of the cavity and m is an integer.

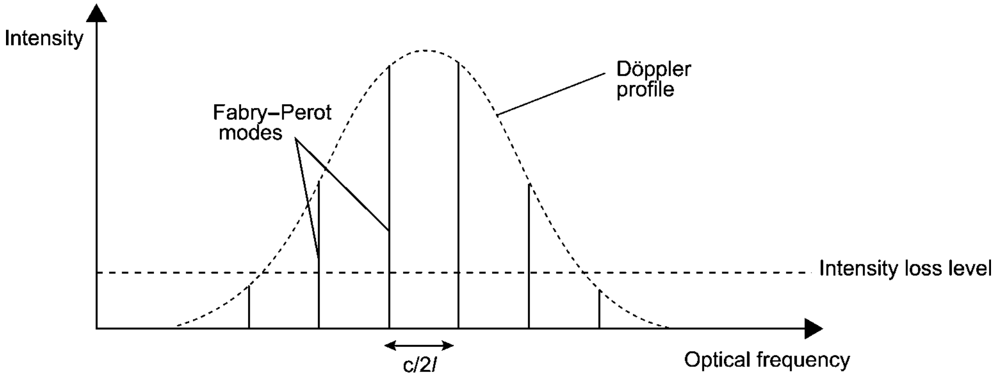

Figure A2.1.6. Laser-cavity spectrum.

From this we can also write

$$\lambda = \frac{2L}{m}; \quad f = \frac{cm}{2L}.$$

At all other wavelengths there is destructive interference. Now the stimulated emission occurs over a small range of wavelengths. This range is determined by the spectral width of the downward transition. The width depends upon a number of factors but primarily (unless cooled to very low temperatures) on the Doppler shift caused by the thermal motion of the molecules. Clearly, at any given time, some molecules will be moving towards the stimulating photon and others away, leading to a spread of Doppler shifts around the central line for the stationary molecule (at absolute zero of temperature!).

The output spectrum of the laser light is thus the result of combining these two features, as shown in figure A2.1.6. Here we can see the Fabry–Perot mode structure enveloped by the natural linewidth of the transition. In order to fix ideas somewhat, let us insert some real numbers into this. Suppose we have a He–Ne gas laser with length 0.5 m. Since, in a gas at less than atmospheric pressure, we have $c \sim 3 \times 10^8 \, \mathrm{ms}^{-1}$, we see that:

$$\frac{c}{2L} = 300 \, \mathrm{MHz}$$

which is the separation of the modes along the frequency axis. Now the Doppler line width of the 632.8 nm transition at 300 K is $\sim$ 1.5 GHz; hence the number of modes within this width is

$$\frac{1.5 \times 10^9}{3 \times 10^8} \sim 5$$

so that we have just five modes in the output spectrum.

So far we have dealt only with longitudinal modes; but off-axis rays also may interfere (figure A2.1.7). The reinforcement condition now depends also on the angle which the ray makes with the long axis, and the result is a variation in intensity over the cross-section of the cavity, and thus over the cross-section of the output laser beam (figure A2.1.7). (The notation used to classify these variations will be described in more detail when we deal with wave guiding (section A2.1.5) but TEM stands for 'transverse electromagnetic' and the two suffixes refer to the number of minima in the pattern in the horizontal and vertical directions, respectively.)

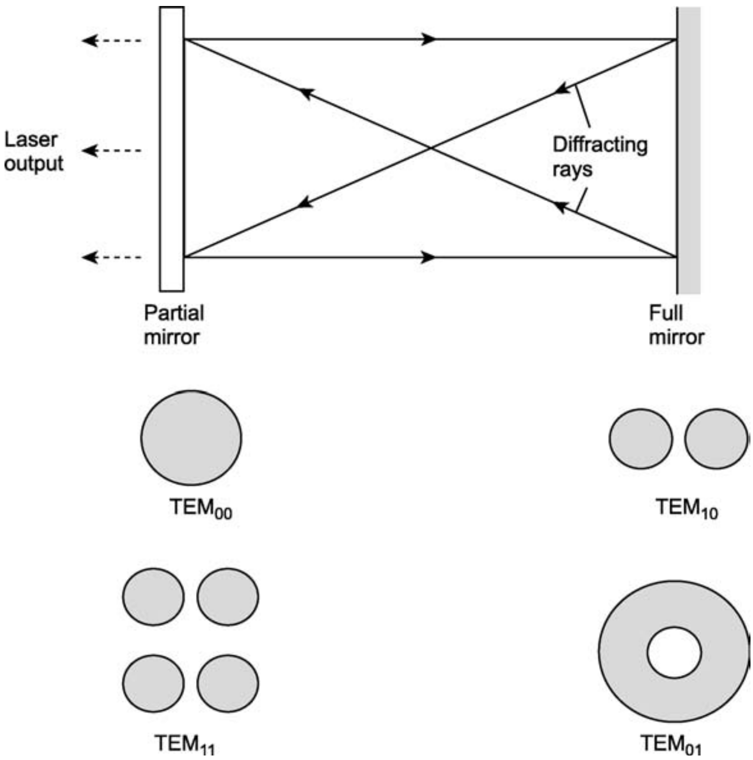

Figure A2.1.7. Transverse cavity modes.

Mode-locking

Let us return now to the longitudinal mode structure of the laser cavity. Normally, these longitudinal modes are entirely independent, since they result from wholly independently-acting interference conditions. Suppose, however, that they were to be locked into a constant phase relationship. In that case we would have a definite relationship, in the frequency domain, between the phases and the amplitudes of the various components of the frequency spectrum. If we were to translate those relationships into the time domain, by means of a Fourier transform, the result would be a series of pulses spaced by the reciprocal of the mode frequency interval, with each pulse shape the Fourier transform of the mode envelope (figure A2.1.8). All we are really saying here, in physical terms, is that if each frequency component bears a constant phase relationship to all the others, when all frequency components are superimposed, then there will be certain points in time where maxima occur (the peaks of the pulses) and others where minima occur (the troughs between pulses). If there is no fixed phase relationship between components both maxima and minima are ‘washed out’ into a uniform-level, randomized continuum.

Now a series of evenly spaced pulses is often a very useful form of laser output, so how can it be achieved?

We must lock the phases of the longitudinal modes. One way of doing this is to include, within the cavity, an amplitude modulator, and then modulate (not necessarily sinusoidally) the amplitudes of the modes at just the mode frequency interval, $c/2L$. Then, each mode generates a

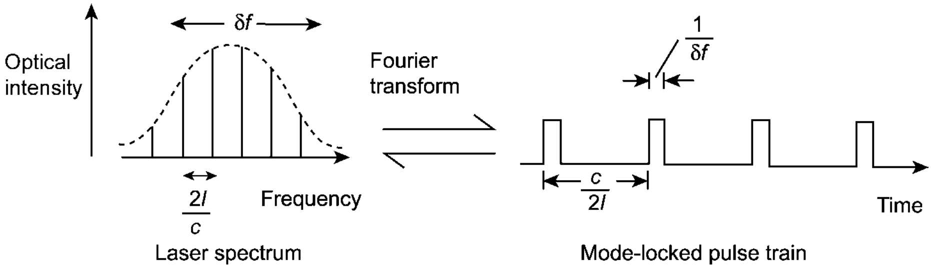

Figure A2.1.8. Mode-locking Fourier transform: spectrum/pulse train.

series of sidebands at frequencies $mc/2L$, which corresponds to the frequencies of the other modes. The result of this is that all the modes are 'pulled' mutually into phase by the driving forces at the other frequencies, and complete phase locking occurs. The inserted modulator thus has the effect of producing, from the laser output, a pulse stream with pulse repetition rate $2L/c$. For example, with the He–Ne laser quoted in section the laser structure the repetition rate is 300 MHz, and each pulse has a width

$$\sim \frac{1}{1.5\times 10^9} \sim 0.67\,\text{ns} \quad \text{(see figure A2.1.8).}$$

The laser is now said to be 'mode-locked' and the pulse stream is a set of 'mode-locked pulses'. Sometimes when a laser is being pumped quite hard and the output levels are high, the laser will 'self-mode lock'. This is due to the fact that the medium has been driven into the nonlinear regime (see section A2.1.7) and the modes generate their own harmonics as a result of the induced optical nonlinearities. Clearly, this will depend upon the medium as well as the driving level, since it will depend on which particular nonlinear threshold is exceeded by the pumping action.

Q-switching

The 'Q' or 'quality factor' of an oscillator refers to its purity, or 'sharpness of resonance'. The lower the loss in an oscillator the narrower is its resonance peak and the longer it will oscillate on its own after a single driving impulse. The equivalent quantity in a Fabry–Perot cavity (an optical oscillator) is the 'finesse', and the two quantities are directly related. From these ideas we can readily understand that if the loss in a resonator is varied then so is its 'Q'.

Suppose we have a laser medium sitting in its usual Fabry–Perot cavity but with a high loss; this means that a large fraction of the light power oscillating between the mirrors is lost per pass: we might, for example, have one of the mirrors with very low reflectivity.

Now the oscillator can only oscillate if the gain which the light receives per double pass between the mirrors exceeds the loss per double pass (section A2.1.2.4.2), and we shall suppose that the loss is very high, so that as we pump more and more molecules of the medium up into the excited state of the inverted population, the loss still exceeds the gain for as hard as our pump source can work. The result is that the inversion of the population becomes very large indeed, for there are very few photons to cause stimulated emission down to the lower state—they are all being lost by other means (e.g. a poor mirror at one end). Having achieved this very highly inverted population suppose that the loss is now suddenly reduced by means of an intercavity switch ('Q' switch) by, for example, speedily rotating to a high-reflectivity mirror (figure A2.1.9). The result is that there is suddenly an enormous number of photons to depopulate the inverted population,

which then rapidly de-excites to emit all its accumulated energy in one giant laser pulse—the Q-switched pulse. Thus we have the means by which very large energy, very high intensity pulses can be obtained, albeit relatively infrequently (~25 pps).

Three further points should be noted concerning Q-switching:

(a) At the end of the pulse the lasing action ceases completely, since the large number of photons suddenly available completely depopulates the upper laser state.

(b) The switching to the low loss condition must take place in a time which is small compared with the stimulated depopulation time of the upper state, so as to allow the pulse to build up very quickly.

(c) The pumping rate must be large compared with the spontaneous decay rate of the upper state so as to allow a large population inversion to occur.

Q-switching can produce pulses with several millijoules of energy with only a few nanoseconds duration. Thus, peak powers of several megawatts can result. Such powers take most media into their nonlinear regimes (many will be evaporated!), so Q-switching is very useful for studying the nonlinear optical effects which will be considered in section A2.1.7.

Both mode-locking and Q-switching require intracavity modulation devices. These can take a variety of forms.

A2.1.2.5 Summary

In this section, we have examined those aspects of the physics of radiation relevant to optoelectronics. It is necessary to understand the essential quantum nature of radiation in order to appreciate fully the way in which light interacts with matter and, in particular, the action of the laser in providing a source of pure light. It was the invention of the laser (in 1960) which launched the subject of optoelectronics.

A2.1.3 Optical polarization

A2.1.3.1 Introduction

The essential idea of optical polarization was introduced in chapter A1.1 but we must now consider this important topic in more detail. We know that the electric and magnetic fields, for a freely propagating light wave, lie transversely to the propagation direction and orthogonally to each other.

Normally, when discussing polarization phenomena, we fix our attention on the electric field, since it is this which has the most direct effect when the wave interacts with matter.

In saying that an optical wave is polarized we are implying that the direction of the optical field is either constant or is changing in an ordered, prescribable manner. In general, the tip of the electric vector circumscribes an ellipse, performing a complete circuit in a time equal to the period of the wave, or in a distance of one wavelength. Clearly, the two parameters are equivalent in this respect.

As is well known, linearly polarized light can conveniently be produced by passing any light beam through a sheet of polarizing film. This is a material which absorbs light of one linear polarization (the ‘acceptance’ direction) to a much smaller extent (~1000 times) than the orthogonal polarization, thus, effectively, allowing just one linear polarization state to pass. The material’s properties result from the fact that it consists of long-chain polymeric molecules aligned in one direction (the acceptance direction) by stretching a plastic, and then stabilizing it. Electrons can move more easily along the chains than transversely to them, and thus the optical wave transmits easily only when its electric field lies along this acceptance direction. The material is cheap and allows the use of large optical apertures. It thus provides a convenient means whereby, for example, a specific linear polarization state can be defined; this state then provides a ready polarization reference which can be used as a starting point for other manipulations. In order to study these manipulations and other aspects of polarization optics, we shall begin by looking more closely at the polarization ellipse.

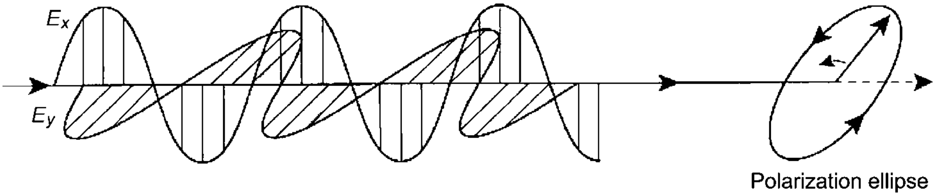

Figure A2.1.10. Components for an elliptically-polarized wave.

A2.1.3.2 The polarization ellipse

In chapter A1.1, the most general form of polarized light wave propagating in the *Oz* direction was derived from the two linearly polarized components in the *Ox* and *Oy* directions (figure A2.1.10):

$$E_x = e_x \cos(\omega t - kz + \delta_x) \quad E_y = e_y \cos(\omega t - kz + \delta_y). \tag{A2.1.15a}$$

If we eliminate $(\omega t - kz)$ from these equations we obtain the expression:

$$\frac{E_x^2}{e_x^2} + \frac{E_y^2}{e_y^2} + \frac{2E_xE_y}{e_xe_y}\cos(\delta_y - \delta_x) = \sin^2(\delta_y - \delta_x) \tag{A2.1.15b}$$

which is the ellipse (in the variables E_x, E_y) circumscribed by the tip of the resultant electric vector at any one point in space over one period of the combined wave. This can only be true, however, if the phase difference $(\delta_y - \delta_x)$ is constant in time, or, at least, changes only slowly when compared with the speed of response of the detector. In other words, we say that the two waves must have a large mutual 'coherence'. If this was not so then relative phases and hence resultant field vectors would vary randomly within the detector response time, giving no ordered pattern to the behaviour of the resultant field and thus presenting to the detector what would be, essentially, unpolarized light.

Assuming that the mutual coherence is good, we may investigate further the properties of the polarization ellipse.

Note, firstly, that the ellipse always lies in the rectangle shown in figure A2.1.11, but that the axes of the ellipse are not parallel with the original x, y directions.

The ellipse is specified as follows: with e_x, e_y, δ $(= \delta_y - \delta_x)$ known, then we define $\tan\beta = e_y/e_x$.

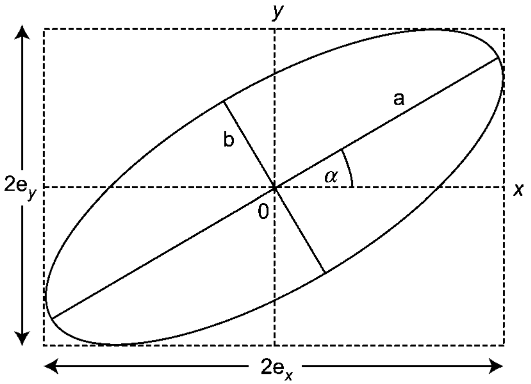

Figure A2.1.11. The polarization ellipse.

The orientation of the ellipse, α, is given by:

$$\tan 2\alpha = \tan 2\beta \cos \delta.$$

Semi-major and semi-minor axes a, b are given by:

$$e_x^2 + e_y^2 = a^2 + b^2 \sim I.$$

The ellipticity of the ellipse (e) is given by $e = \tan\chi = \pm\, b/a$ (the sign determines the sense of the rotation) where:

$$\sin 2\chi = -\sin 2\beta \sin \delta.$$

We should note also that the electric field components along the major and minor axes are always in quadrature (i.e. $\pi/2$ phase difference, the sign of the difference depending on the sense of the rotation).

Linear and circular states of polarization may be regarded as special cases where the polarization ellipse degenerates into a straight line or a circle, respectively.

A linear state is obtained with the components in equation (A2.1.15a) when either:

$$\left.\begin{aligned} e_x &= 0 \\ e_y &\neq 0 \end{aligned}\right\} \quad \text{linearly polarized in } Oy \text{ direction}$$

$$\left.\begin{aligned} e_x &\neq 0 \\ e_y &= 0 \end{aligned}\right\} \quad \text{linearly polarized in } Ox \text{ direction}$$

or,

$$\delta_y - \delta_x = m\pi$$

where m is an integer. In this latter case, the direction of polarization will be at an angle:

$$+\tan^{-1}\left(\frac{e_y}{e_x}\right) \qquad m \text{ even}$$

$$-\tan^{-1}\left(\frac{e_y}{e_x}\right) \qquad m \text{ odd}$$

with respect to the Ox axis.

A circular state is obtained when

$$e_x = e_y$$

and

$$(\delta_y - \delta_x) = (2m + 1)\pi/2$$

i.e. in this case the two waves have equal amplitudes and are in phase quadrature. The waves will be right-hand circularly polarized when m is even and left-hand circularly polarized when m is odd.

Light can become polarized as a result of the intrinsic directional properties of matter: either the matter which is the original source of the light, or the matter through which the light passes. These intrinsic material directional properties are the result of directionality in the bonding which holds together the atoms of which the material is made. This directionality leads to variations in the response of the material according to the direction of an imposed force, be it electric, magnetic or mechanical.

The best known manifestation of directionality in solid materials is the crystal, with the large variety of crystallographic forms, some symmetrical, some asymmetrical. The characteristic shapes which we associate with certain crystals result from the fact that they tend to break preferentially along certain planes known as cleavage planes, which are those planes between which atomic forces are weakest.

It is not surprising, then, to find that directionality in a crystalline material is also evident in the light which it produces, or is impressed upon the light which passes through it.

In order to understand the ways in which we may produce polarized light, control it and use it, we must make a gentle incursion into the subject of crystal optics.

A2.1.3.3 Crystal optics

Light propagates through a material by stimulating the elementary atomic dipoles to oscillate and thus to radiate. In our previous discussions the forced oscillation was assumed to take place in the direction of the driving electric field, but in the case of a medium whose physical properties vary with direction, an anisotropic medium, this is not necessarily the case. If an electron in an atom or molecule can move more easily in one direction than another, then an electric field at some arbitrary angle to the preferred direction will move the electron in a direction which is not parallel with the field direction (figure A2.1.12). As a result, the direction in which the oscillating dipole's radiation is maximized (i.e. normal to its oscillation direction) is not the same as that of the driving wave.

The consequences, for the optics of anisotropic media, of this simple piece of physics are complex.

Immediately we can see that the already-discussed (see chapter A1.1) relationship between the electric displacement $\boldsymbol{D}$ and the electric field $\boldsymbol{E}$, for an *isotropic* (i.e. no directionality) medium:

$$\boldsymbol{D} = \varepsilon_R \varepsilon_0 \boldsymbol{E}$$

must be more complex for an anisotropic medium; in fact the relation must now be written in the form (for any, arbitrary three orthogonal directions Ox, Oy, Oz):

$$D_x = \varepsilon_0(\varepsilon_{xx}E_x + \varepsilon_{xy}E_y + \varepsilon_{xz}E_z) \quad D_y = \varepsilon_0(\varepsilon_{yx}E_x + \varepsilon_{yy}E_y + \varepsilon_{yz}E_z) \quad D_z = \varepsilon_0(\varepsilon_{zx}E_x + \varepsilon_{zy}E_y + \varepsilon_{zz}E_z).$$

Figure A2.1.12. Electron response to an electric field in a dielectric medium.

Clearly what is depicted here is an array which describes the various electric field susceptibilities in the various directions within the crystal: ε_{ij} (a scalar quantity) is a measure of the effect which an electric field in direction j has in direction i within the crystal, i.e. the ease with which it can move electrons in that direction and thus create a dipole moment.

The array can be written in the abbreviated form

$$D_i = \varepsilon_0 \varepsilon_{ij} E_j \quad (i, j = x, y, z)$$

and ε_{ij} is now a *tensor* known, in this case, as the permittivity tensor. A tensor is a physical quantity which characterizes a particular physical property of an anisotropic medium, and takes the form of a matrix. Clearly $\boldsymbol{D}$ is not now (in general) parallel with $\boldsymbol{E}$, and the angle between the two also will depend upon the direction of $\boldsymbol{E}$ in the material.

Now it can be shown from energy considerations that the permittivity tensor is symmetrical, i.e. $\varepsilon_{ij} = \varepsilon_{ji}$. Also, symmetrical tensors can be cast into their diagonal form by referring them to a special set of axes (the principal axes) which are determined by the crystal structure [2]. When this is done, we have:

$$\begin{pmatrix} D_x \\ D_y \\ D_z \end{pmatrix} = \varepsilon_0 \begin{pmatrix} \varepsilon_{xx} & 0 & 0 \\ 0 & \varepsilon_{yy} & 0 \\ 0 & 0 & \varepsilon_{zz} \end{pmatrix} \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix}.$$

The new set of axes, Ox, Oy, Oz, is now this special set.

Suppose now that $\boldsymbol{E} = E_x \boldsymbol{i}$, i.e. we have, entering the crystal, an optical wave whose $\boldsymbol{E}$ field lies in one of these special crystal directions.

In this case, we simply have:

$$D_x = \varepsilon_0 \varepsilon_{xx} E_x$$

as our tensor relation and e_{xx} is, of course, a scalar quantity. In other words, we have $\boldsymbol{D}$ parallel with $\boldsymbol{E}$, just as for an isotropic material, and the light will propagate, with refractive index $e_{xx}^{1/2}$, perfectly normally. Furthermore, the same will be true for:

$$\boldsymbol{E} = E_y \boldsymbol{j}, \quad (\text{refractive index } e_{yy}^{1/2})$$

$$\boldsymbol{E} = E_z \boldsymbol{k}, \quad (\text{refractive index } e_{zz}^{1/2}).$$

Before going further we should note an important consequence of all this: the refractive index varies with the direction of $\boldsymbol{E}$. If we have a wave travelling in direction Oz, its velocity now will depend upon its polarization state: if the wave is linearly polarized in the Ox direction it will travel with velocity $c_0/e_{xx}^{1/2}$ while if it is linearly polarized in the Oy direction its velocity will be $c_0/e_{yy}^{1/2}$. Hence the medium is offering two refractive indices to the wave travelling in this direction: we have the phenomenon known as double refraction or 'birefringence'. A wave which is linearly polarized in a direction at 45° to Ox will split into two components, linearly polarized in directions Ox and Oy, the two components travelling at different velocities. Hence the phase difference between the two components will steadily increase and the composite polarization state of the wave will vary progressively from linear to circular and back to linear again.

This behaviour is a direct consequence of the basic physics which was discussed earlier: it is easier, in the anisotropic crystal, for the electric field to move the atomic electrons in one direction than in another. Hence, for the direction of easy movement, the light polarized in this direction can travel faster than when it is polarized in the direction for which the movement is more sluggish. Birefringence is a long word, but the physical principles which underlie it really are very simple. It follows from these discussions that an anisotropic medium may be characterized by means of three refractive indices, corresponding to polarization directions along Ox, Oy, Oz, and that these will have values $e_{xx}^{1/2}$, $e_{yy}^{1/2}$, $e_{zz}^{1/2}$, respectively. We can use this information to determine the refractive index (and thus the velocity) for a wave in any direction with any given linear polarization state.

To do this we construct an 'index ellipsoid' or 'indicatrix', as it is sometimes called (see figure A2.1.13), from the form of the permittivity tensor for any given crystal. This ellipsoid has the following important properties.

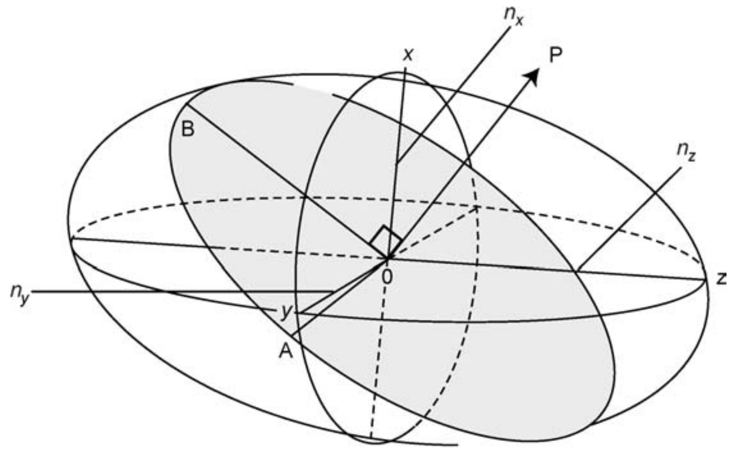
Suppose that we wish to investigate the propagation of light, at an arbitrary angle to the crystal axes (polarization as yet unspecified). We draw a line, OP, corresponding to this direction within the index ellipsoid, passing through its centre O (figure A2.1.13). Now we construct the plane, also passing through O, which lies at right angles to the line. This plane will cut the ellipsoid in an ellipse. This ellipse has the property that the directions of its major and minor axes define the directions of linear polarization for which $\boldsymbol{D}$ and $\boldsymbol{E}$ are parallel for this propagation direction, and the lengths of these axes OA and OB are equal to the refractive indices for these polarizations. Since these two linear polarization states are the only ones which propagate without change of polarization form for this crystal direction, they are sometimes referred to as the 'eigenstates' or 'polarization eigenmodes' for this direction, conforming to the matrix terminology of eigenvectors and eigenvalues.

The propagation direction we first considered, along Oz, corresponds, to one of the axes of the ellipsoid, and the two refractive indices $e_{xx}^{1/2}$ and $e_{yy}^{1/2}$ are the lengths of the other two axes in the central plane normal to Oz.

The refractive indices $e_{xx}^{1/2}$, $e_{yy}^{1/2}$, $e_{zz}^{1/2}$ are referred to as the *principal* refractive indices and we shall henceforth denote them n_x, n_y, n_z. $OxOy$, $OyOz$ and $OzOx$ are the principal planes.

Several other points are very well worth noting. Suppose, firstly, that

$$n_x > n_y > n_z.$$



OA and OB represent the linearly polarized eigenstates for the direction OP

Figure A2.1.13. The index ellipsoid.

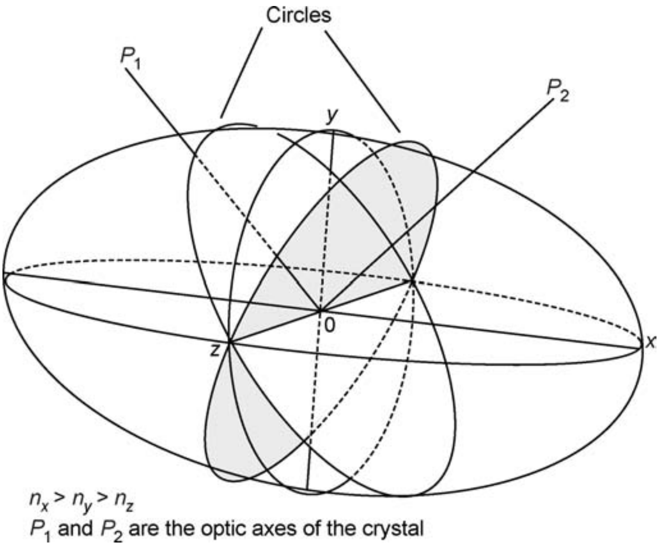


Figure A2.1.14. The ellipsoid for a biaxial crystal.

It follows that there will be a plane which contains *Oz* for which the two axes of interception with the ellipsoid are equal (figure A2.1.14). This plane will be at some angle to the *yz* plane and will thus intersect the ellipsoid in a circle. This means, of course, that, for the light propagation direction corresponding to the normal to this plane, all polarization directions have the same velocity; there is no double refraction for this direction. This direction is an *optic axis* of the crystal and there will, in general, be two such axes, since there must also be such a plane at an equal angle to the *yz* plane on the other side (see figure A2.1.14). Such a crystal with two optic axes is said to be biaxial.

Suppose now that:

$$n_x = n_y = n_\mathrm{o} \quad \text{(say), the `ordinary' index}$$

and

$$n_z = n_\mathrm{e} \quad \text{(say), the `extraordinary' index.}$$

In this case one of the principal planes is a circle and it is the only circular section (containing the origin) which exists. Hence, in this case there is only one optic axis, along the *Oz* direction. Such crystals are said to be uniaxial (figure A2.1.15). The crystal is said to be positive when $n_\mathrm{e} > n_\mathrm{o}$ and negative when $n_\mathrm{e} < n_\mathrm{o}$. For example, quartz is a positive uniaxial crystal, and calcite a negative uniaxial crystal. These features are, of course, determined by the crystal class to which these materials belong.

It is clear that the index ellipsoid is a very useful device for determining the polarization behaviour of anisotropic media.

A2.1.3.4 Circular birefringence

So far we have considered only linear birefringence, where two orthogonal linear polarization eigenstates propagate, each remaining linear, but with different velocities. Some crystals also exhibit circular birefringence. Quartz (again) is one such crystal and its circular birefringence derives from the

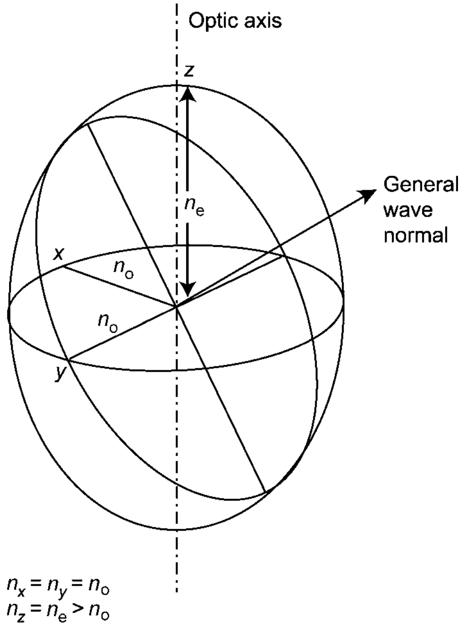

Figure A2.1.15. The ellipsoid for a positive uniaxial crystal.

fact that the crystal structure spirals around the optic axis in a right-handed (dextro-rotatory) or left-handed (laevo-rotatory) sense depending on the crystal specimen: both forms exist in nature.

It is not surprising to find, in view of this knowledge, and our understanding of the easy motions of electrons, that light which is right-hand circularly polarized (clockwise rotation of the tip of the electric vector as viewed by a receiver of the light) will travel faster down the axis of a matching right-hand spiralled crystal structure than left-hand circularly polarized light. We now have circular birefringence: the two circular polarization components propagate without change of form (i.e. they remain circularly polarized) but at different velocities. They are the circular polarization eigenstates for this case.

The term 'optical activity' has been traditionally applied to this phenomenon, and it is usually described in terms of the rotation of the polarization direction of a linearly polarized wave as it passes down the optic axis of an 'optically active' crystal. This fact is exactly equivalent to the interpretation in terms of circular birefringence, since a linear polarization state can be resolved into two oppositely rotating circular components (figure A2.1.16). If these travel at different velocities, a phase difference is inserted between them. As a result of this, when recombined, they again form a resultant which is linearly polarized but rotated with respect to the original direction (figure A2.1.16). Hence 'optical activity' is equivalent to circular birefringence. In general, both linear and circular birefringence might be present simultaneously in a material (such as quartz). In this case the polarization eigenstates which propagate without change of form (and at different velocities) will be elliptical states, the ellipticity and orientation depending upon the ratio of the magnitudes of the linear and circular birefringences, and on the direction of the linear birefringence eigen-axes within the crystal.

It should, again, be emphasised that only the polarization eigenstates propagate without change of form. All other polarization states will be changed into different polarization states by the action of the polarization element (e.g. a crystal component). These changes of polarization state are very useful in opto-electronics. They allow us to control, analyse, modulate and demodulate polarization information impressed upon a light beam, and to measure important directional properties relating to the medium

through which the light has passed. We must now develop a rigorous formalism to handle these more general polarization processes.

A2.1.3.5 Polarization analysis

As has been stated, with both linear and circular birefringence present, the polarization eigenstates (i.e. the states which propagate without change of form) for a given optical element are elliptical states, and the element is said to exhibit elliptical birefringence, since these eigenstates propagate with different velocities.

In general, if we have, as an input to a polarization-optical element, light of one elliptical polarization state, it will be converted, on emergence, into a different elliptical polarization state (the only exceptions being, of course, when the input state is itself an eigenstate). We know that any elliptical polarization state can always be expressed in terms of two orthogonal electric field components defined with respect to chosen axes Ox, Oy, i.e.

$$E_x = e_x \cos(\omega t - kz + \delta_x)$$
$$E_x = e_y \cos(\omega t - kz + \delta_y)$$

or, in complex exponential notation:

$$E_x = |E_x| \exp(\mathrm{i}\varphi_x); \quad \varphi_x = \omega t - kz + \delta_x$$
$$E_y = |E_y| \exp(\mathrm{i}\varphi_y); \quad \varphi_y = \omega t - kz + \delta_y.$$

When this ellipse is converted into another by the action of a lossless polarization element, the new ellipse will be formed from components which are linear combinations of the old, since it results from directional resolutions and rotations of the original fields. Thus these new components can be written:

$$E'_x = m_1 E_x + m_4 E_y$$
$$E'_y = m_3 E_y + m_2 E_y$$

or, in matrix notation

$$\mathbf{E}' = \mathbf{ME}$$

where

$$\mathbf{M} = \begin{pmatrix} m_1 & m_4 \\ m_3 & m_2 \end{pmatrix} \tag{A2.1.16}$$

and the m_n are, in general, complex numbers. **M** is known as a 'Jones' matrix after the mathematician who developed an extremely useful 'Jones calculus' for manipulations in polarization optics [3]. Now in order to make measurements of the input and output states in practice, we need a quick and convenient experimental method.

A convenient method for this practical determination is to use a linear polarizer and a quarter-wave plate, and to measure the light intensities for a series of fixed orientations of these elements.

Suppose that $I(\vartheta, \varepsilon)$ denotes the intensity of the incident light passed by the linear polarizer set at an angle ϑ to Ox, after the Oy component has been retarded by an angle ε as a result of the insertion of the quarter-wave plate with its axes parallel with O_x, O_y. We measure what are called the four Stokes parameters, as follows:

$$\begin{aligned}
S_0 &= I(0^\circ, 0) + I(90^\circ, 0) = e_x^2 + e_y^2 \\
S_1 &= I(0^\circ, 0) - I(90^\circ, 0) = e_x^2 - e_y^2 \\
S_2 &= I(45^\circ, 0) - I(135^\circ, 0) = 2e_x e_y \cos\delta \\
S_3 &= I\left(45^\circ, \frac{\pi}{2}\right) - I\left(135^\circ, \frac{\pi}{2}\right) = 2e_x e_y \sin\delta \\
\delta &= \delta_y - \delta_x.
\end{aligned}$$

If the light is 100% polarized, only three of these parameters are independent, since:

$$S_0^2 = S_1^2 + S_2^2 + S_3^2.$$

S_0 being the total light intensity.

If the light is only partially polarized, the fraction

$$\eta = \frac{S_1^2 + S_2^2 + S_3^2}{S_0^2}$$

defines the degree of polarization. In what follows we shall assume that the light is fully polarized ($\eta = 1$). It is easy to show [4a] that measurement of the S_n provides the ellipticity, e, and the orientation, α, of the polarization ellipse according to the relations:

$$\begin{aligned}
e &= \tan\chi \\
\sin 2\chi &= \frac{S_3}{S_0} \\
\tan 2\alpha &= \frac{S_2}{S_1}.
\end{aligned}$$

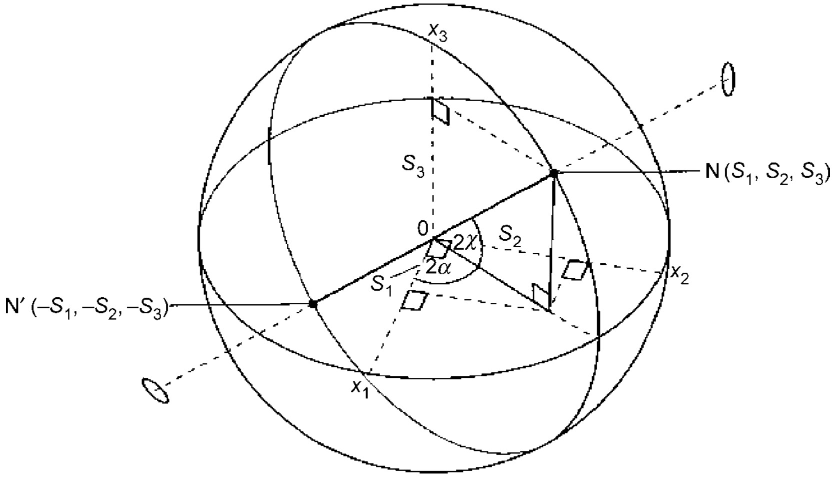

Figure A2.1.17. The Poincaré sphere: the eigenmode diameter (NN′).

Now, the above relations suggest a geometrical construction which provides a powerful and elegant means for description and analysis of polarization-optical phenomena. The Stokes parameters S_1, S_2, S_3 may be regarded as the Cartesian co-ordinates of a point referred to axes Ox_1, Ox_2, Ox_3. Thus every elliptical polarization state corresponds to a unique point in three-dimensional space. For a constant S_0 (lossless medium) it follows that all such points lie on a sphere of radius S_0: the Poincaré sphere (figure A2.1.17). The properties of the sphere are quite well known [5]. We can see that the equator will comprise the continuum of linearly polarized states, while the two poles will correspond to the two oppositely-handed states of circular polarization.

It is clear that any change, resulting from the passage of light through a lossless element, from one polarization state to another, corresponds to a rotation of the sphere about a diameter. Now any such rotation of the sphere may be expressed as a unitary 2 × 2 matrix **M**. Thus, the conversion from one polarization state **E** to another **E**′ may also be expressed in the form:

$$\mathbf{E}' = \mathbf{M}\mathbf{E}$$

or

$$\begin{pmatrix} E'_x \\ E'_y \end{pmatrix} = \begin{pmatrix} m_1 & m_4 \\ m_3 & m_2 \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix}$$

i.e.

$$E'_x = m_1 E_x + m_4 E_y$$
$$E'_y = m_3 E_x + m_2 E_y$$

where

$$\mathbf{M} = \begin{pmatrix} m_1 & m_4 \\ m_3 & m_2 \end{pmatrix}$$

and **M** may be immediately identified with our previous **M** (equation (A2.1.16)).

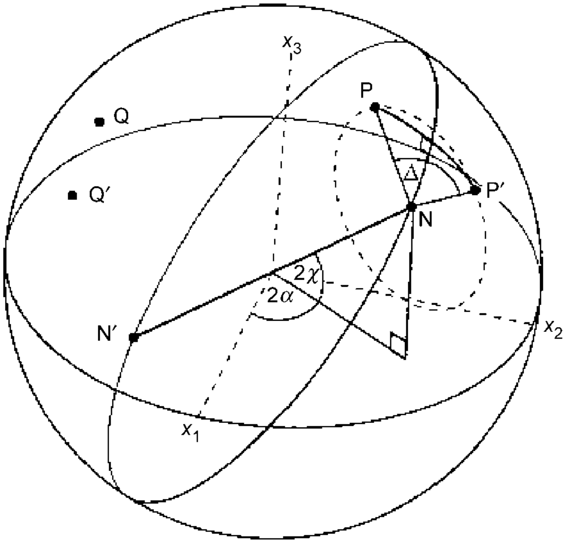

Figure A2.1.18. Rotation of the Poincaré sphere about an eigenmode diameter, NN′.

M is a Jones matrix [3] which completely characterizes the polarization action of the element and is also equivalent to a rotation of the Poincaré sphere.

The two eigenvectors of the matrix correspond to the eigenmodes (or eigenstates) of the element (i.e. those polarization states which can propagate through the element without change of form). These two polarization eigenstates lie at opposite ends of a diameter (NN′) of the Poincaré sphere, and the polarization effect of the element is to rotate the sphere about this diameter (figure A2.1.18) through an angle Δ which is equal to the phase which the polarization element inserts between its eigenstates.

The polarization action of the element may thus be regarded as that of resolving the input polarization state into the two eigenstates with appropriate amplitudes, and then inserting a phase difference between them before recombining to obtain the emergent state. Thus, a pure rotator (e.g. optically active crystal) is equivalent to a rotation about the polar axis, with the two oppositely handed circular polarizations as eigenstates. The phase velocity difference between these two eigenstates is a measure of the circular birefringence. Analogously, a pure linear retarder (such as a wave plate) inserts a phase difference between orthogonal linear polarizations which measures the linear birefringence. The linear retarder's eigenstates lie at opposite ends of an equatorial diameter.

It is useful for many purposes to resolve the polarization action of any given element into its linear and circular birefringence components. The Poincaré sphere makes it clear that this may always be done since any rotation of the sphere can always be resolved into two sub-rotations, one about the polar diameter and the other about an equatorial diameter.

From this brief discussion we can begin to understand the importance of the Poincaré sphere. It is a construction which converts all polarization actions into visualizable relationships in three-dimensional space.

To illustrate this point graphically let us consider a particular problem. Suppose that we ask what is the smallest number of measurements necessary to define completely the polarization properties of a given lossless polarization element, about which we know nothing in advance. Clearly, we must provide known polarization input states and measure their corresponding output states, but how many input/output pairs are necessary: one, two, more?

The Poincaré sphere answers this question easily. The element in question will possess two polarization eigenmodes and these will be at opposite ends of a diameter. We need to identify this diameter. We know that the action of the element is equivalent to a rotation of the sphere about this diameter, and through an angle equal to the phase difference which the element inserts between its eigenmodes. Hence, if we know one input/output pair of polarization states (NN′), we know that the rotation from the input to the output state must have taken place about a diameter which lies in the plane which perpendicularly bisects the line joining the two states (see figure A2.1.18). Two other input/output states (QQ′) will similarly define another such plane, and thus the required diameter is clearly seen as the common line of intersection of these planes.

Further, the phase difference Δ inserted between the eigenstates (i.e. the sphere's rotation angle) is easily calculated from either pair of states, once the diameter is known.

Hence the answer is that *two* pairs of input/output states will define completely the polarization properties of the element. Simple geometry has provided the answer. A good general approach is to use the Poincaré sphere to determine (visualize?) the nature of the solution to a problem, and then to revert to the Jones matrices to perform the precise calculations. Alternatively, some simple results in spherical trigonometry will usually suffice.

A2.1.3.6 Summary

In this section, we have looked closely at the directionality possessed by the optical transverse electric field, i.e. we have looked at optical polarization. We have seen how to describe it, to characterize it, to control it, to analyse it, and how, in some ways, to use it.

We have also looked at the ways in which the transverse electric and magnetic fields interact with directionalities (anisotropies) in material media through which the light propagates. In particular, we first looked at ways in which the interactions allow us to probe the nature and extent of the material directionalities, and thus to understand better the materials themselves.

Secondly, we looked briefly at the ways in which these material interactions allow us to control light: to modulate it, and perhaps to analyse it.

We shall find later that the knowledge we have gained bears upon more advanced phenomena, such as those which allow light to switch light and to process light, opening up a new range of possibilities in the world of very fast (femtosecond: 10^{-15} s) phenomena.

A2.1.4 Optical coherence

A2.1.4.1 Introduction

In dealing with interference and diffraction the assumption usually is made that each of the interfering waves bears a constant phase relationship to the others in both time and space. Such an assumption cannot be valid for all time and space intervals since the atomic emission processes which give rise to light are largely uncorrelated, except for the special case of laser emission. In this section, the topic of 'coherence' will be dealt with. Clearly, it will have a bearing on interference phenomena.

The coherence of a wave describes the extent to which it can be represented by a pure sine wave. A pure sine wave has infinite extension in space and time, and hence cannot exist in reality. Perfect coherence is thus unachievable, but it is nevertheless a valuable concept.

Coherence, in general, is a valuable concept because it is a measure of the constancy of the relationships between one part of a wave (in time and/or space) and another; and between one wave and another. This is why it is so important from the point of view of interference: a wave can only interfere with itself or with another wave (of the same polarization) to produce a sensible interference pattern if

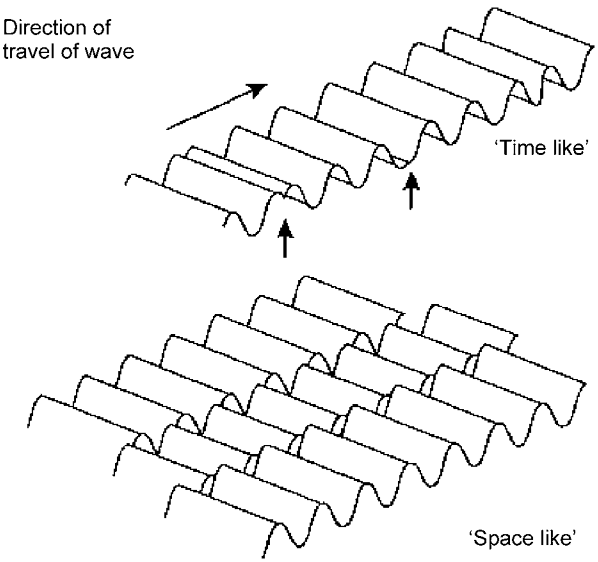

Figure A2.1.19. Illustrations for partial coherence.

the phases and amplitudes remain in constant relationship whilst the pattern is being sensed. Additionally, it is clear that if we wish to impose information on an optical wave by modulating one of its defining parameters (i.e. amplitude, phase, polarization or frequency) then the extent to which that information remains intact is mirrored by the extent to which the modulated parameter remains intact on the wave itself; thus coherence is an important parameter in respect of the optical wave's information-carrying capacity, and our ability generally to control and manipulate it.

Waves which quite accurately can be represented by sine waves for a limited period of time or in a limited region of space are called partially coherent waves. Figure A2.1.19 shows examples of time-like and space-like partial coherence.

A normal light source emits quanta of energy at random. Each quantum conveniently can be regarded as a finite wave train having angular frequency ω_0, say, and duration $2\tau_c$ (figure A2.1.20).

Fourier theory tells us that this wave train can be described in the frequency domain as a set of waves lying in the frequency range $\omega_0/2\pi \pm 1/\tau_c$. For a large number of randomly-emitted wave packets all the components at any given frequency will possess random relative phases. Spatial and temporal (time-like) coherence will thus only exist for, respectively, a distance of the order of the length of one

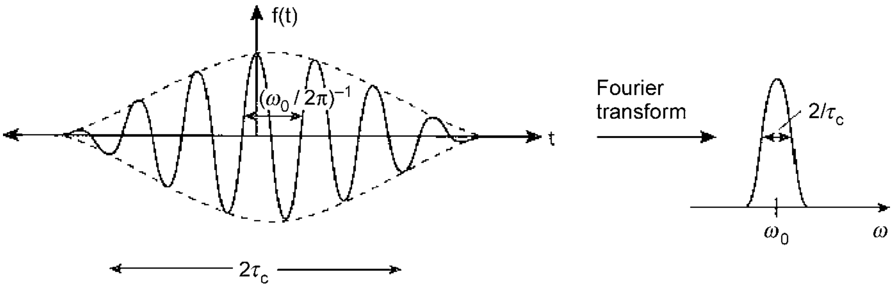

Figure A2.1.20. The optical wave packet.

packet ($2c\tau_c$) and a time of the order of its duration ($2\tau_c$). If the wave packets were of infinitely short duration (δ-function pulses) then Fourier theory tells us that all frequencies would be present in equal amounts and they would be completely uncorrelated in relative phase. This is the condition we call white light. Its spatial and temporal coherence are zero (i.e. there is perfect *incoherence*) and, again, it is an unachievable fiction. Between the two fictions of perfect coherence and perfect incoherence there lies the real world.

In this real world we have to deal with real sources of light. Real sources always have a nonzero spectral width, i.e. the light power is spread over a range of frequencies, and the result of superimposing all the frequency components, as again we know from Fourier theory, is to produce a disturbance which is not a pure sine wave: an example is the wave packet we have just considered. Another is the infinitesimally narrow δ-function.

Hence there is seen to be a clear connection between spectral width and coherence. The two are inversely proportional. The narrower is a pulse of light (or any other waveform) the less it is like a pure sine wave and, by Fourier theory, the greater is its spectral width.

In the practical case of a two-slit interference pattern, the pattern will be sharp and clear if the light used is of narrow linewidth (a laser perhaps); but if a broad-linewidth source, such as a tungsten filament lamp, is used, the pattern is multicoloured, messy and confused.

Of course, we need to quantify these ideas properly if we are to use them effectively.

A2.1.4.2 Measure of coherence

If we are to determine the measurable effect which the degree of coherence is to have on optical systems, especially those which involve interference and diffraction phenomena, we need a quantitative measure of coherence. This must measure the extent to which we can, knowing the (complex) amplitude of a periodic disturbance at one place and/or time, predict its magnitude at another place and/or time. We know that this measure can be expected to have its maximum value for a pure sine wave, and its minimum value for white light. A convenient definition will render these values 1 and 0, respectively.

To fix ideas, and to simplify matters, let us consider first just temporal coherence.

We may sensibly postulate that for a time function $f(t)$ a knowledge of its value at t will provide us with some knowledge of its value up to a later time, say t', when it becomes completely independent of its value at t. If two time functions are completely independent then we expect the average value of their product over a time which is long compared with the characteristic time constant for their variations (i.e. the reciprocal of bandwidth) to be equal to the product of their individual average values, i.e.

$$\langle f(t)f(t')\rangle = \langle f(t)\rangle\langle f(t')\rangle \tag{A2.1.17}$$

and if, as is the case for the vast majority of optical disturbances, the functions oscillate about a zero mean, i.e.

$$\langle f(t)\rangle = \langle f(t')\rangle = 0$$

then it follows from equation (A2.1.17) that:

$$\langle f(t)f(t')\rangle = 0.$$

In words: the product of two independent functions, when averaged over a term which is long compared with the time over which each changes significantly, is zero.

On the other hand, if we set $t = t'$, our 'delay average' above must have its maximum possible value, since a knowledge of the value of $f(t)$ at t enables us to predict its value at that time t with absolute certainty! Hence we have

$$\langle f(t)f(t)\rangle = \langle f^2(t)\rangle$$

and this must be the maximum value of the 'delay-average' function.

Clearly, then the value of this product (for all real-world functions) will fall off from a value of unity when $t' = t$, to a value of zero when the two variations are completely independent, at some other value of t'; and it is also clear that the larger the value of t' for which this occurs, the stronger is the dependence and thus the greater is the coherence. It might well be, then, that the quantity which we seek in order to measure the coherence is a quantity which characterizes the speed at which this product function decays to zero.

Suppose, for example, we consider a pure, temporal sine wave in this context. We know in advance that this is a perfectly coherent disturbance, and conveniently we would thus require our coherence measure to be unity.

Let us write the wave as:

$$f(t) = a \sin \omega t.$$

To obtain the 'delay-average' function we first multiply this by a replica of itself, displaced by time τ (i.e. $t' = t + \tau$) (figure A2.1.21). We have:

$$\begin{aligned} f(t)f(t+\tau) &= a \sin\omega t\, a \sin\omega(t+\tau) \\ &= \frac{1}{2}a^2[\cos\omega\tau - \cos(2\omega t + \omega\tau)]. \end{aligned}$$

We now average this over all time (zero bandwidth gives a characteristic time constant of infinity!) and, since $\langle\cos(2\omega t + \omega\tau)\rangle = 0$, we have:

$$\langle f(t)f(t+\tau)\rangle = \frac{1}{2}a^2\cos\omega\tau.$$

This quantity we call the self-correlation function (sometimes the auto-correlation function), $c(\tau)$, of the disturbance. In more formal mathematical terms we would calculate it according to:

$$c(\tau) = \lim_{T\to\infty}\frac{1}{T}\int_0^T f(t)f(t+\tau)\,\mathrm{d}t \qquad \text{(A2.1.18)}$$

i.e.

$$c(\tau) = \lim_{T\to\infty}\frac{1}{T}\int_0^T \frac{1}{2}a^2[\cos\omega\tau - \cos(2\omega t + \tau)]t$$

and thus, again:

$$c(\tau) = \frac{1}{2}a^2\cos\omega\tau.$$

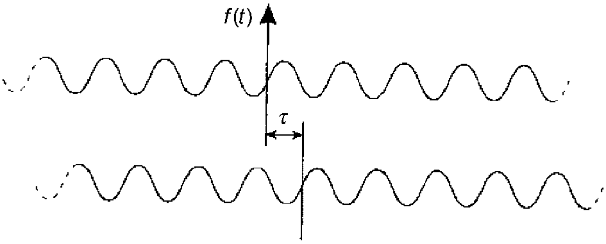

Figure A2.1.21. Self-correlation delay.

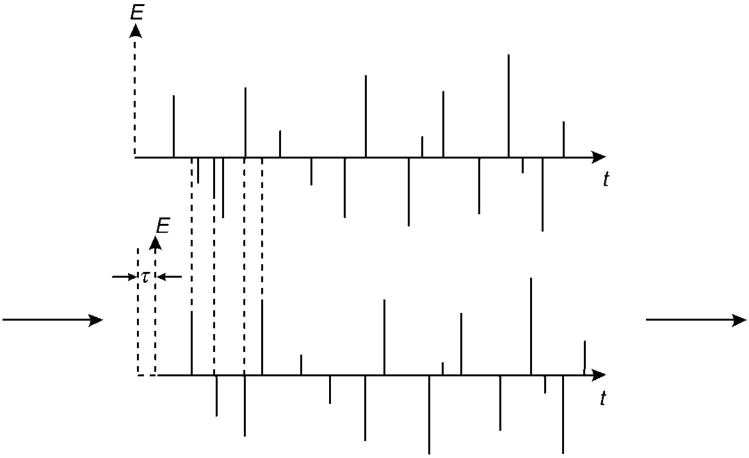

Figure A2.1.22. Auto-correlation for randomly-spaced δ-functions.

This function does not decay, but oscillates with frequency ω and constant *amplitude* $a^2/2$. It is this latter amplitude which we take as our measure of coherence of the light wave, since the sinusoidal term in $\omega\tau$ will always be present for an oscillatory field such as an optical wave, and provides no useful information on the coherence. The mathematical form of $c(\tau)$ is known as a 'convolution' integral.

Since we require, for convenience, that this measure be unity for the sine wave, we choose to normalize it to its value at $\tau = 0$ [i.e. $c(0) = a^2/2$, in this case].

This normalized function we call the coherence function $\gamma(\tau)$, and hence for the case we have considered, $\gamma(\tau) = 1$ (perfect coherence).

Consider now white light. We have noted that this is equivalent to a series of randomly spaced δ-functions which are also randomly positive or negative (figure A2.1.22). Clearly, this series must have a mean amplitude of zero if it is to represent a spread of optical sinusoids over an infinite frequency range, each with a mean amplitude of zero. If now to obtain the 'delay-average' function we multiply this set of δ-functions by a displaced replica of itself, then only a fraction of the total will overlap, and an overlap between two δ-functions of the same sign will have equal probability with that between two of opposite signs. Consequently, the mean value of the overlap function will also be zero, always, regardless of the time delay. Hence for this case, $c(\tau) = 0$ for all τ and $\gamma(\tau) = 0$, (i.e. perfect incoherence).

Consider, finally, a random stream of quanta, or wave packets (figure A2.1.23).

The packets run into each other, but each packet is largely coherent within itself. If this stream waveform is multiplied by a displaced replica of itself the result will be of the form shown in figure A2.1.24(*a*). Only when the displacement exceeds the duration of one packet does the correlation fall essentially to zero. Thus, in this case, we have a decaying sine wave, and the quantity which characterizes the decay rate of its amplitude will be our measure of coherence (for example, time to $1/e$ point for an exponential decay).

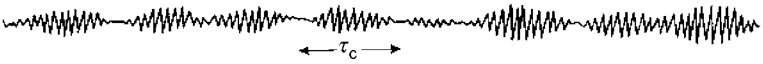

Figure A2.1.23. A random stream of wave packets.

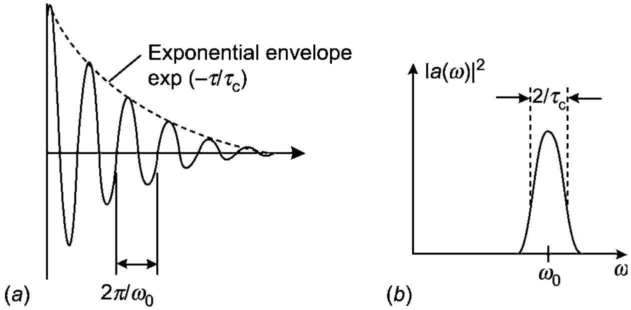

Figure A2.1.24. Stream correlation.

All of the above requirements are taken care of in the general mathematical expression for the coherence function:

$$\gamma(\tau) = \frac{\left|\int_0^\infty f(t) f^*(t+\tau)\mathrm{d}t\right|}{\int_0^\infty f(t) f^*(t)\mathrm{d}t} = \frac{|c(\tau)|}{|c(0)|}.$$

The integration performs the time averaging, the use of the complex form allows the complex conjugate in one of the functions to remove the oscillatory term in the complex exponential representation, the use of the modulus operation returns the complex value to a real value, and the division effects the required normalization. The function $c(\tau)$, as defined in equation (A2.1.18), is called the correlation coefficient and is sometimes separately useful. Note that it is, in general, a complex quantity.

To cement ideas let us just see how these functions work, again for the pure sine wave.

We must express the sine wave as a complex exponential, so that we write:

$$f(t) = a \exp(\mathrm{i}\omega t).$$

Then we have:

$$c(\tau) = \int_0^\infty a \exp(\mathrm{i}\omega t) a \exp[-\mathrm{i}\omega(t+\tau)]\,\mathrm{d}t = a^2 \exp(-\mathrm{i}\omega t)[T]_0^\infty \to \infty$$

and

$$c(0) = \int_0^\infty a \exp(\mathrm{i}\omega t)\, a \exp(-\mathrm{i}\omega t)\mathrm{d}t = a^2[T]_0^\infty \to \infty.$$

Hence

$$\gamma(\tau) = \frac{|c(\tau)|}{|c(0)|} = |\exp(\mathrm{i}\omega\tau)| = 1$$

as required.

The coherence functions for the three cases we have been considering are shown in figure A2.1.25. The sine wave's function does not decay and therefore its coherence time is infinite; the white light's function decays in zero time and thus its coherence time is zero; the 'stream of wave packets' function decays in time τ_c, and thus it is partially coherent with coherence time τ_c. All other temporal functions may have their coherence time quantified in this way. It is clear, also, that the quantity $c\tau_c$ (where c is the velocity of light), will specify a coherence length.

The same ideas, fairly obviously, can also be used for spatial coherence, with τ replaced by σ, the spatial delay. Specifically, in this case:

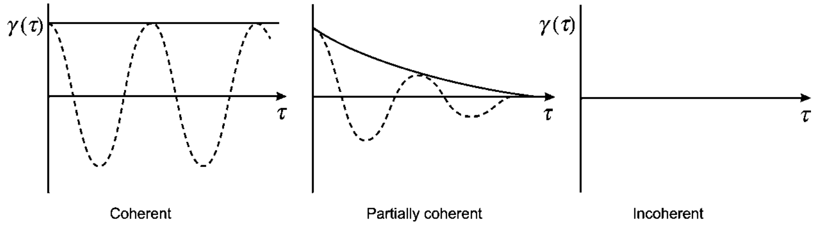

Figure A2.1.25. Coherence functions.

$$\gamma(\sigma) = \frac{\left|\int_0^\infty f(s)\, f^*(s+\sigma)\mathrm{d}s\right|}{\int_0^\infty f(s)\, f^*(s)\mathrm{d}s} = \frac{|c(\sigma)|}{|c(0)|}$$

and a ‘decay’ parameter σ_c will define the coherence length.

Finally, the mutual coherence of two separate functions $f_1(t)$ and $f_2(t)$ may be characterized by a closely similar *mutual coherence* function:

$$\gamma_{12}(\tau) = \frac{\left|\int_0^\infty f_1(t)\, f_2^*(t+\tau)\mathrm{d}t\right|}{\int_0^\infty f_1(t)\, f_2^*(t)\mathrm{d}t} = \frac{|c_{12}(\tau)|}{|c_{12}(0)|}$$

with t, τ again replaceable by s, σ, respectively, for the mutual spatial coherence case.

γ_{12} is sometimes called the ‘degree of coherence’ between the two functions.

A2.1.4.3 Dual-beam interference

We shall first consider in more detail the conditions for interference between two light beams (figure A2.1.26). It is clear, from our previous look at this topic that interference fringes will be formed if the two waves bear a constant phase relationship to each other, but we must now consider the form of the interference pattern for varying degrees of mutual coherence. In particular, we must consider the ‘visibility’ of the pattern; in other words the extent to which it contains measurable structure and contrast.

At the point O (in figure A2.1.26) the (complex) amplitude resulting from the two sources P_1 and P_2 is given by:

$$A = f_1(t'') + f_2(t'')$$

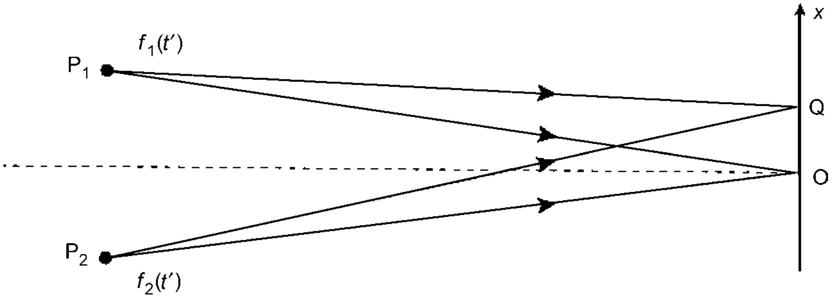

Figure A2.1.26. Two-source interference.

where $t'' = t' + \tau_0$, τ_0 being the time taken for light to travel from P_1 or P_2 to O. If f_1, f_2 represent the electric field amplitudes of the waves, the observed intensity at O will be given by the square of the modulus of this complex number. Remember that the modulus of the complex number: $A = a + \mathrm{i}b$ is written

$$|a + \mathrm{i}b| = (a^2 + b^2)^{1/2}$$

and a convenient stratagem for obtaining the square of the modulus of a complex number is to multiply it by its complex conjugate, i.e.:

$$AA^* = (a + \mathrm{i}b)(a - \mathrm{i}b) = (a^2 + b^2).$$

Hence, in this case the optical intensity is given by

$$I_0 = \langle AA^* \rangle = \langle [f_1(t'') + f_2(t'')][f_1^*(t'') + f_2^*(t'')] \rangle$$

where the triangular brackets indicate an average taken over the response time of the detector (e.g. the human eye) and we assume that f_1 and f_2 contain the required constant of proportionality ($K^{1/2}$) to relate optical intensity with electric field strength, i.e. $I = KE^2$.

At point Q the amplitudes will be:

$$f_1\left(t'' - \frac{1}{2}\tau\right), \quad f_2\left(t'' + \frac{1}{2}\tau\right)$$

τ being the time difference between paths P_2Q and P_1Q.

Writing $t = t' - \frac{1}{2}\tau$ we have the intensity at Q:

$$I_Q = \langle [f_1(t) + f_2(t + \tau)][f_1^*(t) + f_2^*(t + \tau)] \rangle$$

i.e.

$$I_Q = \langle f_1(t)f_1^*(t) \rangle + \langle f_2(t)f_2^*(t) \rangle + \langle f_2(t + \tau)f_1^*(t) \rangle + \langle f_1(t)f_2^*(t + \tau) \rangle.$$

The first two terms are clearly the independent intensities of the two sources at Q. The second two terms have the form of our previously defined mutual correlation function, in fact:

$$\langle f_1(t)f_2^*(t + \tau) \rangle = c_{12}(\tau) \quad \langle f_1^*(t)f_2(t + \tau) \rangle = c_{12}^*(\tau).$$

We may note, in passing, that each of these terms will be zero if f_1 and f_2 have orthogonal polarizations, since in that case neither field amplitude has a component in the direction of the other, there can be no superposition, and the two cannot interfere. Hence the average value of their product is again just the product of their averages, each of which is zero, being a sinusoid.

If $c_{12}(t)$ is now written in the form:

$$c_{12}(\tau) = |c_{12}(\tau)| \exp(\mathrm{i}\omega\tau)$$

(which is valid provided that f_1 and f_2 are sinusoids in ωt) we have:

$$c_{12}(\tau) + c_{12}^*(\tau) = 2|c_{12}(\tau)| \cos \omega\tau.$$

Hence, provided that we observe the light intensity at Q with a detector which has a response time very much greater than the coherence times (self and mutual) of the sources (so that the time averages are valid), then we may write the intensity at Q as:

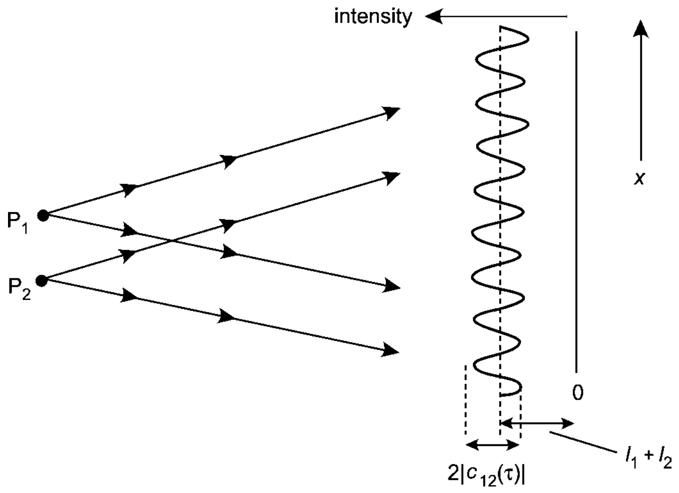

Figure A2.1.27. Mutual coherence function ($|c_{12}(\tau)|$) from the two-source interference pattern.

$$I_Q = I_1 + I_2 + 2|c_{12}(\tau)| \cos \omega t. \tag{A2.1.19}$$

As we move along x we shall effectively increase τ, so we shall see a variation in intensity whose amplitude will be $2|c_{12}(\tau)|$ (i.e. twice the modulus of the mutual coherence function) and which varies about a mean value equal to the sum of the two intensities (figure A2.1.27). Thus we have an experimental method by which the mutual coherence of the sources, $c_{12}(t)$, can be measured.

If we now define a fringe *visibility* for this interference pattern by:

$$V = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}}$$

which quantifies the contrast in the pattern, i.e. the difference between maxima and minima as a fraction of the mean level, then, from equation (A2.1.19):

$$V(\tau) = \frac{2|c_{12}(\tau)|}{(I_1 + I_2)}$$

and with, as previously defined:

$$\gamma(\tau) = \frac{|c_{12}(\tau)|}{|c_{12}(0)|}$$

we note that:

$$|c_{12}(0)| = \left| \int_0^\infty f_1(t)\, f_2^*(t) \mathrm{d}t \right| = K\langle E_1 \rangle \langle E_2 \rangle = (I_1 I_2)^{1/2}$$

and thus:

$$\gamma\,(\tau) = \frac{|c_{12}(\tau)|}{(I_1 I_2)^{1/2}}.$$

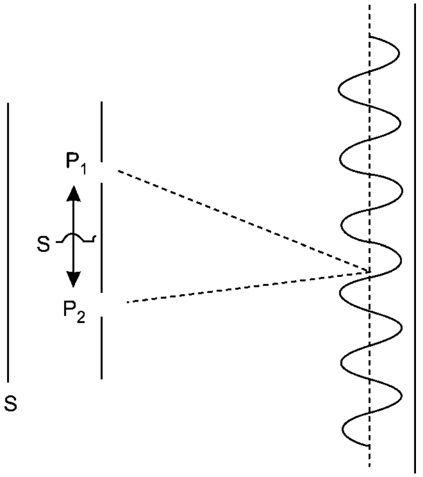

Figure A2.1.28. Extended-source interference.

Hence the visibility function $V(\tau)$ is related to the coherence function $\gamma(\tau)$ by:

$$V(\tau) = \frac{2(I_1 I_2)^{1/2}}{(I_1 + I_2)} \gamma(\tau)$$

and if the two intensities are equal, we have:

$$V(\tau) = \gamma(\tau)$$

i.e. the visibility and coherence functions are identical.

From this we may conclude that, for equal-intensity coherent sources, the visibility is 100% ($\gamma = 1$); for incoherent sources it is zero; and for partially coherent sources the visibility gives a direct measure of the actual coherence.

If we arrange that the points P_1 and P_2 are pinholes equidistant from and illuminated by a single source S, then the visibility function clearly measures the self-coherence of S. Moreover, the Fourier transform of the function will yield the source's power spectrum.

Suppose now that the two holes are placed in front of an extended source, S, as shown in figure A2.1.28, and that their separation is variable. The interference pattern produced by these sources of light now measures the correlation between the two corresponding points on the extended source. If the separation is initially zero and is increased until the visibility first falls to zero, the value of the separation at which this occurs defines a spatial coherence dimension for the extended source. And if the source is isotropic, a coherence area is correspondingly defined. In other words, in this case any given source point has no phase correlation with any point which lies outside the circular area of which it is the centre point.

A2.1.4.4 Summary

In this section, we have looked at the conditions necessary for optical waves to interfere in a consistent and measurable way, with themselves and with other waves. We have seen that the conditions relate to the extent to which properties such as amplitude, phase, frequency and polarization remain constant in time and space or, to put it another way, the extent to which knowledge of the properties at one point in time or space tells us about these properties at other points.

Any interference pattern will only remain detectable as long as coherence persists and, by studying the rise and fall of interference patterns, much can be learned about the sources themselves and about the processes which act upon the light from them.

Coherence also relates critically to the information-carrying capacity of light and to our ability to control and manipulate it sensibly. The design and performance of any device or system which relies on interference or diffraction phenomena must take into account the coherence properties of the sources which are to be used; some of these work to the designer's disadvantage, but others do not.

A2.1.5 Optical waveguiding

A2.1.5.1 Introduction

The basic principles of optical waveguiding are quite straightforward. Waves are guided when they are constrained to lie within a channel between two other media, the refractive index of the channel material being slightly higher than those of the other media, so that the light can 'bounce' along the channel by means of a series of total internal reflections (TIRs) at the boundaries between media. The case shown in figure A2.1.29 is that where a channel of refractive index n_1 lies between two slabs, each with refractive index n_2 ($n_1 > n_2$); this is the easiest arrangement to analyse mathematically, yet it illustrates all the important principles.

The other important point is that, in order to progress down the guide indefinitely, the waves from the successive boundaries must interfere constructively, forming what is essentially a continuous, stable, interference pattern down the guiding channel. If the interference is not fully constructive, the wave will eventually 'self-destruct', owing to the out-of-phase cancellations (although, clearly, if the phasings are almost correct, the wave might persist for a considerable distance, attenuating only slowly). The condition which must be imposed for constructive interference defines for us the guided wave parameters, in particular those angles of bounce which can give rise to the 'modes' of the waveguide, i.e. the various patterns of constructive interference which are allowed by the restrictions (boundary conditions) of the guide geometry.

The ideas involved in waveguiding are thus quite simple. In order to make use of them we need, as always, a proper mathematical description, so we shall in this section develop this description.

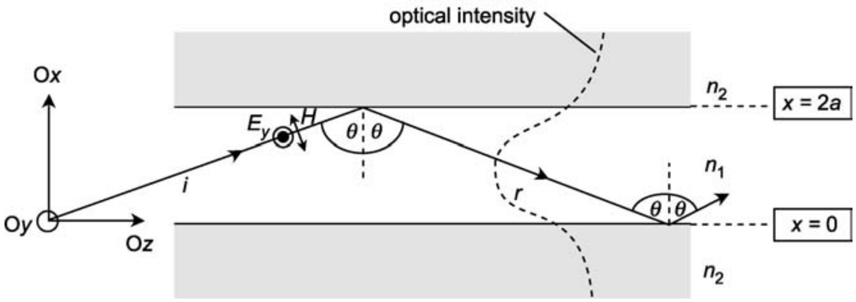

Figure A2.1.29. Optical slab waveguide.

A2.1.5.2 The planar waveguide

We begin by considering the symmetrical slab waveguide shown in figure A2.1.29. The guiding channel consists here of a slab of material of refractive index n_1 surrounded by two outer slabs, each of refractive index n_2. The resultant electric field for light which is linearly polarized in a direction perpendicular to the plane of incidence (the so-called transverse electronic (TE) mode) is given by the sum of the upwards and downwards propagating rays:

$$E_{\mathrm{T}} = E_{\mathrm{i}} + E_{\mathrm{r}}$$

where

$$E_{\mathrm{i}} = E_0 \exp(\mathrm{i}\omega t - \mathrm{i}kn_1 x \cos\vartheta - \mathrm{i}kn_1 z \sin\vartheta)$$

(i.e. a wave travelling in the xz plane at an angle ϑ to the slab boundaries which lie parallel to the yz plane) and

$$E_{\mathrm{r}} = E_0 \exp(\mathrm{i}\omega t + \mathrm{i}kn_1 x \cos\vartheta - \mathrm{i}kn_1 z \sin\vartheta + \mathrm{i}\delta_{\mathrm{s}})$$

which is the wave resulting from the reflection at the boundary, and differs from E_{i} in two aspects: it is now travelling in the negative direction of Ox, hence the change of sign in the x term, and there has been a change of phase at the reflection, hence the $\mathrm{i}\delta_{\mathrm{s}}$ term. We must also remember that δ_{s} depends on the angle, ϑ, the polarization of the wave and, of course, n_1 and n_2 according to the Fresnel equation [4b]. Hence

$$E_{\mathrm{T}} = E_{\mathrm{i}} + E_{\mathrm{r}} \quad = 2E_0 \cos\left(kn_1 x \cos\vartheta + \frac{1}{2}\delta_{\mathrm{s}}\right) \exp\left(\mathrm{i}\omega t - \mathrm{i}kn_1 z \sin\vartheta + \mathrm{i}\frac{1}{2}\delta_{\mathrm{s}}\right) \qquad (\mathrm{A2.1.20}a)$$

which is a wave propagating in the Oz direction, but with amplitude varying in the Ox direction according to $2E_0 \cos\left(kn_1 x \cos\vartheta + \frac{1}{2}\delta_{\mathrm{s}}\right)$ (see figure A2.1.29).

The symmetry of the arrangement tells us that the intensity ($\sim$ *square* of the electric field) of the wave must be the same at the two boundaries and thus that it is the same at $x = 0$ as at $x = 2a$. Hence:

$$\cos^2\left(\frac{1}{2}\delta_{\mathrm{s}}\right) = \cos^2\left(kn_1 2a \cos\vartheta + \frac{1}{2}\delta_{\mathrm{s}}\right)$$

which implies that:

$$2akn_1 \cos\vartheta + \delta_{\mathrm{s}} = m\pi \qquad (\mathrm{A2.1.20}b)$$

where m is an integer. This is our 'transverse resonance condition' and it is a condition on ϑ (remember that δ_{s} also depends on ϑ) which defines a number of allowed values for ϑ (corresponding to the various integer values of m) which in turn define our discrete, allowable modes (or interference patterns) of propagation.

Now the wavenumber, $k = 2\pi/\lambda$, for the free space propagation of the wave has suffered a number of modifications. First, the wavelength of the light is smaller in the medium than in free space (the frequency remains the same, but the velocity is reduced by a factor $n_{1,2}$), so we can conveniently define

$$\beta_1 = n_1 k \quad \beta_2 = n_2 k$$

as the wavenumbers in the guiding and outer slabs, respectively. Secondly, however, if we choose to interpret equation (A2.1.20a) as one describing a wave propagating in the Oz direction with amplitude modulated in the Ox direction, it is convenient to resolve the wavenumber in the guiding medium into components along Oz and Ox, i.e.

along Oz:

$$\beta = n_1 k \sin\vartheta \qquad (\mathrm{A2.1.21}a)$$

along *Ox*

$$q = n_1 k \cos\vartheta. \tag{A2.1.21$b$}$$

Of these two components β is clearly the more important, since it is the effective wavenumber for the propagation down the guide. In fact, equation (A2.1.20*a*) can now be written:

$$E_\mathrm{T} = 2E_0 \cos\left(qx + \frac{1}{2}\delta_\mathrm{s}\right) \exp \mathrm{i}\left(\omega t - \beta z + \mathrm{i}\frac{1}{2}\delta_\mathrm{s}\right).$$

What can be said about the velocity of the wave down the guide? Clearly the phase velocity is given by:

$$c_\mathrm{p} = \frac{\omega}{\beta}.$$

However, we know that this is not the end of the story, for the velocity with which optical energy propagates down the guide is given by the group velocity [5], which, in this case is given by

$$c_\mathrm{g} = \frac{\mathrm{d}\omega}{\mathrm{d}\beta}.$$

What, then, is the dependence of ω upon β?

To answer this, let us start with equation (A2.1.21*a*), i.e.

$$\beta = n_1 k \sin\vartheta.$$

The first thing to note is that, for all real ϑ, this requires:

$$\beta \le n_1 k.$$

Also, since the TIR condition requires that

$$\sin\vartheta \ge \frac{n_2}{n_1}$$

if follows that:

$$\beta = n_1 k \sin\vartheta \ge n_2 k.$$

Hence we have

$$n_1 k \ge \beta \ge n_2 k$$

or

$$\beta_1 \ge \beta \ge \beta_2.$$

In other words, the wavenumber describing the propagation along the guide axis always lies between the wavenumbers for the guiding medium (β_1) and the outer medium (β_2). This we might have expected from the physics, since the propagation lies partly in the guide and partly in the outer medium (evanescent wave). We shall be returning to this point later.

Remember that our present concern is about how β varies with ω between these two limits, so how else does equation (A2.1.21*a*) help?

Clearly, the relation

$$k = \frac{\omega}{c_0}$$

where c_0 is the free space velocity, gives one dependence of β on ω, but what about $\sin\vartheta$? For a given value of m (i.e. a given mode) the transverse resonant condition (A2.1.20*b*) provides the dependence of ϑ on k. However, this is quite complex since, as we know, δ_s is a quite complex function of ϑ. Hence in order to proceed further this dependence must be considered.

The expressions for the phase changes which occur under TIR at a given angle are well known [4]:

$$\tan\frac{1}{2}\delta_s = \frac{(n_1^2\sin^2\vartheta - n_2^2)^{1/2}}{n_1\cos\vartheta}$$

for the case where the electric field is perpendicular to the plane of incidence and

$$\tan\frac{1}{2}\delta_p = \frac{n_1(n_1^2\sin^2\vartheta - n_2^2)^{1/2}}{n_2^2\cos\vartheta}$$

for the case where it lies in the plane of incidence.

Note also that:

$$\tan\frac{1}{2}\delta_p = \frac{n_1^2}{n_2^2}\tan\frac{1}{2}\delta_s.$$

Finally, let us define, for convenience, a parameter, p, where

$$p^2 = \beta^2 - n_2^2k^2 = k^2(n_1^2\sin^2\vartheta - n_2^2). \qquad \text{(A2.1.22)}$$

The physical significance of p will soon become clear.

We now discover that we can cast our ‘transverse resonance’ condition (A2.1.20*b*) into the form

$$\tan\left(aq - \frac{1}{2}m\pi\right) = \frac{p}{q} \quad (E_\perp) \qquad \text{(A2.1.23}a\text{)}$$

for the perpendicular polarization and

$$\tan\left(aq - \frac{1}{2}m\pi\right) = \frac{n_1^2}{n_2^2}\frac{p}{q} \quad (E_\parallel) \qquad \text{(A2.1.23}b\text{)}$$

for the parallel polarization.

The conventional waveguide notation designates these two cases as ‘transverse electric (TE)’ for $E_\perp$ and ‘transverse magnetic (TM)’ for $E_\parallel$. The terms refer, of course, to the direction of the stated fields with respect to the plane of incidence of the ray.

We can use equations (A2.1.23*a*) and (A2.1.23*b*) to characterize the modes for any given slab geometry. The solutions of the equations can be separated into odd and even types according to whether m is odd or even. For odd m we have

$$\tan\left(aq - \frac{1}{2}m_{\mathrm{odd}}\pi\right) = \cot aq \qquad \text{(A2.1.24}a\text{)}$$

and for even m

$$\tan\left(aq - \frac{1}{2}m_{\mathrm{even}}\pi\right) = \tan aq. \qquad \text{(A2.1.24}b\text{)}$$

Taking m to be even we may then write equation (A2.1.23a), for example, in the form:

$$aq \tan aq = ap \quad (E_\perp). \tag{A2.1.25}$$

Now from the definitions of p and q it is clear that:

$$a^2p^2 + a^2q^2 = a^2k^2(n_1^2 - n_2^2). \tag{A2.1.26}$$

Taking rectangular axes ap, aq this latter relation between p and q translates into a circle of radius $ak(n_1^2 - n_2^2)^{1/2}$ (figure A2.1.30). If, on the same axes, we also plot the function aq tan aq, then equation (A2.1.25) is satisfied at all points of intersection between the two functions (figure A2.1.30). (A similar set of solutions clearly can be found for odd m.) These points, therefore, provide the values of ϑ which correspond to the allowed modes of the guide. Having determined a value for ϑ for a given k, β can be determined from:

$$\beta = n_1 k \sin \vartheta$$

and hence β can be determined as a function of k (for a given m) for the TE modes.

Now, finally, with

$$k = \frac{\omega}{c}$$

we have the relationship between β and ω which we have been seeking. For obvious reasons these are called dispersion curves, and are important determinants of waveguide behaviour. They are drawn either

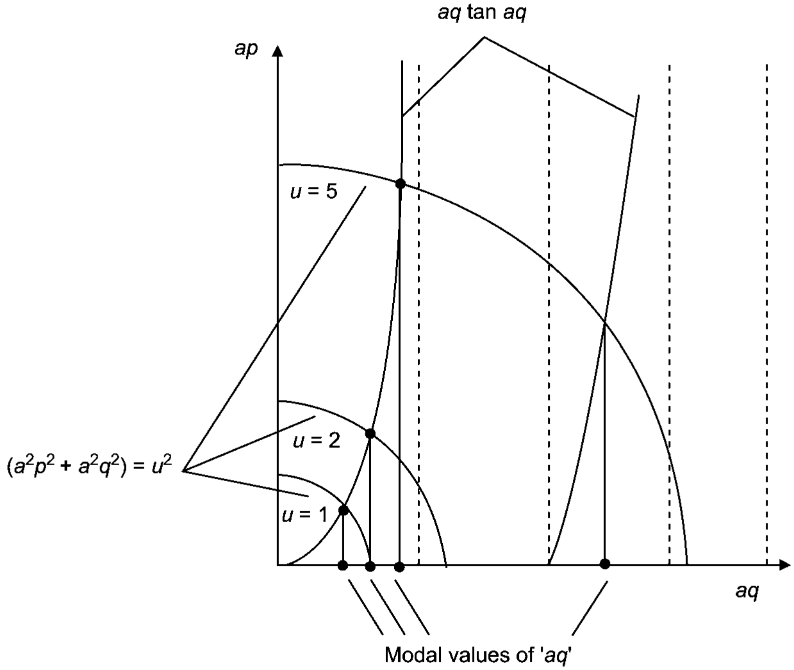

Figure A2.1.30. Graphical solution of the modal equation for the slab waveguide.

as β versus k or as ω versus β. The three lowest order modes for a typical slab waveguide are shown in figure A2.1.31(*a*) using the latter representation. Clearly, this is the more convenient form for determining the group velocity $\mathrm{d}\omega/\mathrm{d}\beta$ by simple differentiation (figure A2.1.31(*b*)).

A final point of great importance should be made. As k decreases, so the quantity

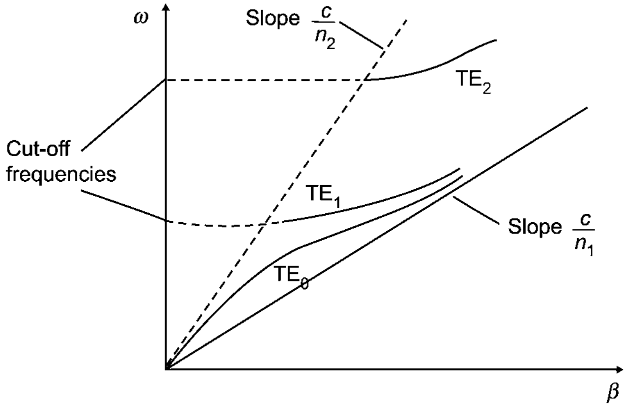
$$a^2p^2 + a^2q^2 = a^2k^2(n_1^2 - n_2^2)$$

decreases and the various modes are sequentially 'cut-off' as the circle (figure A2.1.30) reduces in radius. This is also apparent in figure A2.1.31(*a*) since a reduction in k corresponds to a reduction in ω. Clearly the number of possible modes depends upon the waveguide parameters a, n_1 and n_2. However, it is also clear that there will always be at least one mode, since the circle will always intersect the tan curve at one point, even for a vanishingly small circle radius. If there is only one solution, then figure A2.1.30 shows that the radius of the circle must be less than $\pi/2$, i.e.

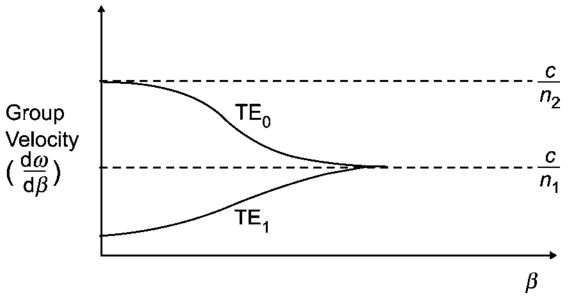
$$ak(n_1^2 - n_2^2)^{1/2} < \frac{1}{2}\pi$$

or

$$\frac{2\pi a}{\lambda}(n_1^2 - n_2^2)^{1/2} < 1.57. \tag{A2.1.27}$$



(*a*) Dispersion diagram for slab waveguide



(*b*) Variation of group velocity with wavenumber

Figure A2.1.31. Dispersion and group velocity for a slab waveguide.

This quantity is another important waveguide parameter, for this and many other reasons. It is given the symbol V and is called the 'normalized frequency', or, quite often, simply the 'V number'. Thus,

$$V = \frac{2\pi a}{\lambda}(n_1^2 - n_2^2)^{1/2}.$$

Equation (A2.1.27) is thus the single-mode condition for this symmetrical slab waveguide. It represents an important case, since the existence of just one mode in a waveguide simplifies considerably the behaviour of radiation within it, and thus facilitates its use in, for example, the transmission of information along it. Physically, equation (A2.1.27) is stating the condition under which it is impossible for constructive interference to occur for any ray other than that which (almost) travels along the guide axis.

Clearly, a very similar analysis can be performed for the TM modes, using equation (A2.1.23*b*).

Look again now at figure A2.1.29. It is clear that there are waves travelling in the outer media with amplitudes falling off the farther we go from the central channel. This is a direct result of the necessity for fields (and their derivatives) to be continuous across the media boundaries. We know from equation (A2.1.20*a*) that the field amplitude in the central channel varies as:

$$E_x = 2E_0 \cos\left(kn_1 x \cos\vartheta + \frac{1}{2}\delta_s\right).$$

How does the field in the outer slabs vary? The evanescent field in the second medium, when TIR occurs, falls off in amplitude according to

$$E_x = E_a \exp\left(-\frac{2\pi x}{\lambda_2}\sinh\gamma\right); \quad x > a$$

where:

(i) E_a is the value of the field at the boundary, i.e.

$$E_a = 2E_0 \cos\left(kn_1 a \cos\vartheta + \frac{1}{2}\delta_s\right)$$

(ii) λ_2 is the wavelength in the second medium, and is equal to λ/n_2

(iii) $2\pi\sinh\gamma/\lambda_2 = k(n_1^2\sin^2\vartheta - n_2^2)^{1/2}$ and this can now be identified with p from equation (A2.1.22). Hence:

$$E_x = E_a \exp(-px); \quad x > a$$

and we see that p is just the exponential decay constant for the amplitude of the evanescent wave (figure A2.1.32) and, from equation (A2.1.22), we note that $p \sim 0.1k$. (It is a fact of any physical analysis that all parameters of mathematical importance will always have a simple physical meaning.)

So the evanescent waves are waves which propagate in the outer media parallel with the boundary but with amplitude falling off exponentially with distance from the boundary.

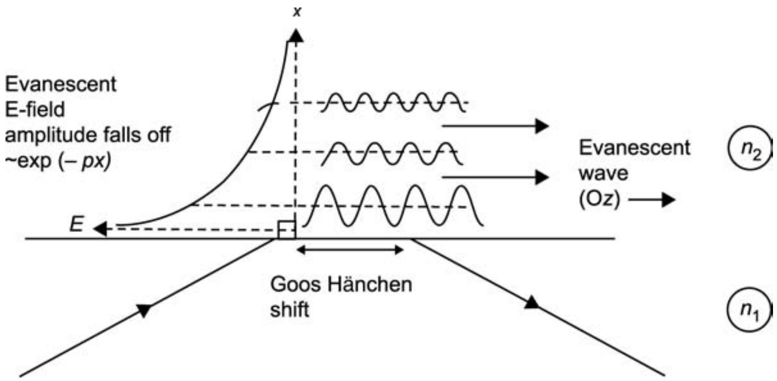


Figure A2.1.32. Evanescent wave decay.

These evanescent waves are very important. First, if the total propagation is not to be disturbed the thickness of each outer slab must be great enough for the evanescent wave to have negligible amplitude at its outer boundary: the wave falls off as $\sim\exp(-x/\lambda)$, so at $x \sim 20\lambda$ it normally will be quite negligible ($\sim 10^{-9}$). At optical wavelengths, then, the slabs should have a thickness $\geq 20\,\mu$m.

Secondly, since energy is travelling (in the *Oz* direction!) in the outer media, the evanescent wave properties will influence the core propagation, in respect, for example, of loss and dispersion.

A2.1.5.3 Integrated optics

Planar waveguides find interesting application in integrated optics. In this, waves are guided by planar channels and are processed in a variety of ways. An example is shown in figure A2.1.33. This is an electro-optic modulator and it utilises electro-optic effect (see section A2.1.7.7) whereby the application of an electric field to a medium alters its refractive index. However, the electric field is acting on a waveguide which, in this case, is a channel (such as we have just been considering) surrounded by ‘outer slabs’ called here a ‘substrate’. The electric field is imposed by means of the two substrate electrodes, and the interaction path is under close control, as a result of the waveguiding. The material of which both the substrate and the waveguide are made should, in this case, clearly be an electro-optic material, such as

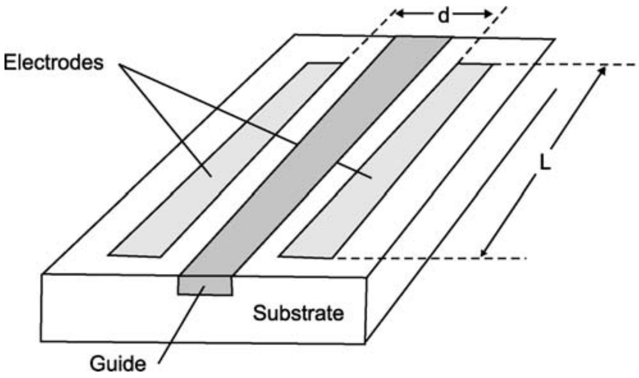

Figure A2.1.33. An integrated-optical electro-optic phase modulator.

lithium tantalate ($LiTaO_3$) whose refractive index depends upon the applied electric field. The central waveguiding channel may be constructed by diffusing ions into it (under careful control); an example of a suitable ion is niobium (Nb), which will thus increase the refractive index of the 'diffused' region and allow total internal reflection to occur at its boundaries with the 'raw' $LiTaO_3$. Many other functions are possible using suitable materials, geometries and field influences. It is possible to fabricate couplers, amplifiers, polarizers, filters, etc. all within a planar 'integrated' geometry.

One of the advantages of this integrated optics technology is that the structures can be produced to high manufactured tolerance by 'mass production' methods, allowing them to be produced cheaply if required numbers are large, as is likely to be the case in optical telecommunications, for example.

A fairly recent, but potentially very powerful, development is that of the 'optoelectronic integrated circuit' (OEIC) which combines optical waveguide functions with electronic ones such as optical source control, photodetection and signal processing, again on a single, planar, readily-manufacturable 'chip'.

Note, finally, that in figure A2.1.33 the 'upper' slab (air) has a different refractive index from the lower one (substrate). This is thus an example of an asymmetrical planar waveguide, the analysis of which is more complex than the symmetrical one which we have considered. However, the basic principles are the same; the mathematics is just more cumbersome, and is covered in many other texts [6].

A2.1.5.4 Cylindrical waveguides

Let us now consider the cylindrical dielectric structure shown in figure A2.1.34. This is the geometry of the optical fibre, the central region being known as the 'core' and the outer region as the 'cladding'. In this case the same basic principles apply as for the dielectric slab, but the circular, rather than planar, symmetry complicates the mathematics. We use, for convenience, cylindrical co-ordinates (r, ϑ, z) as defined in figure A2.1.34. This allows us to cast Maxwell's wave equation for the dielectric structure into the form:

$$\nabla^2 E = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial E}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2 E}{\partial \varphi^2} + \frac{\partial^2 E}{\partial z^2} = \mu\varepsilon\frac{\partial^2 E}{\partial t^2}. \tag{A2.1.28}$$

If we try a solution for E in which all variables are separable, we write:

$$E = E_r(r)E_\varphi(\varphi)E_z(z)E_t(t)$$

and can immediately, from the known physics, take it that:

$$E_z(z)E_t(t) = \exp[\mathrm{i}(\beta z - \omega t)].$$

In other words the wave is progressing along the axis of the cylinder with wavenumber β and with angular frequency ω. It follows, of course, that its (phase) velocity of progression along the axis is given by:

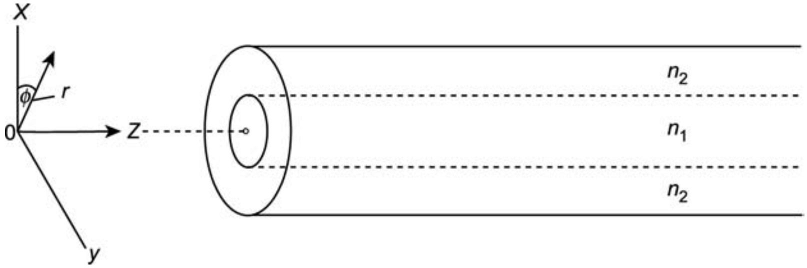

Figure A2.1.34. Cylindrical waveguide geometry.

$$c_{\mathrm{p}} = \frac{\omega}{\beta}.$$

By substitution of these expressions into the wave equation (A2.1.28) we may rewrite it in the form:

$$\frac{\partial}{\partial r}\left(r\frac{\partial(E_r E_\varphi)}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2(E_r E_\varphi)}{\partial\varphi^2} - \beta^2 E_r E_\varphi + \mu\varepsilon\omega^2 E_r E_\varphi = 0.$$

Now if we suggest a periodic function for E_ϑ of the form:

$$E_\varphi = \exp(\pm \mathrm{i} l\varphi)$$

where l is an integer, we can further reduce the equation to:

$$\frac{\partial^2 E_r}{\partial r^2} + \frac{1}{r}\frac{\partial E_r}{\partial r} + \left(n^2k^2 - \beta^2 - \frac{l^2}{r^2}\right)E_r = 0.$$

This is a form of Bessel's equation, and its solutions are Bessel functions (see any advanced mathematical text, e.g. [7]). If we use the same substitutions as for the previous planar case, i.e.

$$n_1^2k^2 - \beta^2 = q^2$$
$$\beta^2 - n_2^2k^2 = p^2$$

we find for $r \le a$ (core)

$$\frac{\partial^2 E_r}{\partial r^2} + \frac{1}{r}\frac{\partial E_r}{\partial r} + \left(q^2 - \frac{l^2}{r^2}\right)E_r = 0$$

and for $r > a$ (cladding)

$$\frac{\partial^2 E_r}{\partial r^2} + \frac{1}{r}\frac{\partial E_r}{\partial r} + \left(p^2 + \frac{l^2}{r^2}\right)E_r = 0.$$

Solutions of these equations are (see figure A2.1.35(*a*)):

$$E_r = E_{\mathrm{c}} J_l(qr);\quad r \le a$$
$$E_r = E_{\mathrm{cl}} K_l(pr);\quad r > a$$

where J_l is a 'Bessel function of the first kind' and K_l is a 'modified Bessel function of the second kind' (sometimes known as a 'modified Hankel function'). The two functions must clearly be continuous at $r = a$, and we have for our full 'trial' solution in the core

$$E = E_{\mathrm{c}} J_l(qr)\exp(\pm \mathrm{i} l\varphi)\exp\ \mathrm{i}(\beta z - \omega t)$$

and a similar one for the cladding

$$E = E_{\mathrm{cl}} J_l(pr)\exp(\pm \mathrm{i} l\varphi)\exp\ \mathrm{i}(\beta z - \omega t).$$

Again we can determine the allowable values for p, q and β by imposing the boundary conditions at $r = a$ [8]. The result is a relationship which provides the β versus k, or 'dispersion' curves, shown in figure A2.1.36. The mathematical manipulations are tedious, but are somewhat eased by using the

Figure A2.1.35. Solution for the cylindrical waveguide equation, and the weakly-guiding approximation.

so-called 'weakly guiding' approximation. This makes use of the fact that if $n_1 \sim n_2$, then the ray's angle of incidence on the boundary must be very large, if TIR is to occur. The ray must bounce down the core almost at grazing incidence. This means that the wave is very nearly a transverse wave, with very small z components. By neglecting the longitudinal components H_z, E_z, a considerable simplification of the mathematics results (figure A2.1.35(b)). Since the wave is, to a first approximation, transverse, it can be resolved conveniently into two linearly polarized components, just as for free space propagation. The

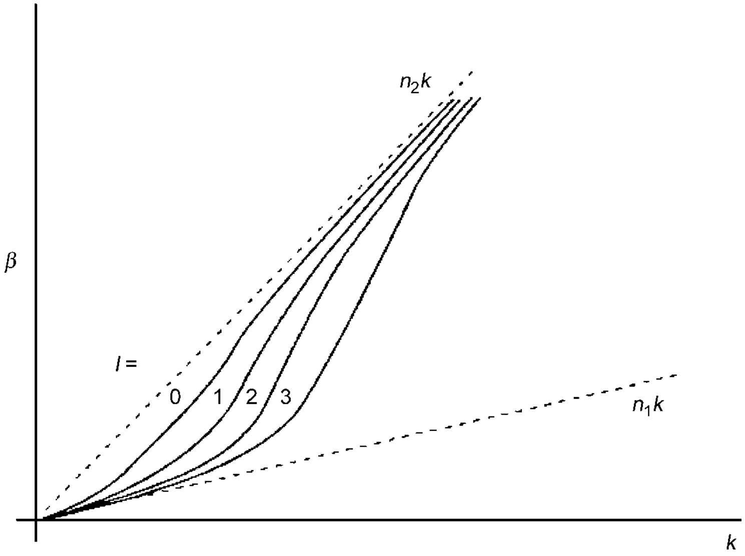

Figure A2.1.36. Dispersion curves for the cylindrical waveguide.

modes are thus dubbed ‘linearly polarized (LP)’ modes, and the notation which describes the profile’s intensity distribution is the ‘LP’ notation.

A2.1.5.5 Optical fibres

The cylindrical geometry relates directly to the optical fibre. The latter has just the geometry we have been considering and, for a typical fibre:

$$\frac{n_1 - n_2}{n_1} \sim 0.01$$

so that the weakly guiding approximation is valid. Some of the low-order ‘LP modes’ of intensity distribution are shown in figure A2.1.37, together with their polarizations, and values for the azimuthal integer, 1. There are, then, two possible linearly polarized optical fibre modes. For the cylindrical geometry the ‘single-mode condition’ is (analogously to equation (A2.1.24) for the planar case):

$$V = \frac{2\pi a}{\lambda}(n_1^2 - n_2^2)^{1/2} < 2.405.$$

The figure 2.405 derives from the value of the argument for which the lowest order Bessel function, J_0, has its first zero. Some important practical features of optical-fibre design can be appreciated by reversion to geometrical (ray) optics.

Let us consider, first, the problem of launching light into the fibre. Referring to figure A2.1.38(*a*), we have for a ray incident on the front face of the fibre at angle ϑ_0, and with refracted angle ϑ_1:

Figure A2.1.38. Ray propagation in optical fibres.

$$n_0 \sin\vartheta_0 = n_1 \sin\vartheta_1$$

where n_0 and n_1 are the refractive indices of air and the fibre core material, respectively. If the angle at which the ray then strikes the core/cladding boundary is ϑ_T, then, for TIR, we must have: $\sin\vartheta > n_2/n_1$ where n_2 is the cladding index.

Since $\vartheta_T = (1/2)\pi - \vartheta_1$ the inequality is equivalent to

$$\cos\vartheta_1 > \frac{n_2}{n_1}$$

so from Snell's law expression above,

$$\cos\vartheta_1 = \left(1 - \frac{n_0^2 \sin^2\vartheta_0}{n_1^2}\right)^{1/2}$$

or

$$n_0 \sin \vartheta_0 < (n_1^2 - n_2^2)^{1/2}.$$

The quantity on the RHS of this inequality is known as the numerical aperture (NA) of the fibre. It is a specification of the 'acceptance' cone of light, this being a cone of apex half-angle ϑ_0. Clearly, a large refractive index difference between core and cladding is necessary for a large acceptance angle; for a typical fibre, $\vartheta_0 \sim 10°$.

The discrete values of reflection angle which are allowed by the transverse resonance condition (within the TIR condition) can be represented by the ray propagations shown in figure A2.1.38(*b*). This makes clear that for a large number of allowable rays (i.e. modes) the TIR angle should be large, implying a large NA. However it is also clear, geometrically, that the rays will progress down the guide at velocities which depend on their angles of reflection: the smaller the angle, the smaller the velocity. This leads to large 'modal dispersion' at large NA since, if the launched light energy is distributed among many modes, the differing velocities will lead to varying times of arrival of the energy components at the far end of the fibre. This is undesirable in, for example, communications applications, since it will lead to a limitation on the communications bandwidth. In a digital system, a pulse cannot be allowed to spread into the pulses before or after it. For greatest bandwidth only one mode should be allowed, and this requires a small NA. Thus a balance must be struck between good signal level (large NA) and large signal bandwidth (small NA).

A fibre design which attempts to attain a better-balanced position between these is shown in figure A2.1.38(*c*). This fibre is known as graded-index (GI) fibre and it possesses a core refractive index profile which falls off parabolically (approximately) from its peak value on the axis. This profile constitutes, effectively, a continuous convex lens, which allows large acceptance angle while limiting the number of allowable modes to a relatively small value. GI fibre is used widely in short and medium distance communications systems. For trunk systems single-mode fibre is invariably used, however. This ensures that the modal dispersion is entirely absent, thus removing this limitation on bandwidth. Single-mode fibre possesses a communications bandwidth which is an order of magnitude greater than that of multimode fibre.

A2.1.5.6 Summary

Optical waveguiding is of primary importance to the optoelectronic designer. With its aid it is possible to confine light and to direct it to where it is needed, over short, medium and long distances.

Furthermore, with the advantage of confinement, it is possible to control the interaction of light with other influences, such as electric, magnetic or acoustic fields, which may be needed to impress information upon it. Control also can be exerted over its intensity distribution, its polarization state and its nonlinear behaviour; this last topic is covered in section A2.1.7.

In short, optical waveguiding is crucial to the control of light. For the designers of devices and systems (especially telecommunications systems, using optical fibres) this control is essential.

A2.1.6 Electrons in solids

A2.1.6.1 Introduction

In order to understand the mechanisms involved in the operation of important solid state devices such as semi-conductor lasers, light-emitting diodes, various types of photodetectors, light modulators, etc it is necessary to look into some of the rather special features of the behaviour of electrons in solid materials, and this is the subject of the present section.

A solid is a state of matter where the constituent atoms or molecules are held in a rigid structure as a result of the fact that the inter-molecular forces are large compared with the forces of thermal motion of the molecules. This can only be true if the molecules are close together, for the molecules are electronically neutral overall, and forces can only exist between them if there is significant overlap among the wavefunctions of the outer electrons. This overlap leads to another important consequence: the energy levels in which the electrons lie are shared levels; they are a property of the material as a whole rather than of the individual molecules, as is the case for a gas, for example.

In order to gain a physical 'feel' for the effect of the strong interaction on the energy level structure in a solid, consider what happens when two simple oscillators, such as two pendulums, interact. If two pendulums each of same length, and thus with the same independent frequency of oscillation, f, are strung from the same support bar, they will interact with each other via the stresses transmitted through the bar, as they swing. For the combined system there are two 'eigenmodes', that is to say two states of oscillation which are stable in time. These are the state where the two pendulums swing together, in phase, and that where they swing in opposition, in antiphase. For all the other states the amplitudes and relative phases of the two pendulums vary with time. The two eigenstates have difference frequencies f_p (in phase) and f_a (in anti-phase) and we find that

$$f_p > f > f_a.$$

The original frequency f is not now a characterizing parameter of the system, having been replaced by two other frequencies, one higher and one lower. If just one of the two pendulums is set swinging it will do so at a frequency in the range f_p to f_a and will set the other pendulum swinging. The second pendulum will acquire maximum amplitude when the first has come to a stop and then the process will reverse. The energy will continuously transfer between the pendulums at a frequency $(f_p - f_a)$. Consider now *three* identical pendulums strung from the same bar. Now there are three eigenstates: (i) all in phase; (ii) outer two in phase, central one in antiphase; (iii) left- or right-hand two in phase, right- or left-hand one in antiphase. Each of these states has its own frequency of oscillation, so we now have three frequencies. It is an easy conceptual extrapolation to n pendulums, where there will be n frequencies centred on the original f, i.e. the original single frequency has become a band of n frequencies. If n is very large, as it is with the number of molecules in a solid, the frequencies are so close together as to comprise essentially a continuous *band* of frequencies, and thus also of electron energy levels. Thus we can expect each discrete energy level of the isolated atom or molecule to form a separate band of allowable energies, and the bands will be separated by gaps which represent energies forbidden to electrons (figure A2.1.39). This feature is crucial to the behaviour of electrons in solids and accounts for most of the properties which are important in optoelectronics. It is, therefore, necessary to study it in more detail before looking at why, exactly, it is so important to us.

A2.1.6.2 Elements of the band theory of solids

Having understood why energy bands form in solids, it is necessary now to understand the ways in which electrons occupy them. This is as crucial to the understanding of the optoelectronic properties of solids as the formation of the bands themselves.

First, it is necessary to remember that electrons obey quantum rules. Associated with each electron is a wave whose wavenumber (~reciprocal of wavelength) is related to the momentum (p) of the electron.

If the electron is propagating freely the relationship is:

$$p = \frac{h}{\lambda} = \frac{hk}{2\pi}$$

and since the kinetic energy of a particle of mass m is related to its momentum p by:

$$E_{\mathrm{k}} = \frac{p^2}{2m}.$$

We have, in the case of the free electron,

$$E_{\mathrm{k}} = \frac{h^2k^2}{8\pi^2 m}. \tag{A2.1.29}$$

We shall need this shortly.

Another consequence of the quantum behaviour of electrons is that they distribute themselves among available energy levels in a rather special way. We say that their distribution obeys 'Fermi–Dirac' statistics, and although it is not necessary to go very deeply into this, it is necessary to understand the basic ideas.

All fundamental particles, such as electrons, protons, neutrons, mesons, quarks, etc, are indistinguishable particles, i.e. there is no way in which an electron, say, can be 'labelled' at one time or place, in such a way that it is possible to recognize it as the same particle at another time or place; and this is not just a 'labelling' problem: it is quite fundamental—a consequence of quantum physics. Hence if two identical (indistinguishable) particles are interchanged in any energy distribution within a system there can be no change in any of the observable macroscopic properties of the system. Now these observable properties depend only on the square of the modulus of the system's overall wavefunction (section A1.8), which is formed from all of the individual electron wavefunctions, i.e.

$$\psi = \psi(1)\psi(2)\cdots\psi(n).$$

If electrons 1 and 2 are interchanged then $|\psi|^2$ must remain the same, i.e.

$$|\psi_{12}|^2 = |\psi_{21}|^2$$

hence

$$\psi_{12} = \pm\psi_{21}.$$

This presents two possibilities: either the interchange leaves the sign of the wavefunction the same, or it reverses it. Particles which leave the sign the same are called symmetrical particles; particles which reverse it are called anti-symmetrical particles.

Now comes the vital point: two anti-symmetrical particles cannot occupy the same quantum state, since the interchange of two identical particles occupying the same quantum state cannot alter the wavefunction in any way at all, not even its sign. Hence no two anti-symmetrical particles can have the same set of 'quantum numbers', numbers which define the quantum state uniquely. This is known as the Pauli exclusion principle. Electrons are anti-symmetrical particles and thus obey the Pauli exclusion principle. In fact all particles with 'half-integral spin', $(n + \frac{1}{2})h/2\pi$, obey the principle, e.g. electrons, protons, neutrons, μ-mesons; these are called fermions (note the small *f* now!). Particles with integral spin, $nh/2\pi$, are symmetrical particles and obey 'Bose–Einstein' statistics: e.g. photons, α-particles, π-mesons; these are called bosons.

The fact that no two electrons can occupy the same quantum state is profound, and is the single most important feature of the behaviour of electrons, in regard to the optoelectronic properties of solids. It means that the available electrons will fill the available quantum states progressively and systematically from bottom to top, like balls in a vertical tube whose diameter is just sufficient to take one ball at a time.

Let us examine this 'filling' process in more detail.

Each allowed energy level in any system contains (in general) more than one quantum state. The number of states which it contains is called the 'degeneracy' of the energy level. (Remember also that each of the bands in the solid state energy structure results from a large number of closely spaced energy levels, so there is also a kind of multiple degeneracy within a band.)

Now suppose, firstly, that the electrons within a given energy band are completely free to move around as if they were an electron 'gas' in the solid. This is approximately true for electrons in a metal, and the only restriction really is that the electrons are not free to leave the solid. How should we calculate the energy states available to the electrons in this case?

Well, fortunately, most of the work necessary for calculating the number of electron states which lie between energies E and $E + \mathrm{d}E$ for this case has already been done, in section A2.1.2.1, for atomic oscillators which give rise to electromagnetic waves; the analogy between electromagnetic waves in a box and electrons in a box is very close. The electron waves are restricted to the same set of discrete values by the box boundaries as were the electromagnetic waves. The only difference is that whereas we had to allow for two polarization states in the electromagnetic case, we now have to allow for two spin directions (e.g. up and down) in the electron case. In both cases we must multiply by a factor of 2, so that equation (A2.1.6*a*) remains valid; i.e. the number of electron states with k values between k and $k + \mathrm{d}k$ is $g(k)$ where

$$g(k)\mathrm{d}k = \frac{k^2\mathrm{d}k}{\pi^2}.$$

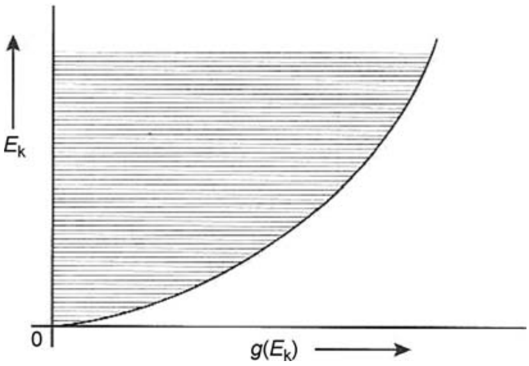

Figure A2.1.40. 'Density of states' function for a metal.

$g(k)$ is known as the degeneracy function. All that is necessary now is to express this in terms of the energy by substituting for k and dk from equation (A2.1.29), i.e.:

$$g(E_{\mathrm{k}})\mathrm{d}E_{\mathrm{k}} = \frac{1}{\pi^2}\frac{8\pi^2 m}{h^2}E_{\mathrm{k}}\left(\frac{8\pi^2 m}{h^2}\right)^{1/2}\frac{1}{2}E_k^{-1/2}\mathrm{d}E_{\mathrm{k}}$$

$$= \frac{4\pi}{h^3}(2m)^{3/2}E_k^{1/2}\mathrm{d}E_{\mathrm{k}}. \qquad \text{(A2.1.30}a\text{)}$$

This function is shown in figure A2.1.40, and in solid state parlance, is usually called the 'density of states' function. It represents the number of states between energies E_{k} and $E_{\mathrm{k}} + \mathrm{d}E_{\mathrm{k}}$.

Hence these are the states which are going to be filled from the bottom up. Each range of E_{k} to $E_{\mathrm{k}} + \mathrm{d}E_{\mathrm{k}}$ will be filled sequentially like the balls in the tube. What, then, is the occupancy of these states? How do the electrons actually distribute themselves among them?

If each energy range is filled in turn, the best way to express this is to plot the fraction of the $g(E_{\mathrm{k}})$ levels which is filled by a total of N_{T} electrons. At the absolute zero of temperature this occupancy function will look like variation A in figure A2.1.41. All the states will be filled up to the level at which the electrons are exhausted. Hence up to that level the fractional occupancy is 1; above that level, it is zero. This level is known as the Fermi level, E_{F}, and is easily calculated if the total number of electrons, N_{T}, is known, for it is necessary only to integrate equation (A2.1.30a) between 0 and E_{F}:

$$N_{\mathrm{T}} = \frac{4\pi}{h^3}(2m)^{3/2}\int_0^{E_{\mathrm{F}}} E_{\mathrm{k}}^{1/2}\mathrm{d}E_{\mathrm{k}}.$$

Hence

$$E_{\mathrm{F}} = \left(\frac{3N_{\mathrm{T}}}{8\pi}\right)^{2/3}\frac{h^2}{2m}. \qquad \text{(A2.1.31)}$$

Using equation (A2.1.31) the density of states function (A2.1.30a) may now conveniently be expressed in the form:

$$g(E)\mathrm{d}E = \frac{3}{2}N_{\mathrm{T}}\frac{E^{1/2}}{E_{\mathrm{F}}^{3/2}}\mathrm{d}E. \qquad \text{(A2.1.30}b\text{)}$$

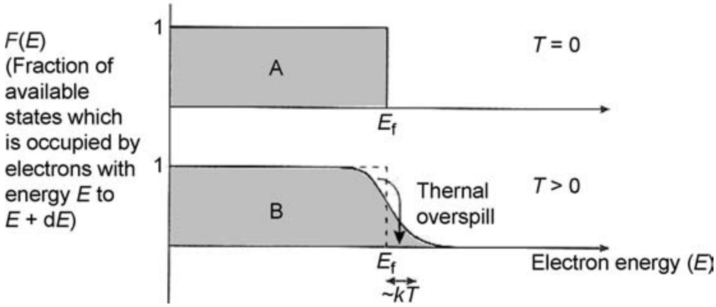

Figure A2.1.41. Fermi–Dirac 'occupancy' distributions.

Suppose now that the temperature rises above absolute zero to a small value $T(>0)$. This makes available to each electron an extra energy $\sim kT(\ll E_F)$. However, most of the electrons cannot take advantage of this because the next available empty level for them is more than kT away. The only electrons which can gain energy are those at the top of the distribution, for they have empty states above them. The distribution thus changes to the one shown as B in figure A2.1.41 for temperature T. Hence the electrons behave very differently from a gas, say, where the average energy of *all* the molecules would increase by kT. (It is for this reason that the specific heat of metals is much smaller ($\sim 1\%$) than was predicted on a free electron theory of metallic conduction; this discrepancy was a great puzzle to physicists in the early years of this century.)

The function which describes the occupancy of the levels at a given temperature is known as the Fermi–Dirac function. It is given by:

$$F(E) = \frac{1}{\exp\left(\frac{E - E_F}{kT}\right) + 1}. \tag{A2.1.32a}$$

Note that it has the behaviour which has already been described:

For $T = 0$ and

$$E < E_F : \exp\left(\frac{E - E_F}{kT}\right) \to 0, \quad F(E) \to 1.$$

For $T = 0$ and

$$E > E_F : \exp\left(\frac{E - E_F}{kT}\right) \to \infty, \quad F(E) \to 0.$$

This clearly corresponds to variation A in figure A2.1.41.

As the temperature rises, the topmost electrons move to higher states and the function develops a 'tail', whose width is $\sim kT$ (curve B in figure A2.1.41). The energy E_F in this case corresponds to the energy for which $F(E) = 0.5$.

Now we are in a position to make the final step: the density of electrons within a given small energy range will be the product of the density of quantum states and the actual occupancy of these states. It will be the product of the density of states function (A2.1.30*b*) and the Fermi–Dirac function (A2.1.32), i.e. $n(E)\mathrm{d}E = g(E)F(E)\mathrm{d}E$ or

$$n(E)\mathrm{d}E = \frac{3}{2}N_{\mathrm{T}}\frac{E^{1/2}}{E_{\mathrm{F}}^{3/2}}\frac{\mathrm{d}E}{\exp\left(\dfrac{E-E_{\mathrm{F}}}{kT}\right)+1} \qquad \text{(A2.1.33}a\text{)}$$

where $n(E)\mathrm{d}E$ is the number per unit volume of electrons with energies between E and $E + \mathrm{d}E$. This function is shown in figure A2.1.42 for $T = 0$ and for $T \neq 0$.

It is interesting to note, before leaving this, that the Fermi–Dirac distribution is a prevalent feature primarily because, in a solid, the number of electrons is comparable with the number of quantum states, and therefore the electrons must be carefully packed according to the quantum rules. If the number of quantum states far exceeds the number of identical particles, as it does in a gas for example, the quantum rules are scarcely noticeable. To see this suppose that, in equation (A2.1.30*b*), $g(E) \gg N_{\mathrm{T}}$, then $E^{1/2} \gg E_{\mathrm{F}}^{3/2}$ and hence $E \gg E_{\mathrm{F}}$. Equation (A2.1.33*a*) becomes:

$$n(E)\mathrm{d}E = \frac{3}{2}N_T\frac{E^{1/2}}{E_{\mathrm{F}}^{3/2}}\exp\left(-\frac{E}{kT}\right)\mathrm{d}E. \qquad \text{(A2.1.33}b\text{)}$$

Expressed in terms of molecular velocity, v, and remembering that the molecular energy in this case is purely kinetic energy of motion, i.e.

$$E = \frac{1}{2}mv^2$$

we have:

$$n(v)\mathrm{d}v = Av^2\exp\left(-\frac{mv^2}{2kT}\right)\mathrm{d}v$$

which is the Maxwell–Boltzmann gas velocity distribution as deduced from classical (i.e. nonquantum) statistical thermodynamics [1].

It turns out that equation (A2.1.33*b*) often also represents a useful approximation in solid state physics. In all cases where the electron distribution is being considered well above the Fermi level (i.e. $E \gg E_{\mathrm{F}}$) the Fermi–Dirac distribution function of equation (A2.1.32*a*) approximates to:

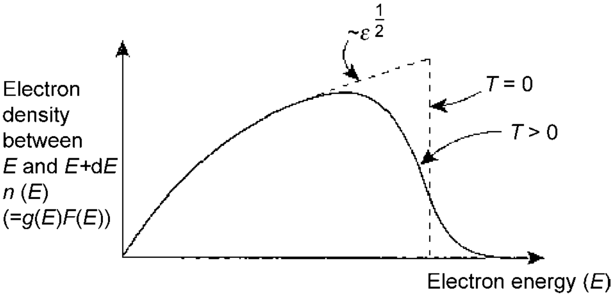

Figure A2.1.42. Electron density distributions for a metal.

$$F(E) = \exp\left(-\frac{E}{kT}\right) \tag{A2.1.32b}$$

which is, of course, the Boltzmann factor. We shall have several occasions to use this later.

A2.1.6.3 Metals, insulators and semiconductors

We are now in a position to understand, qualitatively at first, what it is that distinguishes metals, insulators and semiconductors. It all depends upon the position of the Fermi level.

Consider the solid state band structure in figure A2.1.43. Suppose, first, that a solid consists of atoms or molecules with just one electron in the outermost energy shell. This shell forms a band of energy levels in the solid, as we have seen, and the total number of available states will be $2N$ per unit volume, where N is the number of atoms per unit volume (i.e. two electron spin states per quantum state). But there will be only N electrons per unit volume since there is only one electron per atom. Hence the band is half-filled, and the Fermi level lies halfway up the second band, as in figure A2.1.43(*a*). The electrons at the top of the Fermi–Dirac distribution have easy access to the quantum states above them and can thus move freely in response to, for example, an applied electric field, by gaining small amounts of kinetic energy from it; they can also move to conduct heat energy quickly and easily: we have a metal.

Suppose, secondly, that there are two electrons in the outer shell of the atoms or molecules comprising the solid. The band formed from the shell is now just full and the Fermi level is above the top of the band, as in figure A2.1.43(*b*). The electrons at the top of the band now can only increase their energies by jumping up to the next band. If the energy gap is quite large, neither moderate temperatures nor moderate electric fields can provide sufficient energy for this to happen. Hence, the material does not conduct electricity at all easily: we have an insulator.

Finally, consider the case shown in figure A2.1.43(*c*), again a case where the uppermost level is just full (which will, clearly, be the case for any even number of electrons in the outer shell). Here the Fermi level lies about halfway up the gap between the valence and conduction bands and the gap is now relatively small, say less than $100kT$ for room temperature. (For example the element silicon has a band gap of 1.1 eV, compared with a value for kT, at room temperature, of $\sim 2.5 \times 10^{-2}$ eV. An electron would gain an energy of 1 eV in falling through a potential difference of 1 V.) In this case, although at low temperature the Fermi–Dirac 'tail' does not extend into the upper, conduction band, at higher temperatures it does, giving a small number of electrons in the conduction band. These electrons can then move easily into the abundance of empty states now available to them in this band. Thus the room

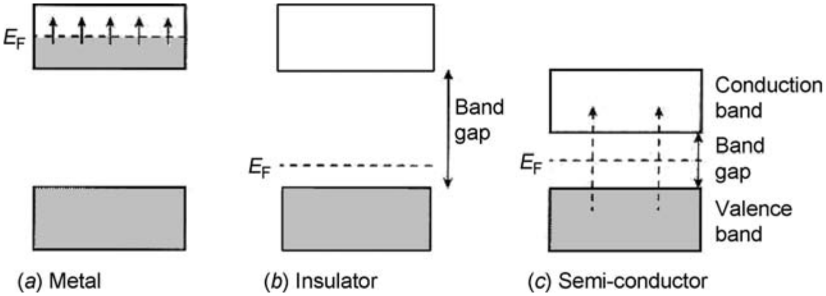

Figure A2.1.43. The Fermi level and the classification of solids.

temperature electrical conductivity is low but measurable; furthermore, it is clear that it will increase quite rapidly with temperature, as the 'tail' extends. We have here a 'semiconductor', more precisely an *intrinsic* semiconductor (it will become clear later why this adjective is necessary). For obvious reasons the upper band is called the conduction band and the lower one the valence band (since it is the stability of electrons in the lower band which provides the atomic forces holding the solid together). There is another important point to be made for the intrinsic semiconductor. When thermal agitation raises an electron from the valence band to the conduction band, it leaves behind an empty state. This state can be filled by another electron, in the valence band, which can then gain energy and contribute to the electrical conduction. These empty states, comprising, as they do, the absence of negative electric charge, are equivalent to positive 'holes' in the valence band, and they effectively move like positive charges as the electrons in the valence band move in the opposite direction to fill them. Positive holes in the valence band comprise an important feature of semiconductor behaviour, and we shall be returning to them shortly.

Before moving on it should be emphasized that the description above is a greatly simplified one, in order to establish the ideas. Solids are complicated states of matter and are three-dimensional, so in general we must not deal just with a single Fermi level but with a three-dimensional Fermi surface, which will have a shape dependent upon the variation of the material's properties with direction. Many important properties of solids depend upon the particular shape which this surface assumes. Especially important is the fact that two energy bands can sometimes overlap, so that it is possible for some elements to behave as metals even though each of their atoms possesses an even number of electrons (the lower band feeds electrons into the middle of the upper band); examples are beryllium, magnesium and zinc. However, this is the stuff of pure solid state physics and, for more, interested readers must refer to one of the many specialist texts on solid state physics [9].

It has become clear then that the position of the Fermi level in relation to the band structure for a particular solid material is vitally important. It is important not only for distinguishing between metals, insulators and semiconductors but also for understanding the detailed behaviour of any particular material.

We have seen how to calculate the Fermi level for the case of electrons moving freely within a solid. However, electrons are not entirely free to move within a crystal, or even a quasi-crystal structure, and this has important consequences which lie within a more detailed consideration of this topic. Space limitations do not allow this treatment here and the interested reader is referred to the literature [9].

A2.1.6.4 Extrinsic semiconductors

Finally, we must consider another very important type of semiconductor material. This is the doped semiconductor, otherwise known as the 'extrinsic' semiconductor. In these materials, the semiconducting properties can be both enhanced and controlled by adding specific impurities in carefully judged quantities. The effect of this is to alter the electron energy distribution in a controlled way.

We begin by considering a particular intrinsic semiconductor, silicon, since, with germanium, it is one of the two most commonly used materials for doping in this way. Both materials have a diamond-like structure, with each atom surrounded symmetrically by four others. Silicon is tetravalent, having an even number of electrons in its valence shell. There will thus be $4N$ available electrons per unit volume. The first valence energy band will be filled with $2N$ electrons and the second band also with $2N$ electrons; thus both lower bands are full and the next higher one is empty, at absolute zero (figure A2.1.44). The gap between the upper valence band and the conduction band is quite small, only 1.1 eV, compared with

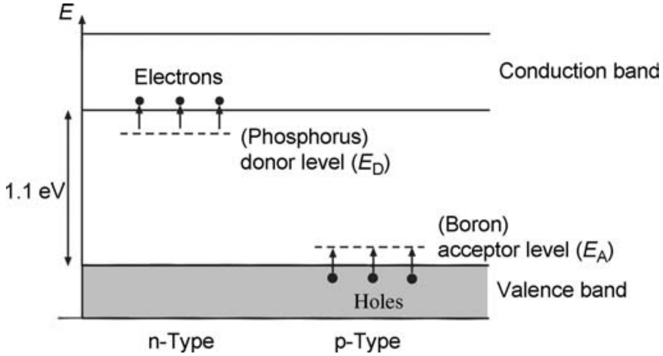

Figure A2.1.44. Energy level diagram for doped silicon.

a room temperature value of kT of $\sim 2.5 \times 10^{-2}$ eV so, although silicon is an intrinsic semiconductor, its semiconductivity is moderate, and it increases exponentially with temperature.

Suppose now that the silicon is doped with a small fraction (between 1 atom in 10^6 and 1 in 10^9) of a pentavalent (valency of five) impurity atom such as phosphorus. This atom sits quite comfortably in the silicon lattice but has one extra electron compared with the silicon atoms by which it is surrounded, and this electron is easily detached to roam through the lattice and add to the conductivity. In energy level parlance we say that it needs little energy to raise it into the conduction band; in fact for this particular case it needs only 4.5×10^{-2} eV, equivalent to only about $2kT$ at room temperature. So the energy level structure looks like figure A2.1.44 with the 'donor' level, E_D, just below the conduction band. Note that the level remains sharp, since the dopant atoms are scarce and spaced well apart in the lattice, and thus their wavefunctions cannot overlap to form a band structure, as do the atoms of the host lattice. Since, in this case, the effect of the phosphorus is to donate electrons (negative charges) to the conductivity, this is called an n-type semiconductor. The really important point is that the conductivity now is entirely under control, via control of the doping level. The greater the concentration of the dopant atoms, the greater will be the concentration of electrons in the conduction band.

Consider, on the other hand, what happens if we dope the silicon with a tervalent (valency of three) impurity such as boron. In this case the impurity atom has one electron fewer than the surrounding silicon atoms, and electrons from the valence band in the silicon can easily move into the space so created. These 'absent' (from the valence band) electrons create positive holes, as we have seen, and these also are effective in increasing the conductivity. For obvious reasons this is now called a p-type semiconductor (figure A2.1.44) and the corresponding energy level is an 'acceptor' level. The 'majority carriers' are holes in this case; in an n-type material the majority carriers are electrons.

Usually, the donor or acceptor dopings dominate the semiconductor behaviour. In other words, it is normally the case that the dopant concentrations exceed the intrinsic carrier concentration n_i. If the dopant concentrations are N_d for donor and N_a for acceptor, it must be that for charge neutrality of the material:

$$n + N_a = p + N_d. \tag{A2.1.33}$$

However, it is also true that, for all circumstances:

$$pn = n_i^2.$$

Hence, for an acceptor doping (p-type material) we have: $N_a \gg N_d, n_i$ and thus from equation (A2.1.33):

$$p = N_a$$

$$n = \frac{n_\mathrm{i}^2}{N_a}.$$

For a donor material (n-type): $N_\mathrm{d} \gg N_\mathrm{a}$, n_i and thus:

$$n = N_\mathrm{d}$$

$$p = \frac{n_\mathrm{i}^2}{N_\mathrm{d}}.$$

It is clear, then, that a knowledge of n_i and the dopant level fixes the carrier concentrations and thus allows the main features of behaviour to be determined. Where are the Fermi levels in these extrinsic semiconductors? We know that in the case of intrinsic semiconductors, the Fermi level lies about halfway between the valence and conduction bands. In an n-type semiconductor the valence band is almost full and most of the conduction is due to electrons donated from the donor levels. Hence it follows that the '50% electron occupancy' level, i.e. the Fermi level, will now lie about half way between the donor level and the bottom of the conduction band, since the top of the 'valence' band can now be identified with the donor level (figure A2.1.45).

Similarly, for p-type semiconductors, it will lie midway between the top of the valence band and the acceptor energy level. However, this can only be the case as long as the donor or acceptor mechanisms dominate. At higher temperatures most of the donor and acceptor sites would have been exhausted and the true valence band then starts to dominate the conduction mechanism. Hence the Fermi level will vary with temperature as shown in figure A2.1.45, until at high enough temperatures, it reverts to the intrinsic value in both p and n cases.

A2.1.6.5 Binary and ternary semiconductors

We cannot leave semiconductors without a mention of some important, relatively new, materials. These are alloys, made from two or more elements in roughly equal proportions and from different groups in the periodic table, and thus with differing numbers of electrons in the outermost shell.

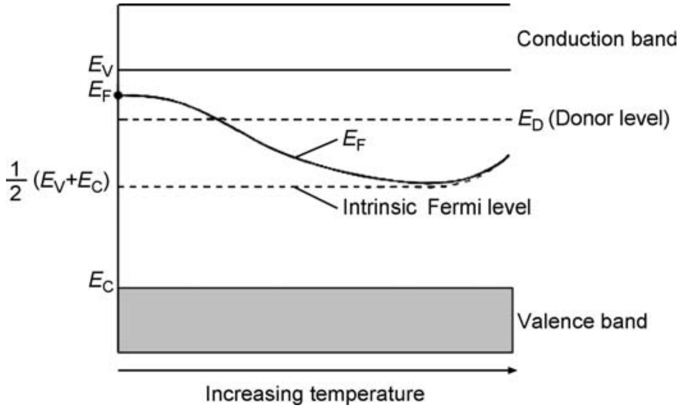

Figure A2.1.45. Fermi level in an n-type intrinsic semiconductor, and its variation with temperature.

The best known of these is gallium arsenide (GaAs) which, since Ga has a valency of III and As of V, is an example of what is called a III–V compound.

An important aspect of these compounds is that we can 'tailor' the band gap by varying the mix. The eight electrons in the two outer shells are shared to some extent and create some ionic bonding, through absence from the parent atom (i.e. it creates a positive ion). The band gap of GaAs when the two elements are present in equal proportions (i.e. same number of molecules per unit volume) is 1.4 eV, but this can be varied by replacing the As by P (GaP, 2.25 eV) or Sb (GaSb, 0.7 eV) for example. Furthermore, the materials can be made p- or n-type by increasing the V(As) over the III(Ga) component, or vice versa.

Another very important aspect of GaAs is that it is a direct-band-gap material: the minimum energy in the conduction-band Brillouin zone occurs at the same *k* value as the maximum energy of the valence band (figure A2.1.46(*a*)). This means that electrons can make the transition between the two bands without having to lose or gain momentum in the process. Any necessary loss or gain of momentum must

always involve a third entity, a ‘phonon’ (quantum of vibration) for example, and this renders the transition much less probable. Hence a direct-band-gap material is much more efficient than an indirect-band-gap material (figure A2.1.46(*b*)) and the processes are much faster, leading to higher device bandwidth.

Quite frequently even finer control is required over the value of the band gap and, for this, ‘band-gap engineers’ turn to ternary alloys, i.e. those involving three elements, where the ratio of III to V composition is still approximately 1:1. An example is the range of alloys which is described by the formula $\mathrm{Al}_x\mathrm{Ga}_{1-x}\,\mathrm{As}$. By varying x, one can move along the line between GaAs and AlAs on figure A2.1.47 and thus vary the band gap appropriately. Figure A2.1.47 shows other materials which can be tailored in this way.

One final difficulty is that, in order to grow the required material one needs a substrate on which to grow it, from either the gas phase (gas-phase epitaxy) or the liquid phase (liquid-phase epitaxy), and this requires that the desired material has approximately the same lattice spacing as the substrate. For the example of $\mathrm{Al}_x\mathrm{Ga}_{1-x}\,\mathrm{As}$ there is little difficulty since the GaAs/AlAs line is almost vertical (figure A2.1.47), and thus the lattice spacing always is close to that of GaAs, which can thus be used as the substrate. For other materials, for example, $\mathrm{InAs}_y\mathrm{Sb}_{1-y}$, this is clearly not the case since the InAs/InSb line is almost horizontal. This problem can be solved by going one stage yet further, to quaternary alloys which lie in the regions bounded by the lines in figure A2.1.47. An example of a quaternary alloy is $\mathrm{In}_x\mathrm{Ga}_{1-x}\,\mathrm{As}_y\mathrm{P}_{1-y}$ and one of these alloys is shown marked x on figure A2.1.47. This has a lattice spacing similar to that of InP, which can thus be used as a satisfactory substrate.

Thus a band-gap engineer generally will choose a substrate, then a suitable quaternary alloy which has the required band gap, probably making sure it is a direct-band-gap material, and then grow the semiconductor.

Band-gap engineering is now a sophisticated, and extremely valuable, technology for the provision of materials for optoelectronic devices; their behaviour and performance depend critically on the material from which they are made.

A2.1.6.6 Summary

Solids are complex states of matter, with their range of overlapping atomic wavefunctions. Many of the ideas are broadly unfamiliar to a nonspecialist physicist. However, many optoelectronic devices and systems rely on the behaviour of electrons in solids, and we need to have a good understanding of this. In studying optoelectronics, we certainly need to draw repeatedly upon the ideas outlined in this section.

A2.1.7 Nonlinear optics

A2.1.7.1 Introduction

In all of the various discussions concerning the propagation of light in material media so far, we have been dealing with linear processes. By this we mean that a light beam of a certain optical frequency which enters a given medium will leave the medium with the same frequency, although the amplitude and phase of the wave will, in general, be altered.

The fundamental physical reason for this linearity lies in the way in which the wave propagates through a material medium. The effect of the electric field of the optical wave on the medium is to set the electrons of the atoms (of which the medium is composed) into forced oscillation; these oscillating electrons then radiate secondary wavelets (since all accelerating electrons radiate) and the secondary wavelets combine with each other and with the original (primary) wave, to form a resultant wave. Now the important point here is that all the forced electrons oscillate at the same frequency (but differing phase, in general) as the primary, driving wave, and thus we have the sum of the waves all of same frequency, but with different amplitudes and phases.

If two such sinusoids are added together:

$$A_{\mathrm{T}} = a_1 \ \sin(\omega t + \varphi_1) + a_2 \ \sin(\omega t + \varphi_2)$$

and we have, from simple trigonometry:

$$A_{\mathrm{T}} = a_{\mathrm{T}} \ \sin(\omega t + \varphi_{\mathrm{T}})$$

where

$$a_{\mathrm{T}}^2 = a_1^2 + a_2^2 + 2a_1a_2 \ \cos(\varphi_1 - \varphi_2)$$

and

$$\tan\varphi_{\mathrm{T}} = \frac{a_1\sin\varphi_1 + a_2\sin\varphi_2}{a_1\cos\varphi_1 + a_2\cos\varphi_2}.$$

In other words, the resultant is a sinusoid of the same frequency but of different amplitude and phase. It follows, then, that no matter how many more such waves are added, the resultant will always be a wave of the same frequency, i.e.

$$A_{\mathrm{T}} = \sum_{n=0}^{N} \ a_n \sin(\omega t + \varphi_n) = \alpha \sin(\omega t + \beta)$$

where α and β are expressible in terms of a_n and ϕ_n.

It follows, further, that if there are two primary input waves, each will have the effect described above independently of the other, for each of the driving forces will act independently and the two will add to produce a vector resultant. We call this the 'principle of superposition' for linear systems since the resultant effect of the two (or more) actions is just the sum of the effects of each on acting on its own.

This has to be the case whilst the displacements of the electrons from their equilibrium positions in the atoms varies linearly with the force of the optical electric fields. Thus, if we pass into a medium, along the same path, two light waves, of angular frequencies ω_1 and ω_2, emerging from the medium will be two light waves (and only two) with those same frequencies, but with different amplitudes and phases from the input waves.

Suppose now, however, that the displacement of the electrons is *not* linear with the driving force. Suppose, for example, that the displacement is so large that the electron is coming close to the point of breaking free from the atom altogether. We are now in a nonlinear regime. Strange things happen here. For example, a given optical frequency input into the medium may give rise to waves of several different frequencies at the output. Two frequencies ω_1 and ω_2 passing in may lead to, among others, sum and difference frequencies $\omega_1 \pm \omega_2$ coming out.

The fundamental reason for this is that the driving sinusoid has caused the atomic electrons to oscillate nonsinusoidally (figure A2.1.48). Our knowledge of Fourier analysis tells us that any periodic nonsinusoidal function contains, in addition to the fundamental component, components at harmonic frequencies, i.e. integral multiples of the fundamental frequency.

This is a fascinating regime. All kinds of interesting new optical phenomena occur here. As might be expected, some are desirable, some are not. Some are valuable in new applications, some just comprise sources of noise. But to use them to advantage, and to minimize their effects when they are a nuisance, we must understand them better. This we shall now try to do.

A2.1.7.2 Nonlinear optics and optical fibres

Let us begin by summarizing the conditions which give rise to optical nonlinearity.

In a semiclassical description of light propagation in dielectric media, the optical electric field drives the atomic/molecular oscillators of which the material is composed, and these oscillators become secondary radiators of the field; the primary and secondary fields then combine vectorially to form the resultant wave. The phase of this wave (being different from that of its primary) determines a velocity of light different from that of free space, and its amplitude determines a scattering/absorption coefficient for the material.

Nonlinear behaviour occurs when the secondary oscillators are driven beyond the linear response; as a result, the oscillations become nonsinusoidal. Fourier theory dictates that, under these conditions, frequencies other than that of the primary wave will be generated (figure A2.1.48).

The fields necessary to do this depend upon the structure of the material, since it is this which dictates the allowable range of sinusoidal oscillation at given frequencies. Clearly, it is easier to generate large amplitudes of oscillation when the optical frequencies are close to natural resonances, and one expects (and obtains) enhanced nonlinearity there. The electric field required to produce nonlinearity in

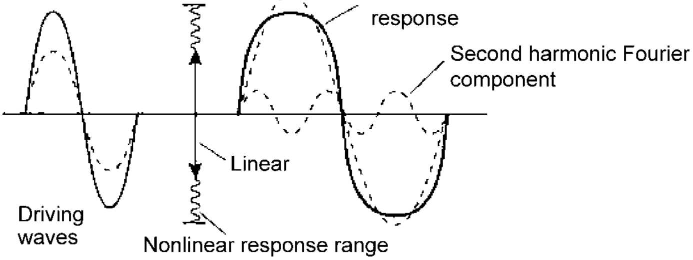

Figure A2.1.48. Nonlinear response to a sinusoidal drive.

material therefore varies widely, from $\sim 10^6$ up to $\sim 10^{11}\,\mathrm{V\,m^{-1}}$, the latter being comparable with the atomic electric field. Even the lower of these figures, however, corresponds to an optical intensity of $\sim 10^9\,\mathrm{W\,m^{-2}}$, which is only achievable practically with laser sources. It is for this reason that the study of nonlinear optics only really began with the invention of the laser, in 1960.

The magnitude of any given nonlinear effect will depend upon the optical intensity, the optical path over which the intensity can be maintained, and the size of the coefficient which characterizes the effect.

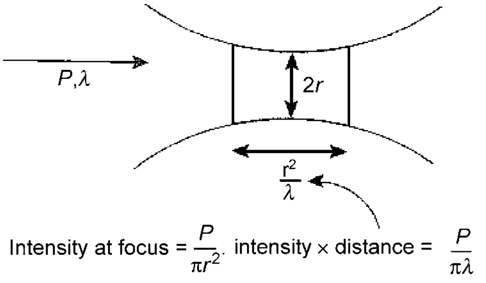
In bulk media, the magnitude of any nonlinearity is limited by diffraction effects. For a beam of power P watts and wavelength λ focused to a spot of radius r, the intensity, $P/\pi r^2$, can be maintained (to within a factor of ~ 2) over a distance $\sim r^2/\lambda$ (Rayleigh distance), beyond which diffraction will rapidly reduce it. Hence the product of intensity and distance is $\sim P/\pi\lambda$, independent of r and of propagation length (figure A2.1.49(*a*)).

However, in an optical fibre the waveguiding properties, in a small diameter core, serve to maintain a high intensity over lengths of up to several kilometers (figure A2.1.49(*b*)). This simple fact allows magnitudes of nonlinearities, in fibres, which are many orders greater than in bulk materials. Further, for maximum overall effect, the various components' effects per elemental propagation distance must add coherently over the total path. This implies a requirement for phase coherence throughout the path which, in turn, implies a single propagation mode: monomode rather than multimode fibres must, in general, be used.

A2.1.7.3 The formalism of nonlinear optics

Under 'normal' propagation conditions we assume a linear relationship between the electric polarization (P) of a medium and the electric field (E) of an optical wave propagating in it, by taking:

$$\chi = \frac{P}{E}$$



P,λ
$2r$
$\frac{r^2}{\lambda}$
Intensity at focus = $\frac{P}{\pi r^2}$, intensity × distance = $\frac{P}{\pi\lambda}$

(in free space, 1 W at 1 μm $\lambda \equiv 3\times10^5$ W M^{-1})

(*b*) Nonlinear facility in optical fibres

Figure A2.1.49. The intensity-distance product for nonlinearity.

where χ is the volume susceptibility of the medium, and is assumed constant. The underlying assumption for this is that the separation of atomic positive and negative charges is proportional to the imposed field, leading to a dipole moment per unit volume (P) which is proportional to the field.

However, it is clear that the linearity of this relationship cannot persist for ever-increasing strengths of field. Any resonant physical system must eventually be torn apart by a sufficiently strong perturbing force and, well before such a catastrophe occurs, we expect the separation of oscillating components to vary nonlinearly with the force. In the case of an atomic system under the influence of the electric field of an optical wave, we can allow for this nonlinear behaviour by writing the electric polarization of the medium in the more general form:

$$P(E) = \chi_1 E + \chi_2 E^2 + \chi_3 E^3 + \chi_j E^j + \cdots. \tag{A2.1.34}$$

The value of χ_j (often written $\chi^{(j)}$) decreases rapidly with increasing j for most materials. Also the importance of the j-th term, compared with the first, varies as $(\chi_j/\chi_1)E^{(j-1)}$, and so depends strongly on E. In practice, only the first three terms are of any great importance, and then only for laser-like intensities, with their large electric fields. It is not until one is dealing with power densities of $\sim 10^9\,\mathrm{W\,m^{-2}}$, and fields $\sim 10^6\,\mathrm{V\,m^{-1}}$, that $\chi_2 E^2$ becomes comparable with $\chi_1 E$.

Let us now consider the refractive index of the medium. From elementary electromagnetism we know that:

$$\varepsilon = 1 + \chi, \quad n^2 = \varepsilon$$

where χ is the electric permittivity of the medium and n is its refractive index.

Hence

$$n = (1 + \chi)^{1/2} = \left(1 + \frac{P}{E}\right)^{1/2}$$

i.e.

$$n = (1 + \chi_1 + \chi_2 E + \cdots \chi_j E^{j-1} + \cdots)^{1/2}. \tag{A2.1.35}$$

Hence we note that the refractive index has become dependent on E. The optical wave, in this nonlinear regime, is altering its own propagation conditions as it travels. This is a central feature of nonlinear optics.

A2.1.7.4 Second harmonic generation and phase matching

Probably the most straightforward consequence of nonlinear optical behaviour in a medium is that of the generation of the second harmonic of a fundamental optical frequency. To appreciate this mathematically, let us assume that the electric polarization of an optical medium is quite satisfactorily described by the first two terms of equation (A2.1.34), i.e.:

$$P(E) = \chi_1 E + \chi_2 E^2. \tag{A2.1.36}$$

Before proceeding, there is an important point to make about equation (A2.1.36).

Let us consider the effect of a change in sign of E. The two values of the field, ± E, will correspond to two values of P:

$$P(+E) = \chi_1 E + \chi_2 E^2$$

$$P(-E) = -\chi_1 E + \chi_2 E^2.$$

These two values clearly have different absolute magnitudes. Now if a medium is isotropic (as is the amorphous silica of which optical fibre is made) there can be no directionality in the medium and thus the matter of the sign of E, i.e. whether the electric field points up or down, cannot be of any physical relevance and cannot possibly have any measurable physical effect. In particular, it cannot possibly affect the value of the electric polarization (which is, of course, readily measurable). We should expect that changing the sign of E will merely change the sign of P, but that the magnitude of P will be exactly the same: the electrons will be displaced by the same amount in the opposite direction, all directions being equivalent. Clearly this can only be so if $\chi_2 = 0$. The same argument extended to higher order terms evidently leads us to the conclusion that all even-order terms *must* be zero for amorphous (isotropic) materials, i.e. $\chi_{2m} = 0$. This is a point to remember. The corollary of this argument is that in order to retain any even order terms the medium must exhibit some anisotropy. It must, for example, have a crystalline structure without a centre of symmetry. It follows that equation (A2.1.36) refers to such a medium.

Suppose now that we represent the electric field of an optical wave entering such a crystalline medium by:

$$E = E_0 \ \cos \omega t.$$

Then substituting into equation (A2.1.36) we find

$$P(E) = \chi_1 E_0 \cos \omega t + \frac{1}{2}\chi_2 E_0^2 + \frac{1}{2}\chi_2 E_0^2 \cos 2\omega t.$$

The last term, the second harmonic term at twice the original frequency, is clearly in evidence. Fundamentally, it is due to the fact that it is easier to polarize the medium in one direction than in the opposite direction, as a result of the crystal asymmetry. A kind of ‘rectification’ occurs.

Now the propagation of the wave through the crystal is the result of adding the original wave to the secondary wavelets from the oscillating dipoles which it induces. These oscillating dipoles are represented by P. Thus $\partial^2 P/\partial t^2$ leads to e/m waves, since radiated power is proportional to the acceleration of charges, and waves at all of P’s frequencies will propagate through the crystal.

Suppose now that an attempt is made to generate a second harmonic over a length L of crystal. At each point along the path of the input wave a second harmonic component will be generated. But, since the crystal medium will almost certainly be dispersive, the fundamental and second harmonic components will travel at different velocities. Hence the successive portions of second harmonic component generated by the fundamental will not, in general, be in phase with each other, and thus will not interfere constructively. Hence, the efficiency of the generation will depend upon the velocity difference between the waves.

A rigorous treatment of this process requires a manipulation involving Maxwell’s equations but a semi-analytical treatment which retains a firm grasp of the physics will be given here.

Suppose that the amplitude of the fundamental (driving) wave between distances z and $z + \mathrm{d}z$ along the optical path in the crystal is $e \cos(\omega t - kz)$. Then from equation (A2.1.34), there will be a component of electric polarization (dipole moment per unit volume) of the form: $\chi_2 e^2 \cos^2(\omega t - kz)$ giving a time-varying second harmonic term $(1/2)\chi_2 e^2 \cos 2(\omega t - kz)$, as before. Consider, then, a slab, in the medium, of unit cross-section, and thickness $\mathrm{d}z$ (figure A2.1.50).

For this slab, the dipole moment will be:

$$P = \frac{1}{2}\chi_2 e^2 \ \cos\, 2(\omega t - kz)\mathrm{d}z.$$

Now a time-varying dipole moment represents a movement of charge, and therefore an electric current.

Faraday's law of induction:
∂/∂z (δE) δz ~ A (∂²P/∂t²) δz

Figure A2.1.50. Infinitesimals for second-harmonic generation along the path of the fundamental.

This current will create a magnetic field. A time-varying magnetic field (second derivative $\partial^2 P/\partial t^2$ of the dipole moment) will generate a voltage around any loop through which it threads (Faraday's law of electromagnetic induction). From figure A2.1.50 it can be seen that, if δE is the elemental component of the second harmonic electric field generated by the changing dipole moment in the thin slab, then this voltage is proportional to $\partial(\delta E)/\partial z$. Hence, we have

$$\frac{\partial(\delta E)}{\partial z} = A\frac{\partial^2 P}{\partial t^2} \tag{A2.1.37}$$

where A is a constant.

Hence, from equation (A2.1.37):

$$\frac{\partial(\delta E)}{\partial z} = -A\cdot 2\omega^2\chi_2 e^2 \cos 2(\omega t - kz)\mathrm{d}z.$$

Integrating this with respect to z gives:

$$\delta E = A\frac{\omega^2}{k}\chi_2 e^2 \sin 2(\omega t - kz)\mathrm{d}z$$

and, with $\omega/k = c$, we have:

$$\delta E = Ac\omega\chi_2 e^2 \sin 2(\omega t - kz)dz$$

as the element of the second harmonic electric field generated by the slab between z and $z + \mathrm{d}z$. But the second harmonic component now propagates with wavenumber k_s, say (since the crystal will have a different refractive index at frequency 2ω, compared with that at ω), so when this component emerges from the crystal after a further distance $L - z$, it will have become:

$$\delta E_{\mathrm{L}} = Ac\omega\chi_2 e^2 \sin[2\omega t - 2kz - k_{\mathrm{s}}(L - z)]dz.$$

Hence the total electric field amplitude generated over the length L of crystal will be, on emergence:

$$E_{\mathrm{L}}(2\omega) = \int_0^L Ac\omega\chi_2 e^2 \sin[2\omega t - 2kz - k_{\mathrm{s}}(L - z)]\mathrm{d}z.$$

Performing this integration gives:

$$E_{\mathrm{L}}(2\omega) = Ac\chi_2 e^2 L\omega \frac{\sin\left(k - \frac{1}{2}k_{\mathrm{s}}\right)L}{\left(k - \frac{1}{2}k_{\mathrm{s}}\right)L} \sin\left[2\omega t - (2k + k_{\mathrm{s}})L\right].$$

The intensity of the emerging second harmonic will be proportional to the square of amplitude of this, i.e.

$$I_{\mathrm{L}}(2\omega) = B\chi_2^2 e^4 L^2 \omega^2 \left[\frac{\sin\left(k - \frac{1}{2}k_{\mathrm{s}}\right)L}{\left(k - \frac{1}{2}k_{\mathrm{s}}\right)L}\right]^2$$

where B is another constant. Now the intensity of the fundamental wave is proportional to e^2, so the intensity of the second harmonic is proportional to the square of the intensity of the fundamental, i.e.

$$I_{\mathrm{L}}(2\omega) = B'\chi_2^2 I_{\mathrm{L}}^2(\omega) L^2 \omega^2 \left[\frac{\sin\left(k - \frac{1}{2}k_{\mathrm{s}}\right)L}{\left(k - \frac{1}{2}k_{\mathrm{s}}\right)L}\right]^2 \tag{A2.1.38}$$

where B' is yet another constant. From this we can define an efficiency η_{SHG} for the second harmonic generation process as:

$$\eta_{\mathrm{SHG}} = \frac{I_{\mathrm{L}}(2\omega)}{I_{\mathrm{L}}(\omega)}.$$

Note that η_{SHG} varies as the square of the fundamental frequency and of the length of the crystal; note also that it increases linearly with the power of the fundamental.

From equation (A2.1.38) it is clear that, for maximum intensity, we require that the sinc^2 function has its maximum value, i.e.

$$k_{\mathrm{s}} = 2k_{\mathrm{f}}.$$

This is the *phase matching condition* for second harmonic generation. Now the velocities of the fundamental and the second harmonic are given by:

$$c_{\mathrm{f}} = \frac{\omega}{k_{\mathrm{f}}}, \quad c_{\mathrm{s}} = \frac{2\omega}{k_{\mathrm{s}}}.$$

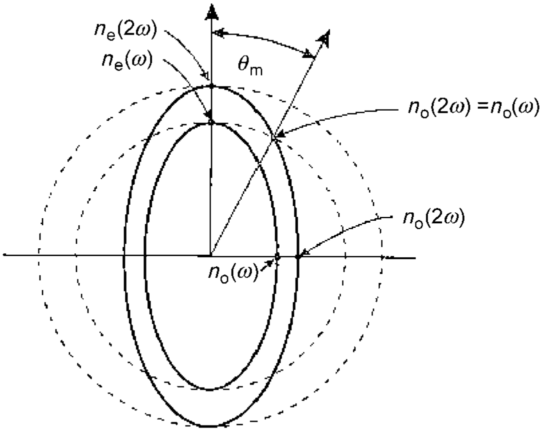
These are equal when $k_{\mathrm{s}} = 2k_{\mathrm{f}}$, so the phase-matching condition is equivalent to a requirement that the two velocities are equal. This is to be expected, since it means that the fundamental generates, at each point in the material, second harmonic components which will interfere constructively. The phase-match condition usually can be satisfied by choosing the optical path to lie in a particular direction within the crystal. It has already been noted that the material must be anisotropic for second harmonic generation to occur; it will also, therefore, exhibit birefringence (section A2.1.3.3). One way of solving the phase-matching problem, therefore, is to arrange that the velocity difference resulting from birefringence is cancelled by that resulting from material dispersion. In a crystal with normal dispersion, the refractive index of both the eigenmodes (i.e. both the ordinary and extraordinary rays) increases with frequency. Suppose we consider the specific example of quartz, which is a positive uniaxial crystal (see section A2.1.3.3). This means that the principal refractive index for the extraordinary ray is greater than that for the ordinary ray, i.e.

$$n_e > n_o.$$

Since quartz is also normally dispersive, it follows that:

$$n_e^{(2\omega)} > n_o^{(\omega)}$$
$$n_o^{(2\omega)} > n_o^{(\omega)}.$$

Hence the index ellipsoids for the two frequencies are as shown in figure A2.1.51(*a*). Now it will be remembered from section A2.1.3.3 that the refractive indices for the 'o' and 'e' rays for any given direction in the crystal are given by the major and minor axes of the ellipse in which the plane normal to



$n_e(2\omega)$
$n_e(\omega)$
θ_m
$n_o(2\omega) = n_o(\omega)$
$n_o(2\omega)$
$n_o(\omega)$

(*b*) Schematic experimental arrangement for SHM generation

Figure A2.1.51. Conditions for second-harmonic generation in quartz.

the direction, and passing through the centre of the index ellipsoid, intersects the surface of the ellipsoid. The geometry (figure A2.1.51(*a*)) thus makes it clear that a direction can be found [10] for which

$$n_{\mathrm{o}}^{(2\omega)}(\vartheta_{\mathrm{m}}) = n_{e}^{(\omega)}(\vartheta_{\mathrm{m}})$$

so SHG phase matching occurs provided that

$$n_{\mathrm{o}}^{(2\omega)} < n_{e}^{(\omega)}.$$

The above is indeed true for quartz over the optical range. Simple trigonometry allows ϑ_{m} to be determined in terms of the principal refractive indices as:

$$\sin^2 \vartheta_{\mathrm{m}} = \frac{(n_{\mathrm{e}}^{(\omega)})^{-2} - (n_{\mathrm{e}}^{(2\omega)})^{-2}}{(n_{\mathrm{o}}^{(2\omega)})^{-2} - (n_{\mathrm{e}}^{(2\omega)})^{-2}}.$$

Hence ϑ_{m} is the angle at which phase matching occurs. It also follows from this that, for second harmonic generation in this case, the wave at the fundamental frequency must be launched at an angle ϑ_{m} with respect to the crystal axis and *must have the 'extraordinary' polarization*; and that the second harmonic component *will appear in the same direction and will have the 'ordinary' polarization*, i.e. the two waves are collinear and have orthogonal linear polarizations! Clearly, other crystal-direction and polarization arrangements also are possible in other crystals.

The required conditions can be satisfied in many crystals but quartz is an especially good one owing to its physical robustness, its ready obtainability with good optical quality and its high optical power-handling capacity.

Provided that the input light propagates along the chosen axis, the conversion efficiency ($\omega \longrightarrow 2\omega$) is a maximum compared with any other path (per unit length) through the crystal. Care must be taken, however, to minimize the divergence of the beam (so that most of the energy travels in the chosen direction) and to ensure that the temperature remains constant (since the birefringence of the crystal will be temperature dependent).

The particle picture of the second harmonic generation process is viewed as an annihilation of two photons at the fundamental frequency, and the creation of one photon at the second harmonic frequency. This pair of processes is necessary in order to conserve energy i.e.

$$2h\nu_{\mathrm{f}} = h(2\nu_{\mathrm{f}}) = h\nu_{\mathrm{s}}.$$

The phase-matching condition is then equivalent to conservation of momentum. The momentum of a photon wave number k is given by:

$$p = \frac{h}{2\pi} k$$

and thus conservation requires that:

$$k_{\mathrm{s}} = 2k_{\mathrm{f}}$$

as in the wave treatment.

Quantum processes which have no need to dispose of excess momentum are again the most probable, and thus this represents the condition for maximum conversion efficiency in the particle picture.

The primary practical importance of second harmonic generation is that it allows laser light to be produced at the higher frequencies, into the blue and ultraviolet, where conditions are not intrinsically favourable for laser action, as was noted earlier (section A2.1.2.4.1). In this context we note again, from equation (A2.1.38), that the efficiency of the generation increases as the square of the fundamental frequency, which is of assistance in producing these higher frequencies.

A2.1.7.5 *Optical mixing*

Optical mixing is a process closely related to second harmonic generation. If, instead of propagating just one laser wave through the same nonlinear crystal, we superimpose two (at different optical frequencies) simultaneously along the same direction, then we shall generate sum and difference frequencies, i.e.

$$E = E_1 \cos \omega_1 t + E_2 \cos \omega_2 t$$

and thus again using equation (A2.1.36):

$$P(E) = \chi_1 (E_1 \cos \omega_1 t + E_2 \cos \omega_2 t) + \chi_2 (E_1 \cos \omega_1 t + E_2 \cos \omega_2 t)^2.$$

This expression for $P(E)$ is seen to contain the term

$$2\chi_2 E_1 E_2 \cos \omega_1 t \cos \omega_2 t = \chi_2 E_1 E_2 \cos(\omega_1 + \omega_2)t + \chi_2 E_1 E_2 \cos(\omega_1 - \omega_2)t$$

giving the required sum and difference frequency terms. Again, for efficient generation of these components, we must ensure that they are phase matched. For example, to generate the sum frequency efficiently we require that:

$$k_1 + k_2 = k_{(1+2)}$$

which is equivalent to

$$\omega_1 n_1 + \omega_2 n_2 = (\omega_1 + \omega_2) n_{(1+2)}$$

where n represents the refractive indices at the suffix frequencies. The condition again is satisfied by choosing an appropriate direction relative to the crystal axes.

This mixing process is particularly useful in the reverse sense. If a suitable crystal is placed in a Fabry–Perot cavity which possesses a resonance at ω_1, say, and is 'pumped' by laser radiation at $\omega_{(1+2)}$, then the latter generates both ω_1 and ω_2. This process is called parametric oscillation: ω_1 is called the signal frequency and ω_2 the idler frequency. It is a useful method for 'down conversion' of an optical frequency i.e. conversion from a higher to a lower value.

The importance of phase matching in nonlinear optics cannot be overstressed. If waves at frequencies different from the fundamental are to be generated efficiently they must be produced with the correct relative phase to allow constructive interference, and this, as we have seen, means that velocities must be equal to allow phase matching to occur. This feature dominates the practical application of nonlinear optics.

A2.1.7.6 *Intensity-dependent refractive index*

It was noted in section A2.1.7.4 that all the even-order terms in expression (A2.1.34) for the nonlinear susceptibility (χ) are zero for an amorphous (i.e. isotropic) medium. This means that in an optical fibre made from amorphous silica, we can expect that $\chi_{(2m)} = 0$, so it will not be possible to generate a second harmonic according to the principles outlined in section A2.1.7.4. (However, second harmonic generation has been observed in fibres [11] for reasons which took some time to understand!) It is possible to generate a third harmonic, however, since to a good approximation the electric polarization in the fibre can be expressed by:

$$P(E) = \chi_1 E + \chi_3 E^3. \qquad \text{(A2.1.39)}$$

Clearly, though, if we wish to generate the third harmonic efficiently we must again phase match it with the fundamental, and this means that somehow we must arrange for the two relevant velocities to be equal, i.e. $c_\omega = c_{3\omega}$. This is very difficult to achieve in practice, although it has been done.

There is, however, a more important application of equation (A2.1.39) in amorphous media. It is clear that the effective refractive index in this case can be written:

$$n_e = (1 + \chi_1 + \chi_3 E^2)^{1/2}$$

and, if $\chi_1, \chi_3 E^2 \ll 1$,

$$n_e \approx 1 + \frac{1}{2}\chi_1 + \frac{1}{2}\chi_3 E^2.$$

Hence:

$$n_e = n_o + \frac{1}{2}\chi_3 E^2 \qquad \text{(A2.1.40}a\text{)}$$

where n_o is the 'normal', linear refractive index of the medium. But we know that the intensity (power/unit area) of the light is proportional to E^2, so that we can write:

$$n_e = n_o + n_2 I \qquad \text{(A2.1.40}b\text{)}$$

where n_2 is a constant for the medium. Equation (A2.1.40*b*) is very important and has a number of practical consequences. We can see immediately that it means that the refractive index of the medium depends upon the intensity of the propagating light: the light is influencing its own velocity as it travels.

In order to fix ideas to some extent let us consider some numbers for silica. For amorphous silica $n_2 \sim 3.2 \times 10^{-20}\,\mathrm{m^2\,W^{-1}}$, which means that a 1% change in refractive index (readily observable) will occur for an intensity $\sim 5 \times 10^{17}\,\mathrm{W\,m^{-2}}$. For a fibre with a core diameter $\sim 5\,\mu\mathrm{m}$ this requires an optical power level of 10 MW. Peak power levels of this magnitude are readily obtainable, for short durations, with modern lasers.

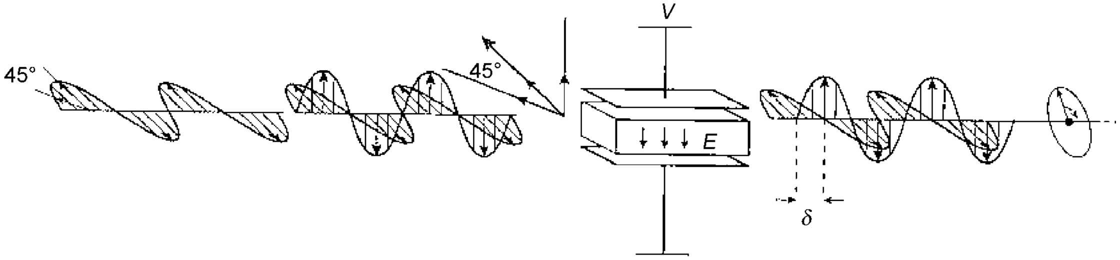
It is interesting to note that this phenomenon is another aspect of the electro-optic effect. Clearly the refractive index of the medium is being altered by an electric field. This will now be considered in more detail.

A2.1.7.7 The electro-optic effect

When an electric field is applied to an optical medium the electrons suffer restricted motion in the direction of the field, when compared with that orthogonal to it. Thus the material becomes linearly birefringent in response to the field. This is known as the electro-optic effect.

Consider the arrangement of figure A2.1.52. Here we have incident light which is linearly polarized at 45° to an electric field and the field acts on a medium transversely to the propagation direction of the light. The field-induced linear birefringence will cause a phase displacement between components of the incident light which lie, respectively, parallel and orthogonal to the field; hence the light will emerge elliptically polarized.

A (perfect) polarizer placed with its acceptance direction parallel with the input polarization direction will of course, pass all the light in the absence of a field. When the field is applied, the fraction of light power which is passed will depend upon the form of the ellipse, which in turn depends upon the phase delay introduced by the field. Consequently, the field can be used to modulate the intensity of the light, and the electro-optic effect is, indeed, very useful for the modulation of light. The phase delay introduced may be proportional either to the field (Pockels effect) or to the square of the field (Kerr effect). All materials manifest a transverse Kerr effect. Only crystalline materials can manifest any



Linear polarization becomes elliptical by passing through an electro-optic medium with applied field E

Figure A2.1.52. The electro-optic effect.

kind of Pockels effect, or longitudinal (***E*** field parallel with propagation direction) Kerr effect. The reason for this is physically quite clear. If a material is to respond linearly to an electric field, the effect of the field must change sign when the field changes sign. This means that the medium must be able to distinguish (for example) between 'up' (positive field) and 'down' (negative field). But it can only do this if it possesses some kind of directionality in itself, otherwise all field directions must be equivalent in their physical effects. Hence, in order to make the necessary distinction between up and down, the material must possess an intrinsic asymmetry, and hence must be crystalline. By a similar argument a longitudinal E field can only produce a directional effect orthogonally to itself (i.e. in the direction of the optical electric field) if the medium is anisotropic (i.e. crystalline) for otherwise all transverse directions will be equivalent. In addition to the modulation of light (phase or intensity/power) it is clear that the electro-optic effect could be used to measure an electric field and/or the voltage which gives rise to it.

A2.1.7.8 Optical Kerr effect

The normal electro-optic Kerr effect is an effect whereby an electric field imposed on a medium induces a linear birefringence with slow axis parallel with the field (figure A2.1.53(*a*)). The value of the induced birefringence is proportional to the square of the electric field. In the optical Kerr effect the electric field involved is that of an optical wave, and thus the birefringence probed by one wave may be that produced by another (figure A2.1.53(*b*)).

The phase difference introduced by an electric field E over an optical path L is given by:

$$\Delta\varphi = \frac{2\pi}{\lambda}\Delta n L$$

where $\Delta n = KE^2$, K being the Kerr constant.

Now from equations (A2.1.40*a*) and (A2.1.40*b*) we have:

$$\Delta n = n_2 I = \frac{1}{2}\chi_3 E^2 = KE^2. \tag{A2.1.41}$$

From elementary electromagnetism we know that:

$$I = c\varepsilon E^2.$$

Hence we have, from equation (A2.1.41)

$$K = n_2 c\varepsilon = \frac{1}{2}\chi_3$$

showing that the electro-optic effect, whether the result of an optical or an external electric field, is a nonlinear phenomenon, depending on χ_3. Using similar arguments it can easily be shown that the electro-optic Pockels effect also is a nonlinear effect, depending on χ_2.

The optical Kerr effect has several other interesting consequences. One of these is self-phase modulation (SPM), which is the next topic for consideration.

A2.1.7.9 Self-phase modulation

The fact that refractive index can be dependent on optical intensity clearly has implications for the phase of the wave propagating in nonlinear medium. We have:

$$\varphi = \frac{2\pi}{\lambda} nL.$$

Hence for $n = n_o + n_2 I$,

$$\varphi = \frac{2\pi L}{\lambda}(n_o + n_2 I).$$

Suppose now that the intensity is a time-dependent function $I(t)$. It follows that φ also will be time dependent, and, since:

$$\omega = \frac{\mathrm{d}\varphi}{\mathrm{d}t}$$

the frequency spectrum will be changed by this effect, which is known as self-phase modulation (SPM).

In a dispersive medium a change in the spectrum of a temporally varying function (e.g. a pulse) will change the shape of the function. For example, pulse broadening or *pulse compression* can be obtained under appropriate circumstances. To see this, consider a Gaussian pulse (figure A2.1.54(*a*)). The Gaussian shape modulates an optical carrier of frequency ω_0, say, and the new instantaneous frequency becomes

$$\omega' = \omega_o + \frac{\mathrm{d}\varphi}{\mathrm{d}t}$$

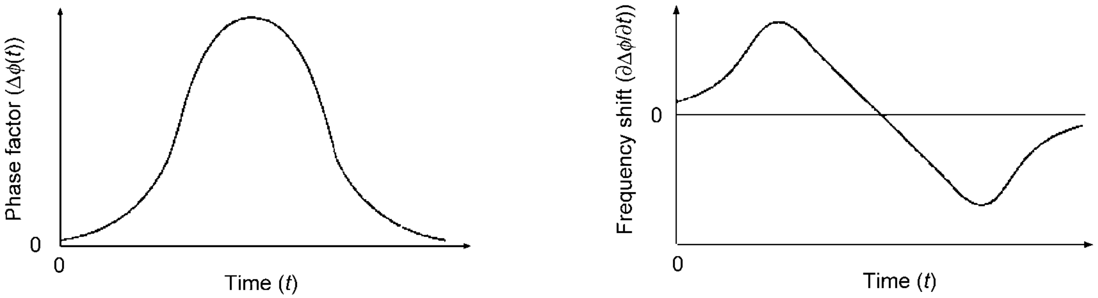
If the pulse is propagating in the Oz direction:

$$\varphi = -\frac{2\pi z}{\lambda}(n_o + n_2 I) \qquad \text{(A2.1.42}a\text{)}$$

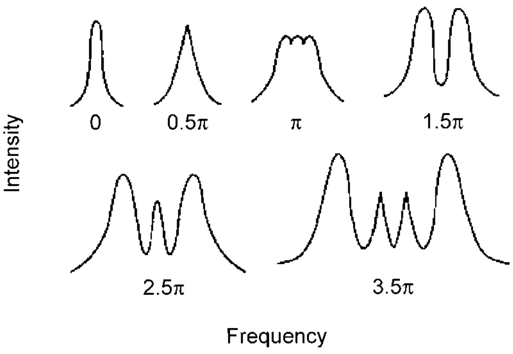
and we have

$$\omega' = \omega_o - \frac{2\pi z}{\lambda} n_2 \frac{\mathrm{d}I}{\mathrm{d}t}. \qquad \text{(A2.1.42}b\text{)}$$

At the leading edge of the pulse $\mathrm{d}I/\mathrm{d}t > 0$, hence



(*a*) Intensity-dependent phase factor for a Gaussian pulse (*b*) The instantaneous frequency shift for (*a*)



(*c*) Frequency spectra for (*a*) designated by maximum phase shift, at peak

Figure A2.1.54. Self-phase modulation for a Gaussian pulse.

$$\omega' = \omega - \omega_{\mathrm{I}}(t).$$

At the trailing edge

$$\frac{\mathrm{d}I}{\mathrm{d}t} < 0$$

and

$$\omega' = \omega + \omega_{\mathrm{I}}(t).$$

Hence the pulse is now ‘chirped’, i.e. the frequency varies across the pulse. Figure A2.1.54(*b*) shows an example of this effect.

Suppose, for example, a pulse from a mode-locked Argon laser, initial width 180 ps, is passed down 100 m of optical fibre. As a result of SPM the frequency spectrum is changed by the propagation. Figure A2.1.54(*c*) shows how the spectrum varies as the initial peak power of the pulse is varied. The peak power will lead to a peak phase change, according to equation (A2.1.42*a*) and this phase change is shown for each of the spectra. It can be seen that the initial spectrum ($\Delta\varphi = 0$) is just due to the modulation of the optical sinusoid (Fourier spectrum of a Gaussian pulse) and, as the value of $\Delta\varphi$ increases, the first effect is a broadening. At $\Delta\varphi = 1.5\pi$ the spectrum has split into two clear peaks, corresponding to the frequency shifts at the back and front edges of the pulse. The spectra then develop multiple peaks.

It is important to realize that this does not necessarily change the shape of the pulse envelope, just the optical frequency within it. However, if the medium through which the pulse is passing is dispersive, the pulse shape will change. This is an interesting possibility and it leads to the phenomenon of soliton propagation [12].

A2.1.7.10 Summary

We have seen in this chapter that nonlinear optics has its advantages and disadvantages. When it is properly under control it can be enormously useful; but on other occasions it can intrude, disturb and degrade.

The processes by which light waves produce light waves of other frequencies need very high optical electric fields and thus high peak intensities. It was for this reason that nonlinear optics only became a serious subject with the advent of the laser. Optical fibres provide a convenient means by which peak intensities can be maintained over relatively long distances, and are thus very useful media for the study and control of nonlinear optical effects.

We must also remember that in order to cause one optical frequency component to generate another, the second must be generated in phase with itself along the generation path: phase matching is an important feature of such processes.

We have seen how the effects which occur when electrons are stretched beyond the comfortable sinusoidal oscillations in their atoms or molecules can yield useful extra optical waves (SHM) and can influence their own propagation conditions (optical Kerr effect, SPM).

Finally we can also use light to alter, permanently or semi-permanently, the optical properties of a medium, and thus provide the means whereby a new class of optical components, especially fibre components, can be fabricated.

There is a wealth of potential here. The exploration of possibilities for nonlinear optics, especially in regard to new, natural or synthetic optical materials (e.g. organics, high T_{c} superconductors) etc, has not even really begun. The prospects, for example, for new storage media, fast switching of light by light, and three-dimensional television, which will be opened up in the future by such materials, are intriguing, and it could well be that nonlinear optical technology soon will become a powerful subject in its own right.

A2.1.8 Conclusions

In this chapter, the aim has been to emphasize the principles which comprise the physical basis of optoelectronics. A thorough grasp of these principles should facilitate a better appreciation of the more advanced treatments of components and systems in later chapters of this Handbook.

Acknowledgments

The majority of the material presented in this chapter first appeared in 'Essentials of Optoelectronics' (Rogers), published by Chapman and Hall, 1997, and is included here with permission.

A2.2

Basic concepts in photometry, radiometry and colorimetry

Yoshi Ohno

A2.2.1 Introduction

The term *photometry* refers to measurement of quantities for optical radiation as evaluated according to a standardized human eye response, and therefore, is limited to the visible spectral region (360–830 nm) [1]. Photometry uses either optical radiation detectors constructed to mimic the spectral response of the eye or spectroradiometry coupled with appropriate calculations for weighting by the spectral response of the eye. Typical photometric units include the lumen (luminous flux), the candela (luminous intensity), the lux (illuminance) and the candela per square metre (luminance). On the other hand, measurement of optical radiation at all wavelengths (approximately in the range from 10 nm to 1000 μm including ultraviolet, visible and infrared) is referred to as *radiometry*. The official definition of radiometry [1] is measurement of the quantities associated with radiant energy. Typical radiometric units include the watt (radiant flux), watt per steradian (radiant intensity), watt per square metre (irradiance) and watt per square metre per steradian (radiance). Radiometry often involves spectrally resolved measurements of these quantities as well as spectrally integrated measurements. Similar to photometry, measurement of colour of light sources and objects also deals with broadband measurement of the visible radiation and is referred to as *colorimetry*. Colorimetry is ascribed to measurement of light spectra weighted by three standardized spectral weighting functions, one of which is identical to the standardized human eye response used in photometry.

Photometry and colorimetry are essential for evaluation of light sources used for lighting, signalling, displays and other applications where light is seen by the human eye. Light-emitting diodes, for example, are now produced in all colour ranges and expected to gain wide acceptance in many applications. This chapter focuses on fundamentals of photometry, but introduces radiometry and colorimetry also because radiometry is closely related to photometry, and colorimetry is also important for evaluation of optoelectronic light sources. Some of the presented materials in this chapter are from [2] by the same author. The terminology used in this chapter follows international standards and recommendations [1,3,4].

A2.2.2 Basis of physical photometry

A2.2.2.1 Visual response

The primary aim of photometry is to measure light (visible optical radiation) in such a way that the results correlate with what the visual sensation is to a normal human observer exposed to that radiation.

Until about 1940, visual comparison techniques of measurements were predominant in photometry. The intensity of one light source is matched to the intensity of another light source using human eyes. In modern photometric practice, measurements are made with photodetectors. This is referred to as physical photometry. In order to achieve the aim of photometry, one must take into account the characteristics of human vision. The relative spectral responsivity of the human eye was first defined by the Commission Internationale de l'Éclairage (CIE) in 1924 [5]. It is called *the spectral luminous efficiency for photopic vision*, with a symbol $V(\lambda)$, defined in the domain from 360 to 830 nm, and is normalized to one at its peak, 555 nm (figure A2.2.1). This model has gained wide acceptance. The values were republished by CIE in 1983 [6], and adopted by Comité International des Poids et Mesures (CIPM) in 1983 [7] to supplement the 1979 definition of the candela. The tabulated values of the function at 1 nm increments are available in [6–8]. In most cases, the region from 380 to 780 nm suffices for calculation with negligible errors because the value of the $V(\lambda)$ function falls below 10^{-4} outside this region.

As specified in the definition of the candela by Conférence Générale des Poids et Mesures (CGPM) in 1979 [9] and a supplemental document from CIPM in 1982 [10], a photometric quantity X_v is now defined in relation to the corresponding radiometric quantity $X_{e,\lambda}$ by the equation:

$$X_v = K_m \int_{360\,\mathrm{nm}}^{830\,\mathrm{nm}} X_{e,\lambda} V(\lambda)\,\mathrm{d}\lambda. \tag{A2.2.1}$$

The constant, K_m, relates the photometric quantities and radiometric quantities, and is called the *maximum spectral luminous efficacy (of radiation) for photopic vision*. The value of K_m is given in the 1979 definition of candela, which defines the spectral luminous efficacy of radiation at the frequency 540×10^{12} Hz (at the wavelength 555.016 nm in standard air) to be $683\,\mathrm{lm\,W^{-1}}$. Note that this is not exactly at the peak of the $V(\lambda)$, 555 nm. The value of K_m is calculated as $683 \times V(555.000\,\mathrm{nm})/V(555.016\,\mathrm{nm}) = 683.002\,\mathrm{lm\,W^{-1}}$ [6]. K_m is normally rounded to $683\,\mathrm{lm\,W^{-1}}$ with negligible errors.

It should be noted that the $V(\lambda)$ function is defined for the *CIE standard photometric observer for photopic vision*, which assumes additivity of sensation and a 2° field of view at relatively high luminance levels (higher than approximately $1\,\mathrm{cd\,m^{-2}}$). The human vision in this level is called *photopic* vision. The spectral responsivity of human eyes deviates significantly at very low levels of luminance (at luminance levels less than approximately $10^{-3}\,\mathrm{cd\,m^{-2}}$) when the rods in the eyes are the dominant receptors. This type of vision is called *scotopic* vision. Its spectral responsivity, peaking at 507 nm, is designated as $V'(\lambda)$, and was defined by CIE in 1951 [11], recognized by CIPM in 1976 [12] and republished by CIPM in 1983 [7]. The human vision in the region between photopic vision and scotopic vision is called

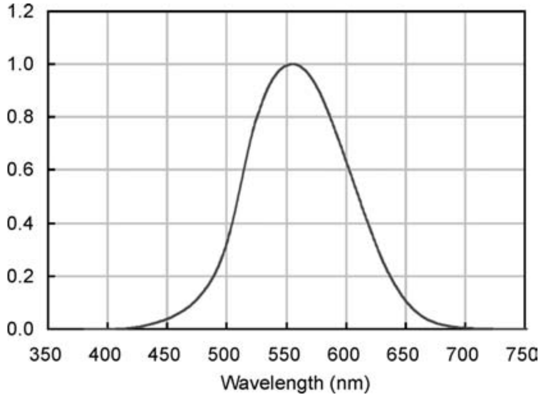

Figure A2.2.1. CIE $V(\lambda)$ function.

mesopic vision. While there have been active researches in this area [13], there is no internationally accepted spectral luminous efficiency function for the mesopic region yet. In current practice, almost all photometric quantities are given in terms of photopic vision, even at such low light levels. Quantities in scotopic vision are seldom used except for special calculations for research purposes. Further details of the contents in this section are available in [6].

A2.2.2.2 Photometric base unit, the candela

The history of photometric standards dates back to the early nineteenth century, when the intensity of light sources was measured in comparison with a standard candle using visual bar photometers [14]. At that time, the flame of a candle was used as a unit of luminous intensity that was called *the candle*. The old name for luminous intensity 'candle power' came from this origin. Standard candles were gradually superseded by flame standards of oil lamps, and in 1920, the unit of luminous intensity, recognized as *the international candle*, was adopted by the CIE. In 1948, it was adopted by the CGPM with a new Latin name 'candela' defined as the luminous intensity of a platinum blackbody at its freezing temperature under specified geometry. Although the 1948 definition served to establish the uniformity of photometric measurements in the world, difficulties in fabricating the blackbodies and in improving accuracy were addressed. In 1979, the candela was redefined in relation to the optical power, watt, so that complicated source standards would not be necessary. The current definition of the candela adopted in 1979 by the CGPM [9] is

> "The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} Hz and that has a radiant intensity in that direction of (1/683) watt per steradian."

The value of K_m ($683\,\mathrm{lm\,W^{-1}}$) was determined in such a way that the consistency from the prior unit was maintained, and was determined based on the measurements by several national laboratories. Technical details on this redefinition of the candela are reported in [15, 16]. This 1979 redefinition of the candela has enabled the derivation of the photometric units from the radiometric units using various techniques.

A2.2.3 Quantities and units in photometry and radiometry

In 1960, the Système International (SI) was established, and the candela became one of the seven SI base units [17]. For further details on the SI, references [17–20] can be consulted. Several quantities and units, defined in different geometries, are used in photometry and radiometry. Table A2.2.1 lists the photometric quantities and units, along with corresponding radiometric quantities and units.

While the candela is the SI base unit, the luminous flux (lumen) is perhaps the most fundamental photometric quantity, as the other photometric quantities are defined in terms of lumen with an appropriate geometric unit. The definitions of these photometric quantities are described later. The descriptions given here are occasionally simplified from the definitions given in official reference [1] for easier understanding. Refer to this reference for official, rigorous definitions.

A2.2.3.1 Radiant flux and luminous flux

Radiant flux (also called *optical power* or *radiant power*) is the energy Q (in joules) radiated by a source per unit of time, expressed as

$$\Phi = \frac{\mathrm{d}Q}{\mathrm{d}t}. \tag{A2.2.2}$$

The unit of radiant flux is the watt ($\mathrm{W} = \mathrm{J\,s^{-1}}$).

Table A2.2.1. Quantities and units used in photometry and radiometry.

Photometric quantity	Unit	Relationship with lumen	Radiometric quantity	Unit
Luminous flux	lm (lumen)		Radiant flux	W (watt)
Luminous intensity	cd (candela)	$\mathrm{lm\,sr^{-1}}$	Radiant intensity	$\mathrm{W\,sr^{-1}}$
Illuminance	lx (lux)	$\mathrm{lm\,m^{-2}}$	Irradiance	$\mathrm{W\,m^{-2}}$
Luminance	$\mathrm{cd\ m^{-2}}$	$\mathrm{lm\,sr^{-1}\,m^{-2}}$	Radiance	$\mathrm{W\,sr^{-1}\,m^{-2}}$
Luminous exitance	$\mathrm{lm\ m^{-2}}$		Radiant exitance	$\mathrm{W\,m^{-2}}$
Luminous exposure	lx s		Radiant exposure	$\mathrm{W\,m^{-2}\,s}$
Luminous energy	lm s		Radiant energy	J (joule)
Total luminous flux	lm (lumen)		Total radiant flux	W (watt)
Colour temperature	K (kelvin)		Radiance temperature	K (kelvin)

Luminous flux (Φ_v) is the time rate of flow of light as weighted by $V(\lambda)$. The unit of luminous flux is the lumen (lm). It is defined as

$$\Phi_\mathrm{v} = K_\mathrm{m} \int_\lambda \Phi_{\mathrm{e},\lambda} V(\lambda)\,\mathrm{d}\lambda \tag{A2.2.3}$$

where $\Phi_{\mathrm{e},\lambda}$ is the spectral concentration of radiant flux as a function of wavelength λ. The term, luminous flux, is often used in the meaning of total luminous flux (see A2.2.3.8) in photometry.

A2.2.3.2 Radiant intensity and luminous intensity

Radiant intensity (I_e) or *luminous intensity* (I_v) is the radiant flux (luminous flux) from a point source emitted per unit solid angle in a given direction, as defined by

$$I = \frac{\mathrm{d}\Phi}{\mathrm{d}\Omega} \tag{A2.2.4}$$

where $\mathrm{d}\Phi$ is the radiant flux or luminous flux leaving the source and propagating in an element of solid angle $\mathrm{d}\Omega$ containing the given direction. The unit of radiant intensity is $\mathrm{W\,sr^{-1}}$, and that of luminous intensity is the candela ($\mathrm{cd} = \mathrm{lm\,sr^{-1}}$) (figure A2.2.2).

The radiant intensity or luminous intensity of a real light source varies with the direction of emission, and is specified or measured for given direction(s) from the light source. In real measurements, the solid angle $\mathrm{d}\Omega$ will be a finite solid angle defined by the area A of the detector surface and distance r from the source (see figure A2.2.3), with $\mathrm{d}\Phi$ being the flux incident on the detector surface. The distance r should be large enough so that the source can be assumed as a point source (far field condition) and the detector area A should be small enough so that $\mathrm{d}\Omega$ is considered negligible. Measurement results tend to vary depending on geometrical conditions if these conditions are not met. See also section A2.2.4.1

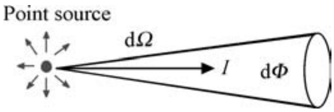

Figure A2.2.2. Radiant intensity and luminous intensity.

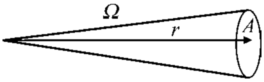

Figure A2.2.3. Solid angle.

for practical aspects of the geometry and reference [30] for the specific measurement geometries recommended for measurement of luminous intensity of LEDs.

Solid angle

The solid angle (Ω) of a cone is defined as the ratio of the area (A) cut out on a spherical surface (with its centre at the apex of that cone) to the square of the radius (r) of the sphere, as given by

$$\Omega = \frac{A}{r^2}. \tag{A2.2.5}$$

The unit of solid angle is steradian (sr), which is a dimensionless unit.

A2.2.3.3 Irradiance and illuminance

Irradiance (E_e) or *illuminance* (E_v) is the density of incident radiant flux or luminous flux at a point on a surface, and is defined as radiant flux or luminous flux per unit area, as given by

$$E = \frac{\mathrm{d}\Phi}{\mathrm{d}A} \tag{A2.2.6}$$

where $\mathrm{d}\Phi$ is the radiant flux or luminous flux incident on an element $\mathrm{d}A$ of the surface containing the point. The unit of irradiance is $\mathrm{W\,m^{-2}}$, and that of illuminance is lux ($\mathrm{lx = lm\,m^{-2}}$) (figure A2.2.4).

By definition, $\mathrm{d}\Phi$ incident on $\mathrm{d}A$ from any angles within the 2π solid angle above the surface contributes to E. Thus, illuminance meters are normally designed to receive light from 2π solid angle (± 90°) with its angular responsivity tailored to follow the cosine function response.

A2.2.3.4 Radiance and luminance

Radiance (L_e) or *luminance* (L_v) is the radiant flux or luminous flux per unit solid angle emitted from a surface element in a given direction, per unit projected area of the surface element perpendicular to the direction (figure A2.2.5). The unit of radiance is $\mathrm{W\,sr^{-1}\,m^{-2}}$, and that of luminance is $\mathrm{cd\,m^{-2}}$. These quantities are defined by

$$L = \frac{\mathrm{d}^2\Phi}{\mathrm{d}\Omega\,\mathrm{d}A\cos\theta} \tag{A2.2.7}$$

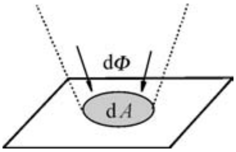

Figure A2.2.4. Irradiance and illuminance.

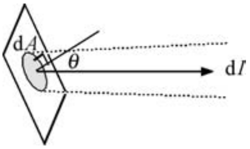

Figure A2.2.5. Radiance and luminance.

where dΦ is the radiant flux (luminous flux) emitted (reflected or transmitted) from the surface element and propagating in the solid angle dΩ containing the given direction. dA is the area of the surface element and θ the angle between the normal to the surface element and the direction of the beam. The term d$A \cos\theta$ gives the projected area of the surface element perpendicular to the direction of measurement.

In photometry, luminance is an important parameter in a sense that it represents how bright objects look to the human eyes. Luminance is important, e.g. to specify the brightness of visual displays. Luminance meters are normally constructed using an imaging optics (like a camera lens) to focus on an object surface and accept light only from a given cone angle (e.g. 0.3°, 1°, 3°, etc) from the meter.

A2.2.3.5 Radiant exitance and luminous exitance

Radiant exitance (M_e) or *luminous exitance* (M_v) is defined to be the density of radiant flux or luminous flux leaving a surface at a point. The unit of radiant exitance is $\mathrm{W\,m^{-2}}$ and that of luminous exitance is $\mathrm{lm\,m^{-2}}$ (but it is not lux) (figure A2.2.6). These quantities are defined by

$$M = \frac{\mathrm{d}\Phi}{\mathrm{d}A} \tag{A2.2.8}$$

where dΦ is the radiant flux or luminous flux leaving the surface element. Luminous exitance is rarely used in the general practice of photometry.

A2.2.3.6 Radiant exposure and luminous exposure

Radiant exposure (H_e) or *luminous exposure* (H_v) is the time integral of irradiance $E_e(t)$ or illuminance $E_v(t)$ over a given duration Δt, as defined by

$$H = \int_{\Delta t} E(t)\,\mathrm{d}t. \tag{A2.2.9}$$

The unit of radiant exposure is $\mathrm{J\,m^{-2}}$, and that of luminous exposure is lux second (lx s). These quantities are often used for pulsed radiation.

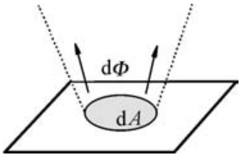

Figure A2.2.6. Radiant exitance and luminous exitance.

A2.2.3.7 Radiant energy and luminous energy

Radiant energy (Q_e) or *luminous energy* (Q_v) is the time integral of the radiant flux $\Phi_e(t)$ or luminous flux $\Phi_v(t)$ over a given duration Δt, as defined by

$$Q = \int_{\Delta t} \Phi(t)\,\mathrm{d}t. \tag{A2.2.10}$$

The unit of radiant energy is joule (J), and that of luminous energy is lumen second (lm s). These quantities are often used for pulsed radiation. Luminous energy is also called *quantity of light*, which is listed in [1].

A2.2.3.8 Total radiant flux and total luminous flux

Total radiant flux or *total luminous flux* (Φ_v) is the geometrically total radiant flux or luminous flux of a light source. It is defined as

$$\Phi = \int_{\Omega} I\,\mathrm{d}\Omega \tag{A2.2.11}$$

or

$$\Phi = \int_{A} E\,\mathrm{d}A \tag{A2.2.12}$$

where I is the radiant or luminous intensity distribution of the light source and E the irradiance or illuminance distribution over a given closed surface surrounding the light source. If the radiant or luminous intensity distribution, or the irradiance or illuminance distribution, is given in polar coordinates (θ, ϕ), the total radiant flux or luminous flux Φ of the light source is given by

$$\Phi = \int_{\phi=0}^{2\pi}\int_{\theta=0}^{\pi} I(\theta,\phi)\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \tag{A2.2.13}$$

or

$$\Phi = r^2\int_{\phi=0}^{2\pi}\int_{\theta=0}^{\pi} E(\theta,\phi)\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi. \tag{A2.2.14}$$

For example, the total luminous flux of an isotropic point source having luminous intensity of 1 cd is 4π lumens.

Total luminous flux (lumen) is a very important quantity to specify lamp products. It represents how much visible light a lamp can produce (for the given wattage of the lamp), no matter what the intensity distributions are. The ratio of the total luminous flux to the input electrical power (lumens per watt) for a light source—called *luminous efficacy of a light source*—is an important parameter concerned with energy saving, and thus, the importance of accurate measurement of total luminous flux. The total luminous flux of light sources is normally measured either with an integrating sphere photometer (see section A2.2.4.5) or a goniophotometer (see [25]).

A2.2.3.9 Radiance temperature and colour temperature

Radiance temperature (unit: kelvin) is the temperature of the Planckian radiator for which the radiance at the specified wavelength has the same spectral concentration as for the thermal radiator considered. It is commonly used for blackbodies and spectral radiance standard lamps.

Colour temperature (unit: kelvin) is the temperature of a Planckian radiator emitting radiation of the same chromaticity (see section A2.2.6.2) as that of the light source in question. However, actual light sources other than blackbodies rarely have exactly the same chromaticity as a Planckian radiator. Therefore, for various lamps used in general lighting (such as fluorescent lamps and other discharge lamps), another term 'correlated colour temperature' is used. See section A2.2.6.3 for further details.

Distribution temperature (unit: kelvin) is the temperature of a blackbody with a spectral power distribution closest to that of the light source in question, and is used for quasi-Planckian sources such as incandescent lamps. Refer to reference [21] for details.

A2.2.3.10 Relationship between SI units and inch–pound system units

The SI units as described earlier should be used in all radiometric and photometric measurements according to international standards and recommendations on SI units. However, some inch–pound system units are still being used in many application areas. The use of these non-SI units is discouraged. The definitions of such inch–pound system units used in photometry are given in table A2.2.2 for conversion purposes only.

The definition of foot–lambert is such that the luminance of a perfect diffuser is 1 fL when illuminated at 1 fc. In the SI unit, the luminance of a perfect diffuser would be $1/\pi$ ($\mathrm{cd\,m^{-2}}$) when illuminated at 1 lx. For convenience of changing from these inch–pound system units to SI units, the conversion factors are listed in table A2.2.3. For example, 1000 lx is the same illuminance as 92.9 fc, and

Table A2.2.2. Inch–pound system units and their definitions.

foot–candle (fc)	Illuminance	Lumen per square foot ($\mathrm{lm\,ft^{-2}}$)
foot–lambert (fL)	Luminance	$1/\pi$ candela per square foot ($\pi^{-1}\,\mathrm{cd\,ft^{-2}}$)

Note: the use of these non-SI units is discouraged.

Table A2.2.3. Conversion between inch–pound system units and SI units.

To obtain the value in	Multiply the value in	By
lx from fc	fc	10.764
fc from lx	lx	0.09290
$\mathrm{cd\,m^{-2}}$ from fL	fL	3.4263
fL from $\mathrm{cd\,m^{-2}}$	$\mathrm{cd\,m^{-2}}$	0.29186
m (metre) from feet	Feet	0.30480
mm (millimetre) from inch	Inch	25.400

Note: the use of these non-SI units is discouraged.

1000 cd m^{-2} is the same luminance as 291.9 fL. Conversion factors to and from many other units are available in [22].

A2.2.4 Principles in photometry and radiometry

Several important theories in practical photometry and radiometry are introduced in this section.

A2.2.4.1 Inverse square law

Illuminance E (lx) at a distance d (m) from a point source having luminous intensity I (cd) is given by

$$E = \frac{I}{d^2}. \qquad \text{(A2.2.15)}$$

For example, if the luminous intensity of a lamp in a given direction is 1000 cd, the illuminance at 2 m from the lamp in this direction is 250 lx. Or, the luminous intensity I of a lamp is obtained by measurement of illuminance E at distance d from the light source. Note that the inverse square law is valid only when the light source is regarded as a point source. Sufficient distances relative to the size of the source are needed to assume this relationship.

A2.2.4.2 Lambert's cosine law

The luminous intensity of a Lambertian surface element is given by

$$I(\theta) = I_n \cos\theta. \qquad \text{(A2.2.16)}$$

Lambertian surface: A surface whose luminance is the same in all directions of the hemisphere above the surface. The total luminous flux Φ of a Lambertian surface shown in figure A2.2.7 is given by

$$\Phi = \pi I_\mathrm{n} = \pi L a \qquad \text{(A2.2.17)}$$

where L is the luminance of the surface and a the area of the surface.

Perfect (reflecting/transmitting) diffuser: A Lambertian diffuser with a reflectance (transmittance) equal to 1.

A2.2.4.3 Relationship between illuminance and luminance

The luminance L (cd m^{-2}) of a perfect diffuser illuminated by E (lx) is given by (figure A2.2.8)

$$L = \frac{E}{\pi} \qquad \text{(A2.2.18)}$$

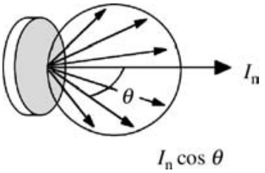

Figure A2.2.7. Lambert's cosine law.

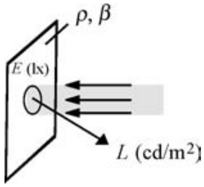

Figure A2.2.8. Relationship between illuminance and luminance.

and, for a Lambertian surface of reflectance ρ,

$$L = \frac{\rho E}{\pi}. \tag{A2.2.19}$$

Reflectance (ρ)

The ratio of the reflected flux to the incident flux in a given condition. The value of ρ can be between 0 and 1.

In the real world, there is neither existing perfect diffuser nor perfectly Lambertian surfaces, and equation (A2.2.19) does not apply for real surfaces. For real object surfaces, the following terms apply.

Luminance factor (β)

Ratio of the luminance of a surface element in a given direction to that of a perfect reflecting or transmitting diffuser under specified conditions of illumination. The value of β can be larger than 1. For a Lambertian surface, reflectance is equal to the luminance factor. Equation (A2.2.19) for a real object is restated using β as

$$L = \frac{\beta E}{\pi}. \tag{A2.2.20}$$

The radiometric term for this quantity is *radiance factor*. Also *reflectance factor* is often used for the same meaning. However, reflectance factor is officially defined for reflected flux in a given cone angle, and it can mean radiance factor (solid angle = 0) or reflectance (solid angle = 2π). See reference [1] for the details.

Note that radiance factor and luminance factor of a real surface vary depending on the illumination and viewing geometry, and thus the geometry must be specified. For example, $\beta_{0/45}$ means radiance (luminance) factor at a 0° incident angle and a 45° viewing angle. See reference [40] for such geometrical notations. Luminance factor also depends on the spectral distribution of the illumination, and thus it must be specified. CIE standard illuminant A or standard illuminant D65 [41] is normally used. Furthermore, radiance factor is given as a function of wavelength.

Luminance coefficient (q)

Quotient of the luminance of a surface element in a given direction by the illuminance on the surface element under specified conditions of illumination.

$$q = \frac{L}{E}. \tag{A2.2.21}$$

Using q, the relationship between luminance and illuminance is thus given by

$$L = qE. \tag{A2.2.22}$$

The radiometric term for this quantity is *radiance coefficient*, used either for light-reflecting or transmitting diffuser materials. The bidirectional reflectance distribution function (BRDF) is also used for the same definition as the radiance coefficient (but expressed as a function of angle of incidence and angle of reflection).

A2.2.4.4 Planck's law

The spectral radiance of a blackbody at a temperature T (K) is given by

$$L_{\mathrm{e}}(\lambda, T) = c_1 n^{-2} \pi^{-1} \lambda^{-5} \left[\exp\left(\frac{c_2}{n\lambda T} \right) - 1 \right]^{-1} \tag{A2.2.23}$$

where $c_1 = 2\pi hc^2 = 3.74177107 \times 10^{-16}\,\mathrm{W\,m^2}$, $c_2 = hc/k = 1.4387752 \times 10^{-2}\,\mathrm{m\,K}$ (1998 CODATA from [23]), h is Planck's constant, c the speed of light in vacuum, k Boltzmann's constant, n the refractive index of medium and λ the wavelength in the medium. $n = 1.00028$ in standard air [6,24].

A2.2.4.5 Principles of integrating sphere

An integrating sphere is a device to achieve spatial integration of luminous flux (or radiant flux) generated (or introduced) in the sphere. In the case of measurement of light sources, the spatial integration is made over the entire solid angle (4π). In figure A2.2.9, assuming that the integrating sphere wall surfaces are perfectly Lambertian, luminance L of a surface element Δa (generated by uniform light incident on this element) creates the equal illuminance E on any part of the sphere surfaces, as given by

$$E = \frac{L\Delta a}{4R^2}. \tag{A2.2.24}$$

In other words, the same amount of flux incident anywhere on the sphere wall will create an equal illuminance on the detector port. In the case of actual integrating spheres, the surface is not perfectly Lambertian, but due to interreflections of light in the sphere, the distribution of reflected light will be sufficiently uniform to approximate the condition assumed in equation (A2.2.24).

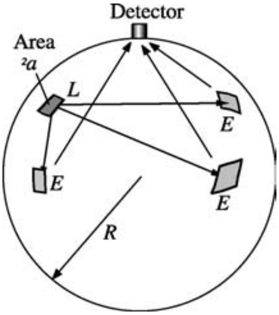

Figure A2.2.9. Flux transfer in an integrating sphere.

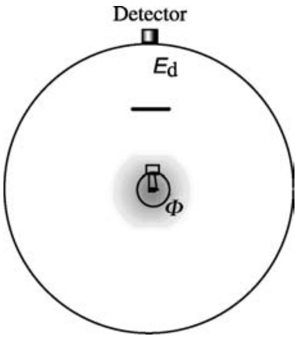

Figure A2.2.10. Integrating sphere photometer.

Integrating sphere photometer

By operating a light source in an integrating sphere as shown in figure A2.2.10, the total luminous flux of the light source is measured using one detector on the sphere wall. Such a device is called an integrating sphere photometer (or Ulbricht sphere). The direct light from an actual light source is normally not uniform, and thus must be shielded from the detector using a baffle. When a light source with luminous flux Φ is operated in a sphere having reflectance ρ, the flux created by interreflections is given by

$$\Phi(\rho + \rho^2 + \rho^3 + \cdots) = \Phi \frac{\rho}{1-\rho}. \tag{A2.2.25}$$

Then, the illuminance E_d created by all the interreflections is given by

$$E_d = \frac{\Phi \rho}{1-\rho} \frac{1}{4\pi R^2}. \tag{A2.2.26}$$

The sphere efficiency (E_d/Φ) is strongly dependent on reflectance ρ due to the term $1-\rho$ in the denominator, where a high reflectance coating such as $\rho = 0.98$ is often used. For this reason, E_d cannot be predicted accurately enough to determine Φ. Real integrating sphere photometers are used as a relative device to measure test lamps against standard lamps whose luminous flux is known. For further details of the integrating sphere photometer, refer to references [25, 26].

A2.2.5 Practice in photometry and radiometry

Photometry and radiometry are practised in many different areas and applications, dealing with various light sources and detectors, and cannot be covered in this chapter. Various references are available on practical measurements in photometry and radiometry. References [26, 27] provide the latest information on standards and practical aspects in photometry. There are a number of publications from CIE on many subjects in photometry including characterization of illuminance meters and luminance meters [28], luminous flux measurement [25], spectroradiometry [29], measurements of LEDs [30], etc. The latest list of CIE publications is available on-line [31]. A series of measurement guide documents are published from the Illuminating Engineering Society of North America (IESNA) for operation and measurement of specific types of lamps [32–34] and luminaires. The American Society for Testing and Materials (ASTM) provides many useful standards and recommendations on optical properties of materials and colour measurements [35]. There are also a number of publications from the National

Institute of Standards and Technology (NIST) on photometry [27], spectral irradiance [36], spectral reflectance [37], spectral responsivity [38], etc.

A2.2.6 Fundamentals of colorimetry

A2.2.6.1 Colour matching functions and tristimulus values

The perception of colour is a psychophysical phenomenon, and the measurement of colour must be defined in such a way that the results correlate accurately with what the visual sensation of colour is to a normal human observer. *Colorimetry* is the measurement science used to quantify and describe physically the human colour perception. The basis of colorimetry was established by CIE in 1931 based on a number of visual experiments that defined a set of three spectral weighting functions [39]. These functions, shown in figure A2.2.11, are called the *CIE 1931 XYZ colour matching functions* denoted as $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, $\bar{z}(\lambda)$. These functions were derived from a linear transformation of the original set of colour matching functions in such a way that $\bar{y}(\lambda)$ is equal to $V(\lambda)$.

By using the colour matching functions, light stimuli having any spectral power distribution $\phi_\lambda(\lambda)$ can be specified for colour by three values:

$$X = k\int_\lambda \phi_\lambda(\lambda)\bar{x}(\lambda)\,\mathrm{d}\lambda, \quad Y = k\int_\lambda \phi_\lambda(\lambda)\bar{y}(\lambda)\,\mathrm{d}\lambda, \quad Z = k\int_\lambda \phi_\lambda(\lambda)\bar{z}(\lambda)\,\mathrm{d}\lambda \tag{A2.2.27}$$

where $\phi_\lambda(\lambda)$ is the spectral distribution of light stimulus and k a normalizing constant. These integrated values are called *tristimulus values*. Two light stimuli having the same tristimulus values have the same colour even if the spectral distributions are different. For light sources and displays, $\phi_\lambda(\lambda)$ is given in quantities such as spectral irradiance and spectral radiance. If $\phi_\lambda(\lambda)$ is given in an absolute unit (such as $\mathrm{W\,m^{-2}\,nm^{-1}}$, $\mathrm{W\,m^{-2}\,sr^{-1}\,nm^{-1}}$) and $k = 683\,\mathrm{lm\,W^{-1}}$ is chosen, Y yields an absolute photometric quantity such as illuminance (in lux) or luminance (in $\mathrm{cd\,m^{-2}}$). For object colours, $\phi_\lambda(\lambda)$ is given as

$$\phi_\lambda(\lambda) = R(\lambda)S(\lambda) \tag{A2.2.28}$$

where $R(\lambda)$ is the spectral reflectance factor of the object, $S(\lambda)$ the relative spectral distribution of the illumination, and

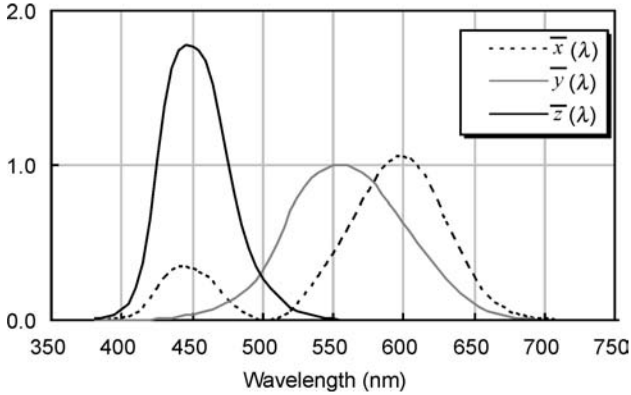

Figure A2.2.11. CIE 1931 XYZ colour matching functions.

$$k = \frac{100}{\int_\lambda S(\lambda)\bar{y}(\lambda)\,\mathrm{d}\lambda} \tag{A2.2.29}$$

so that $Y = 100$ for a perfect diffuser and Y indicates the luminance factor (in %) of the object surface. To calculate colour of objects from spectral reflectance factor $R(\lambda)$, one of the standard illuminants (see section A2.2.6.3) is used.

Tristimulus values can be obtained either by numerical summation of equation (A2.2.27) from the spectral data $\phi_\lambda(\lambda)$ obtained by a spectroradiometer or spectrophotometer, or by broadband measurements using detectors having relative spectral responsivity matched to the colour matching functions. Such a device using three (or four) detector channels is called *tristimulus colorimeter*.

When applying colorimetric data for real visual colour matching, it should be noted that the $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, $\bar{z}(\lambda)$ colour matching functions are based on experiments using 2° field of view and applicable only to narrow fields of view (up to 4°). Such an ideal observer is called the *CIE 1931 standard colorimetric observer*. In 1964, the CIE defined a second set of standard colour matching functions for a 10° field of view, denoted as $\bar{x}_{10}(\lambda)$, $\bar{y}_{10}(\lambda)$, $\bar{z}_{10}(\lambda)$, to supplement those of the 1931 standard observer. This is called the *CIE 1964 supplementary standard colorimetric observer*, and can be used for a field of view greater than 4°. The 2° observer is used in most applications for colorimetry of light sources. The 10° observer is often used in object colour measurements. For further details of colorimetry and colour science, refer to official CIE publications [40–42] and many other general references [43].

A2.2.6.2 Chromaticity diagrams

While the tristimulus values can specify colour, it is difficult to associate what colour it is from the three numbers. By projecting the tristimulus values onto a unit plane ($X + Y + Z = 1$), colour of light can be expressed on a two-dimensional plane. Such a unit plane is known as the *chromaticity diagram*. The colour can be specified by the *chromaticity coordinates* (x,y) defined by

$$x = \frac{X}{X+Y+Z}, \qquad y = \frac{Y}{X+Y+Z}. \tag{A2.2.30}$$

The diagram using the chromaticity coordinates (x,y), as shown in figure A2.2.12(a), is referred to as the *CIE 1931 chromaticity diagram*, or the *CIE (x,y) chromaticity diagram*. The boundaries of this horseshoe-shaped diagram are the plots of monochromatic radiation (called the *spectrum locus)*.

The (x,y) chromaticity diagram is significantly nonuniform in terms of colour difference. The minimum perceivable colour differences in the CIE (x,y) diagram, known as the *MacAdam ellipses*, are shown in figure A2.2.12(a). To improve this, in 1960, CIE defined an improved diagram—*CIE 1960 (u,v) chromaticity diagram* (now obsolete), and in 1976, a further improved diagram—*CIE 1976 uniform chromaticity scale (UCS) diagram*, as shown in figure A2.2.12(b), with its chromaticity coordinate (u',v') given by

$$u' = \frac{4X}{X+15Y+3Z}, \qquad v' = \frac{9Y}{X+15Y+3Z}. \tag{A2.2.31}$$

While the (u',v') chromaticity diagram is a significant improvement from the (x,y) diagram, it is still not satisfactorily uniform. Both of these diagrams are widely used. Note that these chromaticity diagrams are intended to present colour of light sources (emitted light) and not colour of objects (reflected light). Presentation of object colours requires a three-dimensional colour space that incorporates another dimension—lightness (black to white). Refer to other publications [40, 43] for the details of object colour specification.

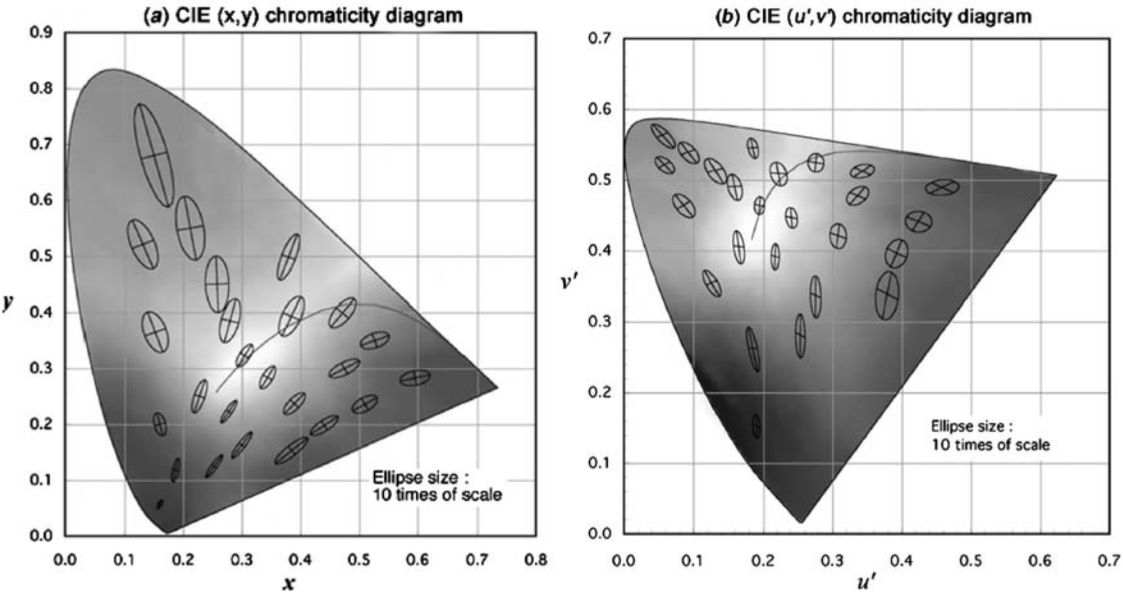

Figure A2.2.12. (*a*) MacAdam ellipses on CIE 1931(x,y) diagram and (*b*) MacAdam ellipses on the CIE 1976 ($u'v'$) diagram. The ellipses are plotted 10 times their actual size. The curve near the centre region is the Planckian locus.

A2.2.6.3 Colour temperature and correlated colour temperature

Figure A2.2.13 shows the trace of the (x,y) chromaticity coordinate of blackbody radiation (see section A2.2.4.4) at its temperature from 1600 to 20 000 K. This trace is called the *Planckian locus*. The colours on the Planckian locus can be specified by the blackbody temperature in kelvin and is called colour *temperature* (see also section A2.2.3.9). The colours around the Planckian locus from about 2500 to 20 000 K can be regarded as *white*, 2500 K being reddish white and 20 000 K being bluish white. The

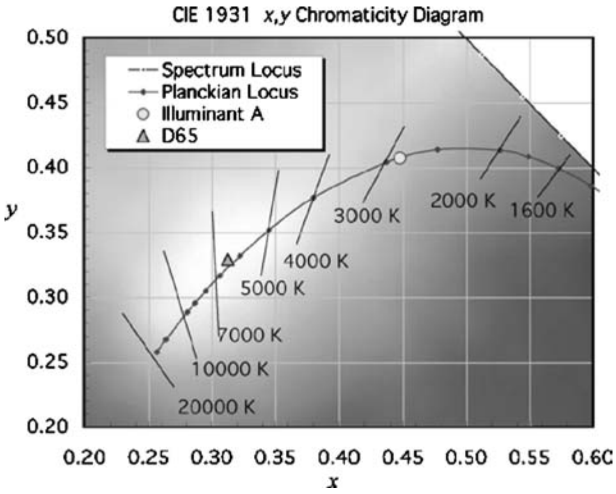

Figure A2.2.13. Planckian locus on (x,y) chromaticity diagram and iso-CCT lines.

point labelled 'Illuminant A' is the typical colour of an incandescent lamp, and 'Illuminant D65' the typical colour of day light, as standardized by the CIE [41]. The colours of most traditional lamps for general lighting fall in the region between these two points (2800–6500 K). Strictly speaking, colour temperature cannot be used for colours away from the Planckian locus, in which case *correlated colour temperature* (CCT) is used. CCT is the temperature of the blackbody whose perceived colour most closely resembles that of the light source in question [2]. Due to the nonuniformity of the x, y diagram, the iso-CCT lines are not perpendicular to the Planckian locus on the x, y diagram (see figure A2.2.13). To calculate CCT, therefore, one of the improved uniform chromaticity diagrams is used. Due to the long tradition, CIE specifies that the 1960 (u,v) diagram (now obsolete for other purposes) be used, where the iso-CCT lines are perpendicular to the Planckian locus by definition. From (u',v') coordinates, (u,v) can be obtained by $u = u'$, $v = 2v'/3$. On the (u,v) diagram, find the point on the Planckian locus that is at the shortest distance from the given chromaticity point. CCT is the temperature of the Planck's radiation at that point. A practical way of computing CCT is available [44].

A2.2.6.4 Colour rendering index

For light sources for lighting applications, it is important to evaluate how well their illumination can render colours of objects. The CIE defines the *colour rendering index* (CRI) [45]. The CRI is calculated from the spectral distribution of light under test and the spectral reflectance factor data of 14 Munsell colour samples. The colour difference ΔE_i (on the 1964 $W^*U^*V^*$ uniform colour space—now obsolete) of each sample illuminated by the light under test and by a reference source (Planckian radiation for CCT < 5000 K or a daylight illuminant for CCT ≥ 5000 K) is calculated taking into account chromatic adaptation. The *special colour rendering index* R_i for each colour sample is calculated by

$$R_i = 100 - 4.6\Delta E_i. \qquad \text{(A2.2.32)}$$

This gives an indication of colour rendering for each particular colour. The *general colour rendering index*, R_a, is given as the average of the first eight colour samples (medium saturation). With the maximum value being 100, R_a gives a scale that expresses well the visual impression of colour rendering. For example, lamps having R_a values greater than 80 may be considered suitable for interior lighting, and R_a greater than 95 for visual inspection purposes, etc. See reference [45] for further details.

A2.2.6.5 Colour quantities for LEDs

In addition to chromaticity coordinates x, y and u', v', the following quantities are used to specify the colour and spectrum of LEDs. The definitions in this section follow reference [30].

Peak wavelength λ_p: The wavelength at the maximum of the spectral distribution.

Spectral bandwidth (at half intensity level) $\Delta\lambda_{0.5}$: Calculated as the width between the wavelengths at half of the peak of spectral distribution, as shown in figure A2.2.14. It is also denoted as $\Delta\lambda$(FWHM).

Centroid wavelength λ_c: Calculated as the 'centre of gravity wavelength', according to the equation

$$\lambda_c = \frac{\int_\lambda \lambda S(\lambda)\, d\lambda}{\int_\lambda S(\lambda)\, d\lambda} \qquad \text{(A2.2.33)}$$

Dominant wavelength λ_d: Wavelength of the monochromatic stimulus that, when additively mixed in suitable proportions with the specified achromatic stimulus, matches the colour stimulus considered. Equal energy spectrum with $(x, y) = (0.3333, 0.3333)$ is used as the achromatic stimulus. See figure A2.2.15, where N denotes the achromatic stimulus.

Exitation purity p_e: Defined as the ratio NC/ND in figure A2.2.15. The value of excitation purity is unity if the chromaticity of the LED is on the spectrum locus.

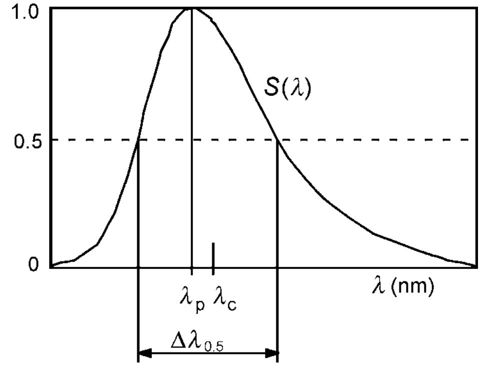

Figure A2.2.14. Typical relative spectral distribution of an LED.

A2.2.6.6 Spectroradiometry for LED colour measurement

Spectroradiometers are commonly used for colour measurement of LEDs. Tristimulus colorimeters are rarely used for LED colour measurements because errors tend to be too large for measurement of quasi-monochromatic sources such as LEDs. Major sources of error in spectroradiometric measurements of LEDs are bandwidth, wavelength error and stray light. To obtain the colour quantities of LEDs accurately, a monochromator bandwidth (FWHM) of 5 nm or less is recommended. The scanning interval should be matched with the bandwidth, or much smaller than the bandwidth. If the bandwidth of the instrument is larger than 5 nm, the bandwidth error can be very large. The errors with a 10 nm bandwidth can be up to 0.005 in x, y depending on the LED peak wavelength [46]. A method for correcting the bandwidth error is available in the case where the bandwidth is a triangular shape and

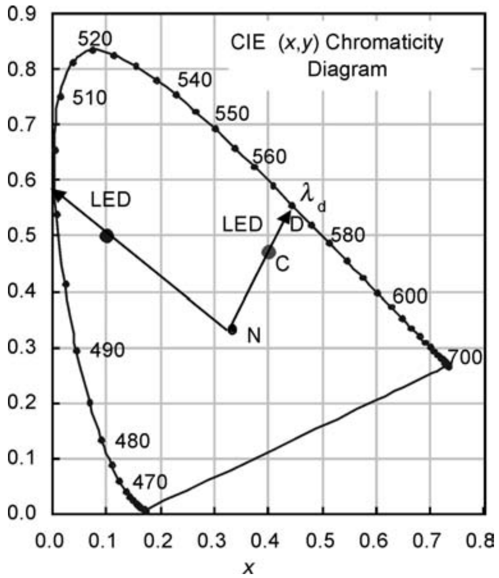

Figure A2.2.15. (x,y) chromaticity diagram showing the dominant wavelength and excitation purity.

is matched with the scanning interval [47]. The wavelength accuracy is also critical for LED colour measurements. An error for 1 nm in wavelength scale would lead to a maximum error of 0.02 in x, y, depending on the LED peak wavelength. The stray light of a monochromator is not very critical for colour measurement of broadband white light sources such as fluorescent lamps, but it is critical for LEDs having narrowband emissions. The errors should be examined for single monochromators including diode-array spectroradiometers. For the details of spectroradiometry in general, refer to other references [29, 48].

A2.3
Nonlinear and short pulse effects

Günter Steinmeyer

A2.3.1 Introduction

In most parts of this handbook, we deal with *linear optical effects*. Linear optics means that the optical power at the outputs of an optical device always scales linearly with input power. The device may spectrally or spatially filter the input beam; it may split the input beam into a multitude of output beams; regardless of what the device does, the output power always relates linearly to the input power. Looking through textbooks on classical optics from the pre-laser era, the impression may arise that the linearity of optical phenomena is a given thing as there is no mention of any *nonlinear effects*. This is in strong contrast, e.g. to acoustics, where nonlinearities are so widespread that the art lies more in their avoidance than in the observation of nonlinearities. One may think of a cheap set of speakers just as one simple example. Increasing the volume, these speakers will start to sound increasingly annoying with more and more audible distortion. This distortion is not related to the frequency-dependence of the speaker's transmission characteristics, because this would be independent of volume. The distortion effect is related to unwanted *harmonics* of the input. These harmonics arise due to nonlinearities between the emitted acoustic wave and the input current to the speaker's solenoid. Beyond a certain drive amplitude, the speaker's membrane position does not linearly follow the current any more. These harmonics are not necessarily bad. All musical instruments also rely on acoustic nonlinearities, giving rise to a characteristic spectrum of overtones of the excited fundamental vibration of a chord. This characteristic spectrum allows us to distinguish different musical instruments. The omnipresence of nonlinearities in acoustics is in strong contrast to optics, where similar effects could not be observed until the advent of the laser.

In a nonlinear system, the output power has to scale nonlinearly with input power. One such effect in optics, which is similar to the harmonics in acoustics, is called *second-harmonic generation* (*SHG*). In this nonlinear optical effect, the *overtone* of an optical wave is generated inside a crystal, e.g. converting the infrared light of a laser into bright green light with half the wavelength of the input light. The output intensity of the green light scales quadratically with the input power, which is a clear indication of a nonlinear optical process of second order. SHG is an example of a *degenerate* nonlinear optical process, i.e. all interacting waves carry the same wavelength. In a crystal with such a second-order nonlinearity, we may also observe *non-degenerate* processes. Non-degeneracy means *mixing* of two input waves with different wavelength, generating the *sum-frequency* or the *difference-frequency* of the two input waves. Now the intensity of the generated sum-frequency light scales with the product of the two input intensities. Note that all nonlinearities discussed so far only involve optical fields. That means that they are *all-optical nonlinear effects*. This has to be seen in contrast to nonlinearities involving one low-frequency electric field (as accessible by conventional electronics) and one optical field. This interaction may be thought of as a limiting case of sum-frequency generation (SFG) with one of the fields close to zero frequency. This mixing effect can be used for building *electro-optical modulators*. However, the *optical* output power of the device scales *linearly* with the *optical* input power. Therefore, electro-optic mixing is not considered a nonlinear optical effect. The same argument holds for *acousto-optics*, where there is in fact mixing between acoustic waves and the optical field. Clearly, acousto-optics is also not considered a nonlinear optical effect, as power scaling is entirely linear for the optical field involved. In the case of the electro-optic effect, we note that this distinction may appear somewhat arbitrary looking at the underlying physics of the process. This distinction will become much clearer from the different regime of applications of all-optical nonlinearities compared to optical modulators.

With the high intensities of laser sources, an all-optical nonlinear regime can easily be reached. The higher the peak power, the more pronounced the nonlinear behaviour of certain optical materials. This makes it clear that a pulsed laser source generates much more abundant nonlinearities compared to a continuous wave source, which is why we refer to nonlinear processes also as *short pulse effects*. In the high-peak-power regime the response of optical materials starts to react nonlinearly, both in amplitude and phase, with incident optical power. A further simple example for nonlinear behaviour may be the bleaching of an optical neutral density filter in a pulsed high-power laser beam. As soon as a certain intensity is surpassed, the attenuation of the filter starts to decrease, because a substantial part of the carriers within the beam cross section is transferred into the conduction band. In turn, the density of carriers in the valence band is decreased. These *carrier-related* effects therefore cause a *saturation* of the absorption in this material.

In optoelectronics, such nonlinear optical behaviour is particularly interesting for the construction of an *all-optical switch*, a device that allows controlling light with light. We will use the term *optical switch* as a general term for very different applications of optical nonlinearities, including optical gates, mode-lockers, and optical limiters. For some applications, one may think of an optical switch acting like an *optical transistor* or *light valve*, employing the nonlinearity for modulation of one light beam by another one. Other applications rely on the *self-action* of intense short pulses in a nonlinear medium. Here the pulse modulates its own amplitude or phase profile via a nonlinear optical effect. Consequently, one talks of *self-amplitude modulation (SAM)* or *self-phase modulation (SPM)*, respectively. Quite generally all methods of all-optical switching outperform acousto-optic or electro-optic concepts in terms of speed. On the other hand, it is very challenging for an all-optical switch to reach anything close to the contrast and efficiency possible with electro-optic switches. This trade-off between speed and switching contrast appears to be the fundamental dilemma of all types of optical switches. In this chapter, we will first give a general overview of nonlinear optical processes. Because of their importance in optoelectronics, we will then concentrate on applications of nonlinear optical processes as all-optical switches.

A2.3.2 Quasi-instantaneous nonlinear optical processes

In the introduction, we have already given examples for the two main types of nonlinear processes. Saturable absorption due to *carrier transfer* into the excited state is a process with *limited response times*, which typically lie in the *picosecond range*. *Non-resonant nonlinearities* such as SHG occur in totally *transparent dielectric* materials and can be significantly faster. As no direct transfer of carriers into any kind of excited state takes place, there is also no limitation by relaxation processes. In the non-resonant case *bound electrons* contribute to the nonlinearity instead. One can coarsely estimate the order of magnitude of the response time τ of nonlinearities in dielectric materials as $\tau = 1/\Delta\nu$, where $\Delta\nu$ is the transparency frequency range of the material. This immediately brings us to single femtoseconds response times for materials that are transparent in the visible [1]. We will therefore refer to these as materials with *quasi-instantaneous* response. For simplicity we will often relate to these nonlinear processes as *instantaneous* effects. Instantaneous effects comprise sum and difference frequency generation, parametric interaction, and also phase effects such as SPM, see figure A2.3.1.

Given the instantaneous nature of the electronic nonlinearities, one can directly write the polarization $\vec{P}$ in a dielectric material as a function of the electric field $\vec{E}$ [1, 2]

$$P_i = \sum_{j=1}^{3} \chi_{ij}^{(1)} E_j + \sum_{j,k=1}^{3} \chi_{ijk}^{(2)} E_j E_k + \sum_{j,k,l=1}^{3} \chi_{ijkl}^{(3)} E_j E_k E_l + \dots \tag{A2.3.1}$$

The susceptibility coefficients $\chi^{(i)}$ are tensors of corresponding rank $i + 1$. The linear optical properties of a material are all included in the first order coefficient $\chi^{(1)}$. In many materials, all tensor elements $\chi_{ij}^{(1)}$ will be identical and we can use simple scalar susceptibility coefficients $\chi^{(1)}$ instead. Only materials exhibiting birefringence or dichroism require a full-blown tensorial treatment of the susceptibility.

Figure A2.3.1. Linear and nonlinear optical processes in the photon picture. Real states are designated by solid horizontal lines; virtual states by dashed lines. Linear absorption is caused by a transition between two real states with the potential relaxation indicated by a dotted arrow, refraction is caused by absorption and delayed re-emission of a photon by a virtual state. In a virtual process, the energy of all photons is conserved. In the virtual $\chi^{(2)}$ processes, three waves interact in different sum and difference frequency generation schemes. In this picture, the $\chi^{(3)}$ process of nonlinear refraction (all-optical Kerr effect) can also be considered as the degenerate case of the more general four-wave mixing process. $\chi^{(2)}$ processes can only occur in anisotropic materials. $\chi^{(3)}$ processes occur in any kind of medium and are of particular interest in fibre optics. Two-photon absorption ends in an excited state. The potential return path is again indicated by a dotted arrow.

Otherwise, we can use a simplified version of equation (A.2.3.1)

$$\vec{P} = \chi^{(1)}\vec{E} + (\chi^{(2)}|\vec{E}|)\vec{E} + (\chi^{(3)}|\vec{E}|^2)\vec{E} + \ldots. \tag{A2.3.2}$$

The complex index of refraction is related to the susceptibility via $n + i\kappa = \sqrt{1 + \chi^{(1)}}$, i.e. $\chi^{(1)}$ contains information about both the refractive index n and the absorption coefficient κ. Nonlinear optical processes are included in the higher-order coefficients and again may affect both the amplitude and the phase of the light. In isotropic materials such as glasses all tensor elements are degenerate and the susceptibility coefficients of even order vanish, i.e. $\chi^{(2)} = \chi^{(4)} = \ldots = 0$. Anisotropy can be found in many crystals and is often, but not necessarily, accompanied by birefringence. Tabulated second-order coefficients $\chi^{(2)}$ for nearly all relevant second order materials can be found in [2].

In figure A2.3.1, some of the most commonly encountered optical nonlinearities up to order three are summarized. The linear processes of absorption and refraction are also included for comparison. For most of these nonlinear optical processes, $\sum_i \pm \hbar\omega_i = 0$ has to hold as a consequence of energy conservation, see figure A2.3.1. This is not true for absorption and two-photon absorption (TPA), where energy is stored in an excited state. Here $\sum_i \pm \hbar\omega_i = E_{\mathrm{abs}}$ has to be fulfilled instead. This means that the sum of all photon energies equals the energy of the excited state E_{abs} in the case of one or multiphoton absorption. If only virtual states are involved, no energy is absorbed in the process and the sum has to vanish. The latter is the case for *SHG*, *difference frequency generation* (*DFG*), and *SFG*. Some of the $\chi^{(3)}$ processes shown in figure A2.3.1 also only involve virtual excited states. In all these non-absorptive cases, momentum conservation $\sum \pm k_i = 0$ also has to hold, where the wavenumber k_i is defined as $\omega_i n/c$. One may think of the real processes absorption and two-photon absorption as frustrated refraction or four-wave mixing processes, respectively. These frustrated processes end in a real rather than virtual state and can therefore not relax back to the ground state.

It is useful to relate equation (A2.3.2) to our initial acoustics example, where the electric field $\vec{E}$ takes the role of the solenoid drive current and the polarization $\vec{P}$ is related to the membrane position. As soon as a significant contribution from the nonlinear terms in equation (A2.3.2) appears, we would expect to see optical harmonics in analogy to acoustics. Let us come back to our original example for nonlinear optical behaviour, i.e. SHG. This effect manifests itself as a parabolic susceptibility term $\chi^{(2)}$ in equation (A2.3.2). In such a medium, the polarization P does not proportionally follow the electric field $E \propto \sin(\omega t)$ of the input field. As illustrated in figure A2.3.2, the resulting polarization

$$P \propto \chi^{(1)}\sin(\omega t) + \chi^{(2)}\sin^2(\omega t) = \chi^{(1)}\sin(\omega t) + \frac{\chi^{(2)}}{2}[1 - \cos(2\omega t)] \tag{A2.3.3}$$

clearly exhibits distortions compared to the sinusoidal input field, which manifest themselves as *frequency-doubled components* in the polarization [1, 3]. The output field therefore consists of the fundamental and its second harmonic (and a constant term, which does not propagate). If we had investigated the $\chi^{(3)}$ term instead, we would find the third harmonic of the input field. Similarly, one can easily show that higher-order terms $\chi^{(i)}$ lead to the generation of the i-th harmonic in the polarization. The coefficients $\chi^{(i)}$ therefore govern the characteristic spectrum of harmonics of a nonlinear material, similar to the relative strength of overtones in acoustics discussed in the introduction. In the non-degenerate case of mixing of two electric fields of different frequency, one observes both the sum and difference frequency mixing terms in the output spectrum.

A2.3.3 Scattering processes—coupling to the lattice

The effects described so far only encompassed interaction of photons and electrons. A third category of nonlinear optical processes comprises scattering processes, in particular those involving phonons in

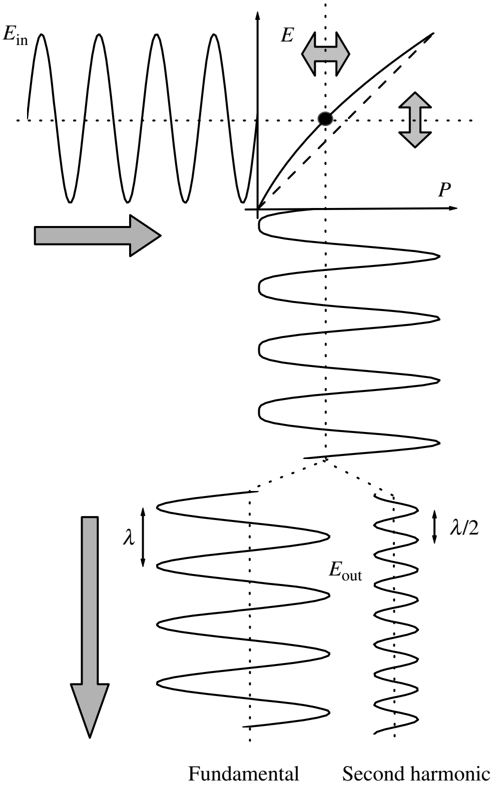

Figure A2.3.2. Generation of the second harmonic. If the polarization P inside a medium does not simply proportionally follow the input field E_{in} but $P(E)$ includes a parabolic term, the resulting polarization contains non-sinusoidal components, which reveal themselves as a harmonic contribution at double the frequency of the input field. Generally, a $\chi^{(i)}$ susceptibility term gives rise to generation of the i-th harmonic in the output field.

solid-state materials. Coupling of lattice vibrations and the electric field give rise to *Brillouin scattering* (acoustic phonons) and *Raman scattering* (optical phonons) [3, 4]. These processes can be understood similar to the DFG and SFG processes but with one photon replaced by a quantized lattice vibration, i.e. a phonon. Again, these processes involve virtual intermediate states, see figure A2.3.1. The decay of one input photon into a photon of smaller energy and one phonon is referred to as the Stokes process. The wavelength shift accompanying this scattering process is called the *Stokes-shift*. Therefore, looking at scattering processes from a photon point of view, energy conservation does not appear to hold as the excess energy is transferred into the phonon. The sum of all particle energies, however, is conserved. At high light intensities, the opposite process similar to the sum-frequency process may also show up. In this case, a previously generated phonon may add to the energy of one photon, with a resulting shorter-wavelength photon as the product of this so-called anti-Stokes process.

The scattering processes are difficult to categorize, as they rely on the same kind of mechanism as SFG but are linear in terms of optical power. Therefore, they do not qualify as nonlinear optical processes similar to the electro-optic processes discussed in the introduction. Nevertheless, the appearance of Raman and Brillouin scattering is closely related to nonlinear processes as are the electro-optic processes.

At high pump intensities a new phenomenon called stimulated scattering can be observed. Here an exponential increase of the Stokes wave with input power is observed. This process is nonlinear, whereas the spontaneous scattering described above has to be considered a linear optical process. These processes have found many applications in fibre optics, e.g. for Raman lasers and frequency conversion. For a detailed description of stimulated scattering processes and their applications we refer the reader to specialized literature on nonlinear fibre optics [4].

A2.3.4 Saturable absorbers

A2.3.4.1 Types of saturable absorbers

So far, we have mainly addressed processes which follow the polarization in the medium instantaneously. Many nonlinear processes, in particular those involving *generation of free carriers*, exhibit a non-instantaneous response. For continuous light exposure or at long pulse durations, the nonlinearity of these processes can also be expressed as a perturbative series like equation (A2.3.2). On shorter time scales, however, these processes may not relax quickly enough, and the number of free carriers grows linearly with the accumulated exposure. As the number of carriers is responsible for the nonlinearity, there is also a cumulative effect for the nonlinearity of the process. For short pulses (short meaning faster than the relaxation time constant), the nonlinearity therefore rather scales with pulse energy than with peak power.

Saturable absorption is the prime example of such an effect. It is also a very useful effect for constructing nonlinear optoelectronic devices. A *saturable absorber* acts like a switch that allows, for example, discrimination of low-energy pulses inside a laser. As short pulses with sufficiently high energy experience a decreased optical loss by the saturable absorption, a saturable absorber effectively favours pulsed operation of the laser over continuous operation. Such devices typically contain one or several saturable absorbers and a reflector. These devices have been named *saturable Bragg reflector* (SBR, [5, 6]) or *semiconductor saturable absorber mirror* (SESAM, [7]) or sometimes simply *saturable absorber mirror*. As these optoelectronic devices have become an important element in the construction of mode-locked lasers, we will outline some fundamental physical processes contributing to the nonlinearity of such devices. We will also give an overview on the construction of these optoelectronic building blocks.

In principle, any absorbing material could be used to build a saturable absorber. Dyes have been very popular for that purpose in the 1970s and 1980s [8, 9]. Dyes offer some adaptability by changing concentration and the centre wavelength of the absorber. Several solid-state materials based on doped glasses have been proposed as an alternative [10, 11]. As a crystalline material, Cr:YAG has found widespread applications as an intracavity switch [12–15]. The potential of semiconductor materials for electro-optical switches, in particular that of quantum well absorbers, has already been recognized in the 1970s and 1980s [16–20]. As the optical properties of quantum wells can be tailored in the most flexible way of all materials discussed so far [21, 22], this type of saturable absorber has become the method of choice for all-optical switches and has found widespread use.

A2.3.4.2 The physics of saturable absorption

The fundamental processes involved in saturable absorption are schematically illustrated in figure A2.3.3. Initially, a short laser pulse transfers electrons from the valence band of the absorber into the conduction band of the material. Again, short means that there is only insignificant relaxation back to the valence band within the pulse duration and some time after. By depleting the valence band this process therefore reduces the density of carriers that are capable of absorbing the laser light, which effectively decreases absorption [21]. A short powerful laser pulse can generate a *nonthermal carrier*

Figure A2.3.3. A detailed look at saturable absorption. After excitation of carriers from the valence band of a semiconductor into its conductance band (*a*), the initial non-thermal distribution tends to rapidly cool (*b*) with a time constant τ_1. On this time scale of int*ra*band relaxation, the majority of carriers is still in the excited state and only relaxes into the valence band on longer time scale, which is called int*er*band relaxation (*c*). Introducing additional mid-gap states as shown in (*d*) may greatly accelerate the interband recombination. Monitoring the induced transmission change $\Delta T/T$ as shown in (*e*) identifies intraband and interband relaxation by two distinct time constants, τ_1 and τ_2. (*f*) shows the typical dependence of the induced increase of transmission as a function of input fluence. For input fluence well below the saturation fluence F_{sat}, the overall loss of the device amounts to the sum of saturable and non-saturable losses. At higher fluences, the loss starts to roll off in the vicinity of F_{sat} and reaches a minimum value dictated by non-saturable losses L_{NS}. At still higher fluence, one may observe an increased loss due to two-photon processes.

distribution high up in the valence band [22, 23] as schematically shown in figure A2.3.3(*b*). These hot electrons are not in thermal equilibrium with the lattice and tend to rapidly cool via phonon scattering processes. Typically, this *intraband relaxation process* occurs on a time scale of $\tau_1 \approx 100\,\mathrm{fs}$ (figure A2.3.3(*c*)). The cooled carriers will fill the bottom of the conduction band, relaxing to the valence band on much longer time scales τ_2, which are typically of the order of nanoseconds. This is also called *interband relaxation*. The two different timescales of carrier cooling and recombination generate a marked *bitemporal behaviour* [7] of the absorption *vs*. time, as shown in figure A2.3.3(*e*).

$$L(t) = \begin{cases} L_{\mathrm{NS}} - L_1[1 - \exp(-t/\tau_1)] - L_2[1 - \exp(-t/\tau_2)] & t \geq 0 \\ L_{\mathrm{NS}} & t < 0. \end{cases} \tag{A2.3.4}$$

The time-dependent loss $L(t)$ includes two saturable contributions with strength L_1 and L_2, and a non-saturable term L_{NS}. The nonlinear response of equation (A2.3.4) can be measured using *pump-probe spectroscopy*. Pump-probe spectroscopy employs a second weaker pulse to monitor the depletion at variable delays after the strong pump pulse at $t = 0$. From a logarithmic plot of the measured response, one can easily retrieve the time constants τ_1 and τ_2. Figure A2.3.3(*e*) qualitatively shows the bitemporal behaviour. The induced transmission is strongest when all excited carriers are still in resonance with the pump that created them. Cooling processes rapidly broaden the initial hot distribution of electrons, with more and more electrons being transferred to the bottom of the conduction band. This is the first effect reducing the induced transmission signal. On longer time scales, the signal is further weakened by recombination back into the valence band until it will eventually vanish, which typically happens on the nanosecond time scale.

For applications of saturable absorbers in lasers, the time constants τ_1 and τ_2 are important device parameters. These time constants are to be compared with the pulse duration of the laser. Despite the fact that it is possible to generate pulses that are more than one order of magnitude shorter than the dominant response time of the absorber [24, 25], the usefulness of an absorber is greatly enhanced the faster its response. Clearly, a recombination time constant τ_2 of a few nanoseconds, i.e. approaching typical cavity roundtrip times, is problematic. Significant efforts went into *acceleration of the recombination process*. One method of doing so is the introduction of *additional mid-gap* states into the material as schematically shown in figure A2.3.3(*d*). These additional states can be generated by a variety of processes. The first observation that *defect-induced* additional states contribute to an accelerated relaxation of a saturable absorber was reported by Ippen *et al* [26]. Later several methods for introducing defects in a controlled way were explored, including low-temperature growth [27, 28], ion implantation [29], proton bombardment [30, 31], or impurity implantation [32]. Lifetimes have been pushed down to one to several picoseconds, which constitutes an improvement of about three orders of magnitude compared to low-defect materials.

A2.3.4.3 Design of saturable absorber mirrors

Apart from the time constants, the relative strength of the nonlinear absorption and its wavelength characteristics are further important design parameters of the SESAM. Both bulk absorption and *quantum wells* are used for generating saturable absorption in SESAMs. Quantum wells exhibit a relatively strong nonlinear response because of *quantum confinement* effects [21]. The number and position of intrinsic and excitonic states of a quantum well can be influenced both by the material and by the thickness of the quantum well. Note that saturable absorption extends to below the nominal band gap of a quantum well, as there are also strong *excitonic effects* in semiconductor heterostructures. Excitonic contributions tend to be faster but also weaker than contributions from band filling. The design of the quantum wells allows for some *tailoring of the wavelength response* and also of the strength of the saturable absorption. The latter can be further influenced by a multitude of design parameters, namely the number of quantum wells, their position relative to the nodes of the electric field, and also by the optical design of the SESAM [7]. If the quantum well is positioned at a maximum of the standing wave inside the laser cavity, its response is coupled much tighter to the electric field than if it were positioned at a node of the field (see figure A2.3.4).

Figure A2.3.4 shows two different aspects of the design of a SESAM device, its *bandgap structure* and its *refractive index structure*. The index structure is responsible for positioning of the nodes and the reflection properties [7]. The bandgap structure is engineered to provide suitable saturation properties,

Figure A2.3.4. Schematic refractive index and band gap structure of a saturable absorber mirror. A Bragg reflector at the bottom of the device provides a high reflectivity and is typically implemented as a quarter wave layer stack of two different semiconductor materials. The index of refraction is alternating in this stack. Both materials should have a band gap larger than the photon energy in the device. Saturable absorption is produced by one or several quantum wells. In these quantum well regions, discrete states exist. Additionally excitonic effects may contribute to the absorption behaviour of the quantum wells. The quantum well position relative to the nodes of the field allows us to tailor the strength of the nonlinear response. The field strength at the quantum wells can be additionally manipulated by an external Fabry–Perot structure. For this purpose an additional mirror is coated on top of the device. This mirror can either be highly reflecting (HR, high-finesse case) or be an antireflection coating (AR).

as was explained above. As the SESAM has to also act as a mirror, the absorber structure is deposited on a highly reflecting mirror reflector. In the simplest case, a *Bragg mirror*, i.e. a combination of quarter-wave layers of alternating index of refraction, is used as outlined in figure A2.3.4. The bandgap of the materials used in the reflector is significantly higher than the photon energy, therefore negligible absorption takes place in the mirror structure. One of the disadvantages of the Bragg mirror approach is its limited bandwidth which is mainly caused by the weak index contrast of the available transparent semiconductor materials. Typically, a Bragg mirror consisting of AlGaAs and AlAs, as suggested in figure A2.3.4, only covers a bandwidth of about 100 nm at an 800-nm centre wavelength. Alternatively, metal mirrors have also been employed for providing more broadband reflectivity [33, 34]. This approach, however, is much more demanding in terms of manufacturing.

Apart from the Bragg reflector and the absorber, a second mirror structure can be added on top of the absorber towards the interface to air. The reflectivity of the top mirror can reach from more than 50% down to an antireflection coating. The case of high reflectivity results in a high finesse Fabry–Perot-like structure. Typically, high-finesse SESAMs are used in antiresonance (*antiresonant Fabry–Perot saturable absorber*, A-FPSA [35]). The antiresonance decreases the intensity of the light inside the absorber relative to the main cavity. For example, a 95% reflectivity top mirror increases the saturation fluence by about a factor 100 [7]. In more recent SESAM configurations, lower reflectivities of the top reflector were used and scaling of the nonlinearity was obtained by other means already discussed above [36]. The top mirror or antireflection structure can either be manufactured by semiconductor technologies or using dielectric materials such as TiO_2 or SiO_2. Very simple but efficient antireflection coatings can be manufactured by depositing a single half-wave layer of a material with index of refraction $n_{AR} = \sqrt{n_{top}}$, where n_{top} is the top layer refractive index.

Depending on the pulse duration being larger or smaller than the dominant time constant of the SESAM, one either observes a functional dependence of the reflectivity with pulse peak power or pulse energy, respectively. On a femtosecond time scale, the response of the SESAM generally scales with energy, because significant interband relaxation has not set in yet. In this case, one can write the power dependent reflectivity of a SESAM as

$$R(F) = R_0 + \Delta R(1 - \exp(-F/F_{sat})) \tag{A2.3.5}$$

where F is the fluence in Joule per unit area, F_{sat} is the saturation fluence, R_0 is the small-signal reflectivity, and ΔR is the modulation coefficient [7], which is connected to the coefficients L_1 and L_2 in equation (A2.3.4). The functional dependence of the reflectivity on the flux is shown in figure A2.3.3(*f*). At very high fluence $F > 10F_{sat}$, additional effects may contribute, which are treated below. For lower fluences, the saturable ΔR may range from L_2 to $L_1 + L_2$, depending on pulse duration. In the absence of non-saturable losses, $R_0 + \Delta R$ should add up to unity reflectivity. In reality, *non-saturable losses* $L_{NS} = 1 - R_0 - \Delta R$ are typically on the same order of magnitude as ΔR itself, i.e. a few percent. The onset of saturation is governed by the parameter F_{sat}. The saturation fluence is related to the *cross section* σ of the absorber by the relation

$$F_{sat} = \frac{h\nu}{N\sigma} \tag{A2.3.6}$$

i.e. the *saturation fluence* is reached when on average one photon with energy $h\nu$ impinges on the cross-sectional area σ. Inside a linear laser cavity, this may happen twice ($N = 2$). In a ring cavity or otherwise $N = 1$. The saturation fluence is a decisive engineering parameter of the SESAM, and should be characterized carefully prior to use of a SESAM inside a laser. The saturation fluence of the absorber has to be carefully balanced with the saturation fluence of the laser gain material to avoid spiking of the laser. The gain saturation fluence is related to the gain cross section as defined in equation (A2.3.6) [37].

For clean mode-locked pulse trains, it is of paramount importance to scale spot sizes in the gain medium and on the absorber accordingly. Guidelines for a suitable layout of a laser cavity are given in [38].

A2.3.4.4 Two-photon absorption in saturable absorber mirrors

For extremely high peak intensities, the nonlinear response of a saturable absorber may be affected by *TPA* giving rise to an additional term in equation (A2.3.4) [39–41]. As TPA is a quasi-instantaneous nonlinear process (see figure A2.3.1), this mechanism always scales with peak intensity $I(t)$, regardless of the pulse duration regime.

$$\Delta R_{\mathrm{TPA}} = -\beta_2 I. \tag{A2.3.7}$$

As TPA creates additional absorption for high enough peak powers, it defeats the effect of saturable absorption at extremely high power levels, as shown in figure A2.3.3(*f*). At first sight, TPA may appear as a limitation of SESAMs. However, this effect can be beneficial, causing a stabilization of the pulse duration and preventing pulse break up, stabilizing the laser pulse duration and the average power of the laser. This effect can also reduce the spiking tendency of the laser [41] and help to provide clean mode-locked pulse trains with stable pulse energy.

A2.3.4.5 Devices closely related to saturable absorber mirrors

The SESAM has found widespread use as intracavity saturable absorbers for generating short optical pulse [7, 23]. Several similar devices have been proposed and demonstrated. The SESAM's main application is *self-amplitude modulation*. In a slightly modified geometry, saturable absorption can also be used to modulate one laser beam with the aid of another one [42]. Here the control light is fed into a waveguide and bleaches out an arrangement of several quantum wells. This saturable absorption modulates a light beam that crosses the quantum wells at normal incidence to the waveguide direction.

Other nonlinear optical switches have been proposed, which do not directly rely on the absorptive properties of quantum wells or semiconductor bulk materials. These devices embed the saturable absorber in between a high-finesse Fabry–Perot structure. Other than with the A-FPSA approach previously mentioned, the Fabry–Perot is used at resonance and relies on refractive index changes accompanying the creation of free carriers in the conduction band of the semiconductor. While SESAMs can be understood as amplitude modulators, this type of *Fabry–Perot modulator* (FPM) relies on *phase modulation*. For inducing mode-locking inside a laser resonator, the SPM has to be converted back into an amplitude modulation, compare 'Nonlinear interferometers as switches' section. This is accomplished by the Fabry–Perot structure. The index change causes a tuning of the Fabry–Perot resonances. If the length is chosen such that the additional index change increases the overall reflectivity of the device, such a device can also be used as an optical switch for mode-locking [43]. Moreover, one can further exploit the phase modulation aspect of such Fabry–Perot structures for synchronizing lasers as shown in [44]. Using a laser with a photon energy above the band gap of the spacer material in the FPM, one can modulate index of refraction for light below gap without inducing any losses. This index modulation allows control of the cavity roundtrip time and passive locking of cavity repetition rates.

A2.3.4.6 Inverse saturable absorption—optical limiting

For many applications, an effect with exactly the reverse behaviour of saturable absorption is desirable. One example could be protection of a sensitive photo-detector from intense light pulses that might otherwise destroy the detector. Such a device requires a transmission that decreases with increasing light intensities, a characteristic that is referred to as *optical limiting*. The previous discussion already addressed *two-photon absorption* in semiconductor materials as one possible mechanism showing exactly the right sign of saturable absorption needed for an optical limiter ([39–41], see equation (A2.3.7) and figure A2.3.3(*f*)). In fact, semiconductor materials such as GaAs have been suggested early on for this purpose [45, 46]. Additionally *self-defocusing* may contribute to optical limiting in these devices, an effect that will be explained in the following section. Rather than using semiconductors, one can again also use dyes for the same purpose [44–46]. One of the major mechanisms for reverse saturable absorption in complex organic molecules is the generation of excited electronic states with an absorption cross section larger than the ground state absorption. *Excited state absorption* has been reported for several classes of organic chromophores [47]. Apart from sequential single-photon absorption, TPA may also contribute to optical limiting in dye molecules [48, 49]. Different chemical compounds, such as fullerenes, organometallics, or carbon black suspensions have been discussed for optical limiting devices. Optically induced scattering, e.g. by localized melting of the limiter material, has also been suggested as a mechanism for optical limiting [50]. However, in spite of the variety of nonlinearities, materials, and device configurations that have been used to implement passive optical limiters, no single device or combination of devices has yet been identified that will protect any given sensor from all potential optical threats.

A2.3.5 The all-optical Kerr effect and nonlinear refraction

A2.3.5.1 Kerr-based switches and Kerr gates

From the point of view of optoelectronics, saturable absorption is probably the most interesting process among the variety of nonlinear optical processes, as it allows us to build an *all-optical switch*. Depleting carriers by means of a pump pulse, one can influence the transmission properties of a saturable absorber and thereby control the energy of a second probe pulse. In some way, this device may be thought as an all-optical transistor or *light valve*, despite the fact that one needs rather large light intensities to control relatively small ones. Apart from acting as a light valve, a technologically important aspect of an all-optical switch is that it forms the product of optical waveforms. Multiplying an unknown waveform with a known one is at the heart of optical sampling techniques and allows characterization of unknown optical pulse shapes with the aid of known ones. Unfortunately, with SESAMs one can do neither of these arbitrarily fast, as saturable absorption is a rather slow process with picosecond relaxation times even when midstate traps are used to accelerate this process. This calls for methods that benefit from *quasi-instantaneous nonlinearities* (cf 'Quasi-instantaneous nonlinear optical processes' section).

It is rather clear that the temporal response of carrier-related effects cannot be much further accelerated without sacrificing modulation depth. Instead, many approaches have been pursued to employ bound-electronic optical processes to build an all-optical switch. These approaches rely nearly exclusively on *nonlinear refraction*, i.e. the change of the index of refraction with instantaneous intensity. First and foremost, nonlinear refraction is a phase effect that requires *translation into an amplitude effect* to be effective as a nonlinear optical switch. In the following, we will first review the physics of nonlinear refraction and point out that it is inseparably connected to TPA and other nonlinear optical effects. In fact, this connection between nonlinear refraction and TPA poses a stringent limitation of all-optical valves. We will then give an overview of several architectures of all-optical switches based on nonlinear refraction. These switches have found widespread use in rather distinct applications of optics ranging from telecommunications to measurement techniques for short pulses.

A2.3.5.2 The physics of nonlinear refraction

The propagation (phase) velocity of light v_φ in a dielectric medium is governed by the refractive index n according to $v_\varphi = c/n$. The refractive index n is a function of wavelength and can be computed from the complete knowledge of absorbing resonances in the ultraviolet and infrared spectral region using *Kramers–Kronig relationship* [51]. The slightest changes, e.g. of the lattice constant or temperature of a solid-state material, will automatically affect the refractive index when they modify the spectral position or relative strength of the resonances. In dielectric media this will cause the index of refraction change according to

$$n(I) = n_0 + n_2 I. \tag{A2.3.8}$$

This effect of an intensity-dependent refractive index is called the *all-optical Kerr effect* [1, 3, 4]. The coefficient n_2 is called the *nonlinear index of refraction* and is related to the real part of the susceptibility tensor $\chi^{(3)}$ via

$$n_2 = \frac{3}{8n} Re\chi^{(3)} \tag{A2.3.9}$$

where it was assumed that the light is linearly polarized such that only one component of the third-rank tensor $\chi^{(3)}$ contributes. Often, $\chi^{(3)}$ is quoted using electrostatic units (esu). One can convert to the more useful W cm^{-2} employing the relation

$$n_2(\mathrm{cm}^2\,\mathrm{W}^{-1}) = \frac{12\pi^2}{n_0^2 c} Re\chi^{(3)}(\mathrm{esu}). \tag{A2.3.10}$$

Typical values for n_2 of optical glasses lie in the range of a few $10^{-16}\,\mathrm{cm}^2\,\mathrm{W}^{-1}$ [4, 52, 53]. The main effect in a dielectric medium far away from the bandgap is electronic polarization, which has a response time of 1 fs or faster. In other materials, additional effects such as molecular orientation or atomic resonances can create much stronger nonlinear refraction, at the expense of a greatly slowed response and a much narrower bandwidth. In the following, we will restrict ourselves on the Kerr effect in dielectrics and semiconductors and focus on nonlinear refraction induced by electronic polarization.

A power-dependent index of refraction means that the phase velocity of the light has become a function of intensity, with high peak power pulses travelling slower than a low peak power beam with identical cross section would do, see equation (A.2.3.8). This self-action of the light is called SPM

$$\Delta\varphi(I) = \frac{2\pi}{\lambda} n_2 I L \tag{A2.3.11}$$

where λ is the length of the medium and L the wavelength of the light. The importance of nonlinear refraction can be estimated from inverting equation (A2.3.11) to find the critical intensity that is necessary to create a macroscopic 2π phase shift

$$I_{\mathrm{crit}} = \frac{\lambda}{n_2 L}. \tag{A2.3.12}$$

Plugging in numbers for a 1 cm long piece of glass, one finds a critical intensity level on the order of $10^{11}\,\mathrm{W\,cm}^{-2}$. This makes it immediately clear that SPM only becomes important when laser pulses are either extremely tightly focused or when a very long interaction length can be used as in optical fibres. In fact, SPM is extensively used in *nonlinear fibre optics* [4].

A2.3.5.3 Connection of nonlinear refraction and TPA

As nonlinear refraction is the most important effect for building quasi-instantaneous optical switches, a somewhat deeper insight into the underlying physics is important to gain an understanding on some of the limitations. The Kerr effect can be generated by a variety of different mechanisms, including molecular orientation, saturated absorption, and electrostriction [1]. In a wider sense, also thermal effects create refractive index changes. With response times of picosecond to milliseconds, application of these effects is much less interesting than use of the Kerr effect induced by electronic polarization changes. For all practical applications this response can be considered instantaneous. Quite generally, there appears to be wide-ranging inverse connection between the response time of the effect and its relative strength. Investigations of the electronic Kerr effect therefore were motivated by finding a material that combines quasi-instantaneous response with maximum nonlinear susceptibility.

In semiconductors, an *inverse Kerr effect* has been observed, i.e. high intensities travel at higher velocity than low intensities, other than in dielectric materials. This sign change can normally be explained by the *generation of free carriers*, which is a strong indication for the onset of multiphoton absorption in the material. The magnitude of the nonlinear response shows a dramatic increase close to the band gap of an optical material [54]. This renders semiconductors very interesting for building all-optical switches. Figure A2.3.5 shows the fundamental behaviour of nonlinear refraction and TPA *vs*. photon energy. This curve is based on the theoretical model of Sheik-Bahae *et al* for nonlinear refraction. The computation is based on the *Kramers–Kronig relationship*, which allows us to calculate refraction changes directly from absorption changes [51, 55]. The main effect contributing to the nonlinear absorption is *two-photon absorption*, which sets in above half the band gap of the material.

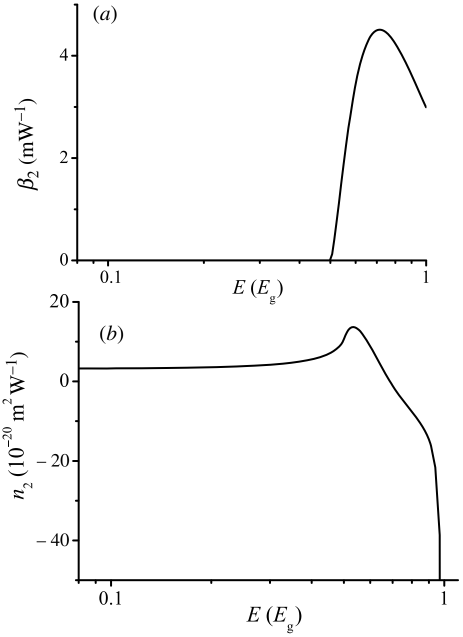

Figure A2.3.5. Behaviour of two-photon absorption (*a*) and nonlinear refraction (*b*) as a function of photon energy. These calculations are based on material parameters of silica. The photon energy is scaled in units of the band gap of the material. Nonlinear refraction is rather constant at low energies, exhibits a peak above half the band gap and then turns negative close to the band gap.

Other effects, such as the *Stark effect* and *Raman* contributions, also play a role and have been accounted for in figure A2.3.5. It is important to understand that TPA poses a severe limitation on using the Kerr effect for a switching application. Excessive TPA will destroy the switch. From the behaviour of nonlinear refraction alone, one would tend to go as close to the band gap as possible to create the maximum nonlinear response. Unfortunately, such a device would also suffer from strong possible TPA. For switching applications, it has been found that an optimum between both effects is reached when the photon energy is about 70% of the band gap energy [55].

A2.3.5.4 The Kerr lens as a nonlinear optical switch

The earliest switching method that was based on the Kerr effect is the so-called Kerr gate [56], which is illustrated in figure A2.3.6. In a Kerr gate, a probe pulse is sent through a Kerr medium, in which its path crosses the path of a strong pump pulse. Crossed polarizers prevent detection of the probe light in the absence of an overlap with the pump. Only if the pump induces a *polarization rotation* inside the Kerr medium, is some portion of the probe transmitted at the polarizer. This Kerr gate is instantaneous, provided that the Kerr nonlinearity is sufficiently fast. In the more recent literature, interferometer based switches are also referred to as optical gates (see e.g. [57]). We will treat these methods of translating

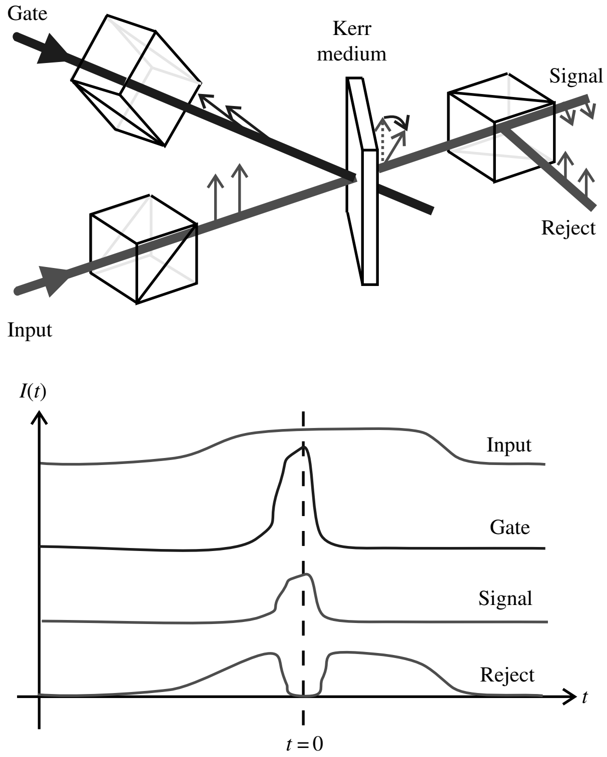

Figure A2.3.6. Kerr gate based on polarization rotation. The gating pulse and the input pulse are crossed inside a Kerr medium. Both pulses are linearly polarized, with the polarization of the gating pulse rotated 45° relative to the input pulse. The Kerr effect causes a polarization rotation of the input pulse. A second crossed polarizer in the input beam line allows separation of the gated pulse from the rejected part of the input pulse. An example for the temporal behaviour of the gating pulse, the input pulse, and the two output pulses are shown below for comparison.

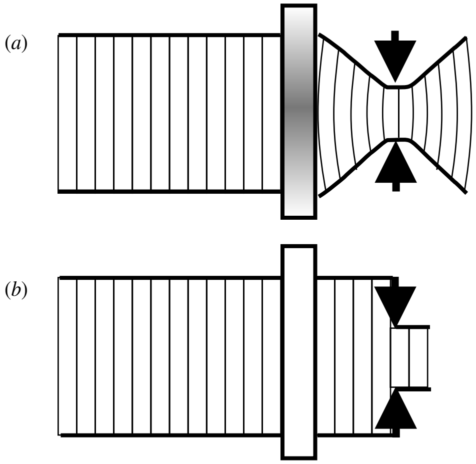

Figure A2.3.7. Kerr gate based on Kerr lensing. Schematically shown are propagating wavefronts of a high-intensity and a low-intensity beam, (*a*) and (*b*), respectively. For sufficiently high intensities, an transverse index profile is induced by the pulse as indicated by grey shades. The stronger the induced change of the refractive index, the stronger the corresponding part of the beam front is retarded. This causes an additional beam front curvature, i.e. the Kerr effect transversally acts like a lens. A subsequent aperture can be used to convert the lensing effect into an effective amplitude modulation. The combination of the Kerr lens and an aperture acts similar to the gate of figure A2.3.6, but is not background-free.

an instantaneous phase nonlinearity into an amplitude nonlinearity below. Instantaneous optical gates can be built from Kerr induced polarization changes, Kerr lenses, or nonlinear interferometers.

A further Kerr-related effect that can be used for building a switch is *self-focusing*. This method is illustrated in figure A2.3.7 [3, 58, 59]. When the central most intense part of a beam experiences a phase delay according to equation (A.2.3.8), this is equivalent to the focusing action of a convex lens. In a convex lens the phase shift is generated by the larger amount of glass in the beam path of the central rays. Other than in an ideal conventional lens, however, the wavefront change induced by the nonlinear Kerr lens is not exactly spherical, but proportional to the spatial beam profile. For example, if the beam profile is Gaussian, only the central part of the Kerr lens can be approximated by a conventional lens. A nonlinear *gradient-index duct* [37, 59, 60] is normally a better approximation for the Kerr lens.

As the Kerr lens only focuses the most intense parts of a short pulse, one can use it to build an ultrafast optical switch, which is also illustrated in figure A2.3.7. If an aperture is suitably placed in the focus of the Kerr lens, it will introduce losses for cw laser light of low intensity, whereas high intensity light can pass through as it sees the focusing action of the Kerr lens. This kind of self-switching is used in lasers to discriminate short pulses and create losses for any kind of low intensity background. Placed in a cavity, the Kerr lens switch strips off a pulse pedestal, recleaning the pulse on every passage. This is used for generating some of the shortest pulses ever generated from a laser with a method called *Kerr-lens mode-locking* [59–62].

A2.3.5.5 Nonlinear interferometers as switches

Another method to build a switch is based on SPM (compare equation (A2.3.11)). Here the Kerr effect is translated into an effective SAM in a *nonlinear interferometer*. The basic idea is illustrated in figure A2.3.8 with a Michelson interferometer. If one introduces a Kerr medium in only one arm of the interferometer, high light intensities will experience a phase shift compared to low intensities. Provided

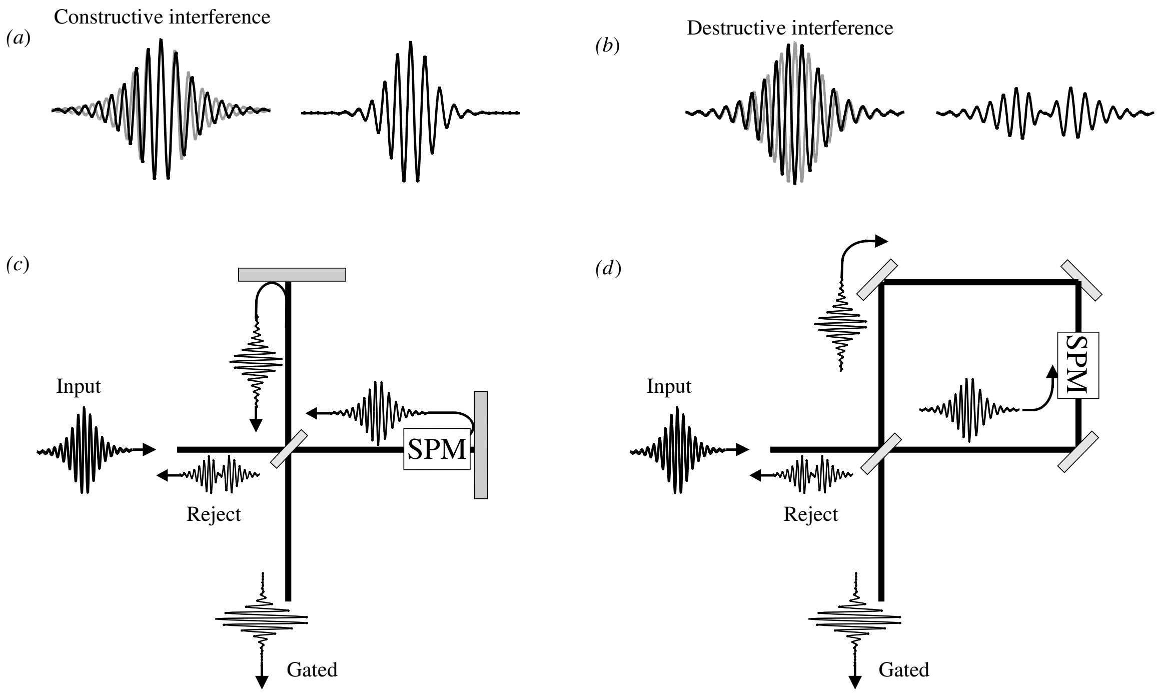

Figure A2.3.8. Kerr gate based on nonlinear interferometers. (*a*) and (*b*) show interference of an unmodulated pulse (grey line) with a self-phase modulated pulse (black line). If the bias phase at pulse centre is chosen for constructive interference as in (*a*), destructive interference in the wings compresses the resulting pulse. The opposite case is shown in (*b*), resulting in a lengthened pulse. (*c*) shows a Michelson configuration, where cases (*a*) and (*b*) appear in the two different output ports of the interferometer. A Sagnac configuration (*d*) works in a similar way, at the added advantage that no stabilization of the bias phase is required.

the bias phase and the nonlinear phase are properly set, low intensities will be back-reflected into the input port whereas high intensities go into the opposite port. Sending pulses in such a nonlinear Michelson interferometer, only the central and most intense part of the pulse will go into the output port. The weaker parts of the pulse will be redirected into the input port, effectively leading to a compression of the input pulse. A Michelson interferometer is not the ideal configuration for such a nonlinear switch, because it will require active means to stabilize the bias phase of the interferometer. Mach–Zehnder interferometers can be built in a micro-optical configuration, dramatically reducing problems of phase drift [57]. A *Sagnac* configuration, as has first been suggested by Blow and Doran [63], is typically the method of choice. In the *nonlinear optical loop mirror* (NOLM) the two interferometer arms consist of different direction of propagation in a fibre loop (see figure A2.3.8). An imbalance of the Kerr effect between the two directions of propagation is simply induced by asymmetric beam splitting. Otherwise the function is identical to the previously discussed case. The high-intensity portion of the pulse is switched into one port of the interferometer, the pedestal goes into the other port, effectively leading to pulse compression. Such Sagnac interferometers have been used for pulse shape cleaning and also to induce mode-locking.

As the impression may arise that the exact type of interferometer does not matter for the principle of operation, it needs to be pointed out that the interferometer types discussed so far only exploit dual-beam interference. Using a Fabry–Perot interferometer instead, interference of many pulses may create complex behaviour. A nonlinear Fabry–Perot switch has been extensively discussed as an all-optical switch as it exhibits bistability and hysteresis, a behaviour analogous to what a *Schmitt trigger* does in electronics. Using nonlinear systems with large feedback is interesting for applications as it allows us to switch large light powers with relatively small ones. However, this method has not found very widespread use because of several disadvantages. The nonlinear Fabry–Perot has extremely rich nonlinear dynamics, including *period-doubling* and *chaotic behaviour* [64, 65]. Generally, this type of behaviour becomes more pronounced the stronger the feedback inside the system is. Another disadvantage of all nonlinear interferometers is the delay of the interferometer arms. In the case of two-pulse interference the actual switching action happens after single propagation through the interferometer. In the case of the nonlinear Fabry–Perot, the switching time amounts to many roundtrips through the interferometer. However, despite these problems, nonlinear Fabry–Perot interferometers have been successfully incorporated into lasers to initiate and sustain mode-locking [66–69]. Compared to saturable-absorber mode-locking or Kerr-lens mode-locking, these lasers require a stabilization of the interferometer phase.

A2.3.5.6 Applications of nonlinear optical switches

One important application of a nonlinear optical switch has already been addressed in the previous section—mode-locking. For generation of short pulses the nonlinear optical switch is inserted into the laser cavity. Its main purpose is the *suppression of low light levels* and a preference for high light levels. Such a preferred transmission of high peak powers leads to a temporal focusing of the entire energy contents of the cavity into one short pulse. Continuous operation of the cavity is discouraged by the higher losses induced by the nonlinear switch. As the switch reduces the power in the pulse's pedestals compared to its peak power, one may also think of the switch *recompressing the pulse* every round-trip [68]. The nonlinear switch initializes the mode-locking process from noise and stabilizes it in the steady-state regime. Additional processes such as dispersion and spectral broadening contribute during the steady-state operation and determine the pulse duration of the mode-locked laser.

A second application of a nonlinear switch is *pulse characterization*. One can use the geometry of the Kerr gate, e.g. to sample one unknown pulse with the aid of another one, simply by varying the delay between pump and probe in the Kerr gate. This is known as *cross-correlation*. Moreover, one can also try to sample one pulse by itself, i.e. perform an *autocorrelation*. Pulse retrieval from autocorrelation is ambiguous and impossible without further knowledge on the pulse shape. Advanced methods to measure and characterize pulse shapes are discussed in chapter B7.

Telecommunication also strongly relies on optical switches. For many applications, electro-optic switches are still fast enough for data processing. However, there is a strong tendency to substitute electro-optical methods by all-optical variants, in particular when approaching data rates in the tens of Gbit s^{-1}. One potential application lies in the area of *time-domain multiplexing and demultiplexing* of optical data streams. One can use fibre-based switches similar to those previously discussed to selectively extract, e.g. every fourth or sixteenth pulse from a stream of pulses. The extracted pulse train then has a much smaller data rate than the original one and can be processed with slower electro-optic components. An optical switch based on a polarization discriminating Mach–Zehnder interferometer has been demonstrated with up to 1500 GB s^{-1} data rates and 200-fs pulse duration [70]. Many different switch architectures have been proposed for demultiplexing applications [42, 71–75]. Another application of all-optical switches is optical memories. It has been demonstrated that pulse sequences can be *stored* inside fibre ring resonators. A pulse sequence is launched into the ring and later extracted by an optical switch [76, 77]. For launching or extracting an entire sequence at once, no particular fast switch is needed. With an all-optical switch, however, individual pulses can be launched or extracted from the optical ring buffer, which greatly enhances the utility of such optical memories.

A2.3.6 Summary

Optical nonlinearities are important building blocks in optoelectronic devices, which have a variety of different applications as optical switches. Two fundamentally different basic concepts have evolved. One of them is the *saturable absorber*, which is based on saturation of an electronic transition. Given the very strong interaction of quantum wells and light, extremely compact all-optical switches can be built using modern semiconductor manufacturing technology. These devices have found widespread application for mode locking of lasers. Their only limitation is the limited switching speed, which cannot easily be pushed below 1 ps. A second concept employs *quasi-instantaneous nonlinearities*, namely the *Kerr effect*, to overcome speed limitations of the device. As this nonlinearity is a phase-nonlinearity, some means of phase to amplitude conversion has to be incorporated into the device to make it an effective saturable absorber with practically unlimited switching speed. This translation can be accomplished either by an interferometer, by polarization switching, or by using the Kerr lens mechanism. As the Kerr effect is a third-order nonlinearity, it is typically much weaker than saturable absorption of a quantum well. Often, sufficient nonlinearity can only be accumulated by propagation through a long piece of fibre. Therefore, many concepts for using the Kerr nonlinearity as a switch involve relatively long delays compared to the more directly switching semiconductor-based saturable absorbers. It strongly depends on the application, which of the two fundamental concepts is to be preferred.

B1.1
Visible light-emitting diodes

Klaus Streubel

B1.1.1 Introduction

Light-emitting semiconductor diodes (LEDs) are light sources that were developed in the last few decades. For most of this time, they have been used as small indicator lights in a wide range of consumer applications. Some 10 years ago, two new material systems, AlGaInP and InGaN, entered the LED arena and gave birth to a new generation of light-emitting diodes: the high-brightness LEDs. This was an important breakthrough for the entire LED business, which enhanced the prospects of LED use in a much wider range of applications. Now, with InGaN covering the emission range from blue to green and AlGaInP from yellow to red, the entire visible spectrum has become accessible to LED light (figure B1.1.1). Furthermore, the continuously improving material quality, together with better chip and package designs, have led to much enhanced performances in terms of efficiency and total output power. Today, at certain wavelengths, LEDs achieve more than 50% energy efficiency in the laboratory and ones with more than 20% efficiency are commercially available. The internal conversion of electrical power into light is sometimes close to 100% and the only task left is to extract as much light as possible out of the semiconductor material without it being lost internally. It can be projected that the good performance at certain colours will eventually be extended to the entire spectrum and the efficiency of commercial LEDs is expected to exceed 50%. Another attractive feature of LEDs is their very long lifetime, of at least some ten thousand hours or several years of continuous operation. Finally, the availability of highly efficient LEDs covering the range from violet to red has now allowed the generation of white light and enabled the LED to enter the wide field of illumination and lighting.

This chapter will give a brief overview of the field of visible light-emitting diodes. The history of the development of visible diodes will be summarized, starting with the early GaAsP and GaP-based devices and continuing up to the development of high-brightness AlGaInP and InGaN LEDs. Next, some basic aspects of the physics of LEDs will be described, with emphasis on their optical and electrical properties. The major semiconductor material systems used for visible LEDs and their fundamental properties are then introduced. Technologies for enhanced light extraction, such as wafer bonding on transparent substrates (TSs), wafer-soldering for substrate-less devices or resonant-cavity and photonic-bandgap designs are discussed next, followed by a description of the most common ways of generating white LED light. Finally, the standard packages for LEDs and some of the most important applications of high-brightness LEDs will be presented. The appendix A includes an introduction into the standard Commission Internationale de L'Eclairage (CIE) colour system, a description of the human eye sensitivity curves and an overview of the most important radiometric and photometric units that are frequently used to describe the properties of LEDs.

At this point, it might be helpful to define some conventions for the following chapter. The most important parameters to characterize an LED are the efficiency and the output power. If not specified

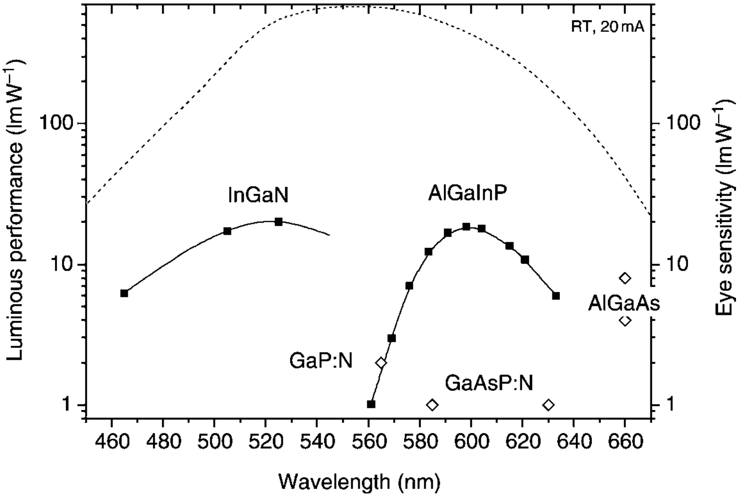

Figure B1.1.1. Luminous performance of commercial high-brightness InGaN and AlGaInP LEDs, compared with a few conventional GaP and GaAsP-based devices. The dotted line shows the human eye sensitivity.

otherwise, efficiency measures the conversion of electrical to optical power and is usually expressed in per cent. For many applications, however, it is more relevant to measure the power of light as perceived by the human eye. In this case, it is convenient to use photometric units such as lumen and candela. The lumen is a measure of the total light power, weighed according to the human eye sensitivity. Efficiency is then expressed in lumens per (electrical)watt. Candelas are a measure of brightness emitted into a certain direction per unit of solid angle and is expressed in lumens per steradian. In the following, the performance of LEDs will be expressed in lumens and lumens per watt (lm W^{-1}) with a few exceptions where mW and per cents are used. Another parameter is the colour of the LED emission. If nothing else is specified, the emission wavelength normally means the peak wavelength of the optical spectrum, which has to be distinguished from the dominant apparent wavelength when the human eye perception is taken into account (see appendix A).

B1.1.1.1 Historical review

In the very beginning of the last century in 1907, H.J. Round discovered a 'curious phenomenon' when he applied a large voltage, of more than 100 V, to a SiC crystal: electroluminescence—the conversion from electrical current to light [1]. Many years later, in the early sixties, electroluminescence was studied extensively on III–V semiconductor alloys such as GaAs or GaAsP. In 1962, the first visible red emitting LEDs were made of GaAsP with a P-fraction of 40%. The devices were fabricated by vapour phase epitaxy on GaAs-substrates, with a pn-junction formed by selective Zn-diffusion into a thick n-type layer. For low P-fractions, GaAsP has a direct energy gap (see section B1.1.3.1) and is almost lattice matched to GaAs. As the P-content is increased, in order to achieve shorter wavelengths, the lattice mismatch and thus the defect density in the material increases appreciably, leading to rather low efficiencies. In 1968, the first commercial red GaAsP LEDs, with luminous efficiencies around 0.2 lm W^{-1}, were introduced to the marketplace by Hewlett Packard. Shortly thereafter, more efficient devices based on GaP doped with Zn and O, were developed using liquid phase epitaxy (LPE) on GaP wafers. GaP:Zn–O LEDs emit at 700 nm, where the human eye sensitivity is down to 0.4% of its maximum value, resulting in luminous efficiencies around $0.4\,\mathrm{lm\,W^{-1}}$. A breakthrough for the early LEDs was the discovery that isoelectronic impurities, such as nitrogen, can act as efficient radiative recombination centres in GaP and GaAsP. GaAsP:N and GaP:N based LEDs already showed efficiencies around $1\,\mathrm{lm\,W^{-1}}$, about one order of magnitude more than the first GaAsP diodes.

In the early 1970s, AlGaAs/GaAs single heterojunction diodes were developed, also using LPE as the method of crystal growth. Starting with emission in the infrared spectral range, the emission wavelength was continuously reduced by increasing the Al-fraction, until red 660 nm emitting diodes were achieved in 1980. The next advance was the introduction of double heterostructures (DHs) for more efficient confinement of the electrical carriers in the active region of the device. The first commercial AlGaAs DH LED with an efficiency around $4\,\mathrm{lm\,W^{-1}}$ was introduced in 1985.

Although more efficient as a result of a better carrier confinement and direct band transitions, AlGaAs/GaAs LEDs had one obvious disadvantage compared to the early GaP-based diodes: unlike GaP, GaAs is not transparent to visible light. The introduction of LPE grown, transparent AlGaAs substrates solved this problem and enhanced the efficiency by almost a factor of two. The first TS LEDs were introduced in 1987 as ‘super-high-brightness devices’ with efficiencies around $8\,\mathrm{lm\,W^{-1}}$.

Because the AlGaAs bandstructure becomes indirect at high Al-fractions, it was not possible to fabricate AlGaAs LEDs emitting at wavelengths shorter than 660 nm. Therefore, a new material system, AlGaInP lattice matched to GaAs, was investigated intensively. Epitaxial growth was only possible using the new method of metal-organic vapour phase epitaxy (MOVPE). The quaternary composition of AlGaInP offered an additional advantage: the bandgap could be tuned from yellow-green to red while maintaining the same lattice constant thus allowing lattice matching on GaAs. With the new material, efficiencies in the order of $10\,\mathrm{lm\,W^{-1}}$ were achieved. As previously with the AlGaAs/GaAs LEDs, the efficiency of AlGaInP/GaAs devices was limited by absorption in the GaAs substrate. A TS AlGaInP LED was therefore developed by Hewlett Packard, using the novel technology of direct wafer bonding. After the growth of the AlGaInP layers on GaAs, the original GaAs substrate was removed and the thin AlGaInP film was transferred (‘wafer-bonded’) to a transparent GaP wafer. As before in the case of TS-AlGaAs LEDs, the efficiency of TS-AlGaInP LEDs was doubled compared to absorbing substrate (AS) LEDs and efficiencies of more than $20\,\mathrm{lm\,W^{-1}}$ were demonstrated on red devices. Another successful method for high efficiency developed at that time was the introduction of thick, transparent window layers giving better current spreading and improved light extraction. In commercial AlGaInP-LEDs, both AlGaAs and GaP windows were employed.

The performance of TS-AlGaInP LEDs was further improved by optimizing the size and optical properties of the chips, yielding efficiencies of more than $70\,\mathrm{lm\,W^{-1}}$ for red emission. Recently, this already impressive performance was further enhanced by shaping the TS-die into truncated inverted pyramids. Record high efficiencies of $>100\,\mathrm{lm\,W^{-1}}$ (610 nm) or >50% (630 nm) were achieved with this technology. Alternatively, Osram-OS started to solder the AlGaInP epitaxial structure onto a new carrier and to remove the original GaAs substrate. The advantage of the wafer-soldering process is its suitability for mass production and its potential to achieve high yields on large diameter wafers. The best ‘substrate-less’ AlGaInP LEDs achieve $>60\,\mathrm{lm\,W^{-1}}$ (615 nm) or up to 40% efficiency (630 nm) with the potential for further improvements.

The early blue emitting LEDs were made of SiC with efficiencies of only $0.1\text{–}0.2\,\mathrm{lm\,W^{-1}}$. In parallel, researchers started to investigate the electroluminescence of GaN-based devices in 1970 [2]. Green and ‘violet’ emitting devices were fabricated but the devices were very inefficient, mainly due to the almost unsolvable problem of p-doping in GaN. The major breakthrough came in 1989, when a Japanese group achieved real p-conductivity by activating Mg dopants with low-energy electron-beam irradiation. Nichia Chemicals finally developed a new technique for efficient Mg-activation by high-temperature annealing and brought the first commercial blue, GaN-based LEDs to the market in 1994.

The GaN was deposited by MOVPE on sapphire substrates. The bandgap of nitride-based LEDs can be tailored over a wide range, from 362 nm (3.4 eV) to 615 nm (2 eV), by adding additional In to the InGaN alloy. This allowed the fabrication of green LEDs and the first blue-green (500 nm) and green (520 nm) devices were also produced by Nichia, for application in traffic lights. As an alternative to the growth on sapphire, which is electrically insulating, InGaN can also be grown epitaxially on SiC wafers. This technology was developed by Cree Research and resulted in the 'superbright' GaN/SiC LED chip introduced in 1995.

With efficient blue and green LEDs at hand to complement the high-brightness red emitters, it became possible to fabricate white LEDs. Several companies developed white LEDs, using a combination of blue, green and red emitting dies in a single package. An alternative approach to generate white light was developed independently in Japan and Germany: the conversion of blue LED light into white using a phosphor wavelength converter. Osram-OS (formerly part of Siemens) developed a phosphor based on $Y_3Al_5O_{12}$ garnet, doped with cerium ions, that absorbed part of the blue emission of a GaN-LED and produced yellow luminescence. The combination of blue and yellow emission produces white light. The phosphor is either suspended in the epoxy resin used for encapsulation or is directly coated on the chip surface. Commercial white LEDs were introduced to the marketplace in 1998 by Osram-OS and Nichia.

B1.1.2 Physics of LEDs

The basic function of an LED is to generate light following the injection of an electrical current into the semiconductor material. The conversion of electrical carriers (electrons) into light (photons) is called electroluminescence and involves two important processes: the excitation of electrons into higher energy states and the relaxation of excited electrons back to empty lower states. If the relaxing electrons release most or all of the energy difference in form of electromagnetic radiation, the process is called a radiative transition. In the case of non-radiative transitions, the energy difference in such a relaxation process is released in form of heat (phonons). The band structure of the semiconductor material plays an important role for the transition processes of excited electrons. In semiconductors with a direct band structure (figure B1.1.2), the excited electrons in the conduction band can relax into states in the valence band under momentum conservation. In materials with an indirect band structure, the transition process requires the assistance of a phonon in order to conserve momentum. Indirect band transitions are therefore much less probable.

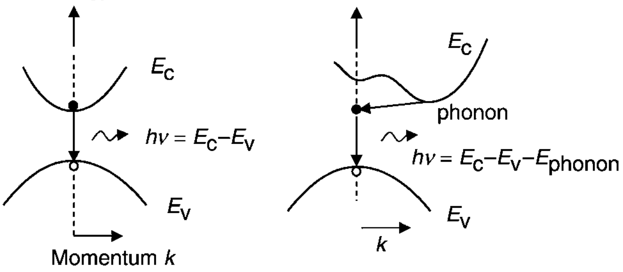

Figure B1.1.2. Left: radiative band–band transitions in a direct bandgap material; right: radiative transition in an indirect bandgap material.

B1.1.2.1 Optical properties of LEDs

Radiative recombination

Figure B1.1.3 shows a number of possible radiative and non-radiative transitions in a simplified band diagram. The direct band–band transition is shown in figure B1.1.3*a*. Because two particles, electrons n and holes p, are involved, this process is called bimolecular recombination. The recombination rate, R (recombinations, per unit volume, per second), is proportional to the density of carriers in the upper state (electrons) and the density of empty lower states (holes) and is given by:

$$R = -\frac{\mathrm{d}n}{\mathrm{d}t} = -\frac{\mathrm{d}p}{\mathrm{d}t} = Bnp \tag{B1.1.1}$$

where n and p are the electron and hole concentrations. The proportionality factor B is a measure of the probability of radiative recombination and is called the bimolecular recombination coefficient. It can be calculated from a few basic material parameters such as the bandgap energy, the absorption coefficient and the refractive index [3] which are all experimentally accessible. For most III–V semiconductors, the bimolecular recombination coefficient is in the order of $1\text{–}10 \times 10^{-10}\,\mathrm{cm^3\,s^{-1}}$. At very high carrier concentrations, as for instance in laser diodes, B starts to decrease and equation (B1.1.1) has to be modified [4].

If the carrier concentrations deviate from the equilibrium, e.g. in the case of electrical or optical excitation, n and p can be written as $n = n_0 + \Delta n$ and $p = p_0 + \Delta p$, and the recombination rate can be split into two parts, an equilibrium recombination rate R_0 and an excess recombination rate ΔR:

$$R_0 + \Delta R = B(n_0 + \Delta n)(p_0 + \Delta p). \tag{B1.1.2}$$

The small term $\Delta n \Delta p$ in equation (B1.1.2) can be neglected. With $R_0 = Bn_0p_0$, the expression can be written as:

$$\frac{\Delta R}{R_0} = \frac{\Delta n}{n_0} + \frac{\Delta p}{p_0} \tag{B1.1.3}$$

with the excess recombination rate given by:

$$\Delta R = B(n_0 + p_0)\Delta n. \tag{B1.1.4}$$

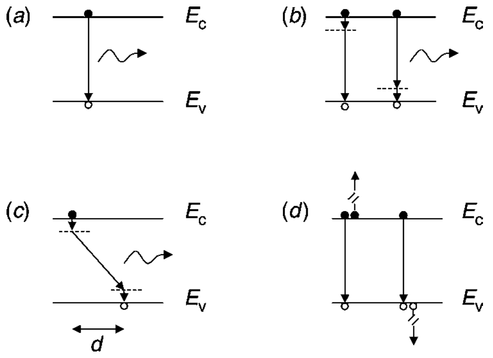

Figure B1.1.3. Recombination mechanisms in a simple band diagram: (*a*) radiative band–band transition; (*b*) band-impurity level transitions; (*c*) donor–acceptor transition; (*d*) Auger recombination process.

In the case of low excitation, with an excess carrier concentration much smaller than $(n_0 + p_0)$, the excess carriers will decay exponentially with time

$$\Delta n(t) = \Delta n_0 \exp\left(-\frac{t}{\tau}\right) \tag{B1.1.5}$$

which gives the time-dependent recombination rate as:

$$\Delta R(t) = -\frac{\mathrm{d}\Delta n(t)}{\mathrm{d}t} = \frac{\Delta n_0}{\tau}\exp\left(-\frac{t}{\tau}\right). \tag{B1.1.6}$$

Comparing equations (B1.1.4) and (B1.1.6), the decay lifetime is obtained as:

$$\tau = \frac{\Delta n}{\Delta R} = \frac{1}{B(n_0 + p_0)} = \frac{1}{R_0}\frac{n_0 p_0}{n_0 + p_0}. \tag{B1.1.7}$$

In the intrinsic case of an undoped semiconductor, with $n_0 = p_0 = n_\mathrm{i}$, equation (B1.1.7) reduces to

$$\tau = \frac{1}{2Bn_\mathrm{i}} = \frac{n_\mathrm{i}}{2R_0}. \tag{B1.1.8}$$

By inserting equation (B1.1.8) in equation (B1.1.1), the radiative recombination rate can be expressed as:

$$R = Bnp = \frac{np}{2n_\mathrm{i}\tau}. \tag{B1.1.9}$$

For n-type materials, the electron is referred to as the majority carrier and the hole as the minority carrier, since $n_0 \gg p_0$. For p-type semiconductors, the roles are reversed. For an n-type semiconductor, we have $n_0 \gg \Delta n \gg p_0$, meaning that the excess carrier concentration is much smaller than the majority carrier concentration, yet much larger than the minority carrier concentration. Because both types of carriers are required for the recombination process, the carrier lifetime that determines the radiative decay of the excess carriers, is the minority carrier lifetime. A very large fraction of majority carriers cannot find a minority carrier for recombination and thus the average majority carrier lifetime is much longer. In the case of doping, the carrier lifetimes become $\tau_\mathrm{n} = 1/(Bp_0)$ and $\tau_\mathrm{p} = 1/(Bn_0)$, for p- and n-doped semiconductors, respectively.

Intermediate states in the semiconductor bandgap may also contribute to the transition from the upper conduction band to the lower valence band, as shown in figure B1.1.3*b*. Examples are transitions from the conduction band to acceptor states or transitions from donor states to the valence band. If the impurity level is deep inside the bandgap, such transitions can be highly probable. Because the impurity has a well-defined position in the crystal lattice, its wave function extends widely in the momentum space. This permits momentum-conserving transitions to occur with reasonable probability even in indirect bandgap materials such as GaP.

Apart from band-impurity level transitions, transitions between two impurity levels are also possible (figure B1.1.3*c*). These donor–acceptor transitions can be rather effective and are very useful for light-emitting diodes. Photons generated in this process have an energy, $h\nu$, given by:

$$h\nu = E_\mathrm{c} - E_\mathrm{v} - (E_\mathrm{D} + E_\mathrm{A}) \tag{B1.1.10}$$

where E_D and E_A are the donor and acceptor binding energies. Coulomb interaction between the donor and acceptor atoms increases the energy of the excited states by an increment of $q^2/\varepsilon d$, where ε is the dielectric constant of the semiconductor host crystal and d the distance between donor and acceptor atoms. This additional energy increases inversely with the separation, d, between donors and acceptors.

Because the spatial distance between donors and acceptors in the host crystal can vary largely, the Coulomb energy increment varies accordingly, causing a wide range of possible photon energies and thus a broad emission spectrum.

Non-radiative recombination

Radiative transitions are electron–hole recombinations in which the excess energy is used to generate a photon. Non-radiative transitions are all other transitions having one feature in common, namely that no photon is generated in the transition process. In fact, in many semiconductors non-radiative carrier recombination is the dominant process. In semiconductors with indirect band structure, such as Si or Ge, the measured radiative lifetime is three orders of magnitude smaller than the calculated value, due to the much larger probability of non-radiative transitions. Experimentally, non-radiative transitions are much more difficult to characterize than radiative transitions, because no characteristic photons are generated. They can be measured only indirectly by analysing the radiative efficiency or the dynamics of the radiation process after external excitation.

The most relevant non-radiative process for optoelectronic devices is recombination via states related to crystal defects. Examples of such defects are dislocations, pores, grain boundaries, vacancies, inclusions or precipitates. Carriers within a diffusion length of the defect will usually be trapped by the defect states and recombine there. The recombination rate scales linearly with the carrier concentration:

$$R_{\mathrm{nr}} = A^{*} n \tag{B1.1.11}$$

where the proportionality factor A^{*} increases with the density of non-radiative centres.

Usually a defect deforms the bandstructure, either by trapping charges or by deforming the lattice, thereby inducing local strain. In either case, the deformation produces a potential barrier of the height, E_{act}, which has to be overcome by the carriers. Therefore, the process recombination has a thermal dependence of the form:

$$R_{\mathrm{nr}}(T) = R^{*} \exp\left(-\frac{E_{\mathrm{act}}}{kT}\right) \tag{B1.1.12}$$

where $R_{\mathrm{nr}}(T)$ is the non-radiative recombination rate and R^{*} a temperature independent coefficient. The temperature dependence of the radiative transition can be neglected. Therefore, as the temperature is reduced, the non-radiative recombination rate decreases exponentially and the radiative processes become more dominant. The temperature dependence of the radiative recombinations over the total number of recombinations is then:

$$\eta_{\mathrm{qi}}(T) = \frac{R_{\mathrm{r}}}{R_{\mathrm{r}} + R_{\mathrm{nr}}} = \frac{1}{1 + \mathrm{z}\dfrac{R^{*}}{R_{\mathrm{r}}} \exp\left(-\dfrac{E_{\mathrm{act}}}{kT}\right)} \tag{B1.1.13}$$

where the ratio R^{*}/R_{r} is constant. The quantity $\eta_{\mathrm{qi}}(T)$ is the internal quantum efficiency.

So far, we have been looking at non-radiative processes inside the semiconductor material. Additionally, minority carriers reaching the surface of the LED are lost due to surface recombination [5]. At the semiconductor surface, the periodic arrangement of atoms, which is the basis for the band structure model, no longer exists. Thus, the surface is a perturbation of the crystal lattice with a strong impact on the band diagram. Due to the lack of neighbours, surface atoms have dangling bonds, partly filled electron orbitals, which can be described as deep or shallow energy levels in the bandgap which may act as recombination centres. The recombination of carriers via surface states is dependent on the semiconductor material and is phenomenologically described by a parameter called the surface recombination velocity, S. It is particularly high in GaAs ($S = 10^6\,\mathrm{cm\,s^{-1}}$) compared to InP ($S = 10^3\,\mathrm{cm\,s^{-1}}$) or Si ($S = 10^1\,\mathrm{cm\,s^{-1}}$). In Al-containing alloys such as AlGaInP, the surface recombination scales appreciably with the Al-fraction [6]. S increases from $10^5\,\mathrm{cm\,s^{-1}}$ for $(\mathrm{Al_{0.1}Ga_{0.9}})_{0.5}\mathrm{In_{0.5}P}$ to $10^6\,\mathrm{cm\,s^{-1}}$ for AlInP.

When designing LEDs, it is very important to consider surface recombination. Carrier injection into the active region of the device should take place several diffusion lengths away from any surface. Recombination at the top-surface of the LED is usually prevented by a high-bandgap confinement layer above the active region and a thick current-spreading or window layer. In some LEDs, light extraction shapes are etched deeply into these top layers. Theoretically, very high extraction efficiencies should be achievable if such shapes would penetrate the pn-junction, but then a substantial number of carriers could recombine at the surface states. However, as long as the active region remains planar, surface recombination can be neglected due to the lack of minority carriers above the confinement layers. In LEDs with a planar surface, carrier diffusion to the lateral edges is reduced by placing the top electrode in the centre of the die.

Instead of generating a photon, the energy released during carrier recombination can also be transferred to other carriers (electrons or holes) and then be dissipated as phonons. This non-radiative process is called Auger recombination. Two examples for Auger processes are shown in figure B1.1.3*d*, but many other processes are possible, depending on the nature and occupation of the involved electronic states. Since two carriers of one type and one carrier of the opposite type are required for the Auger process, the recombination rate is proportional to either np^2 or pn^2. The proportionality factor C is called the Auger coefficient and has typical values for III–V materials of 10^{-28}–$10^{-29}\,\mathrm{cm^6\,s^{-1}}$. It is described as

$$R_{\mathrm{Auger}} = C_{\mathrm{p}}np^2 + C_{\mathrm{n}}pn^2 \tag{B1.1.14}$$

or, in the intrinsic case:

$$R_{\mathrm{Auger}} = Cn_{\mathrm{i}}^3. \tag{B1.1.15}$$

The Auger recombination thereby scales as the cube of the carrier concentration. For LEDs where typical carrier densities are low compared to lasers, the Auger recombination plays a minor role in the device efficiency. However, the Auger effect becomes more prominent in materials with small bandgap energies such as infrared emitting devices.

Emission wavelength

The centre emission wavelength of an LED is mainly given by the bandgap energy $\lambda = hc/E_{\mathrm{g}}$. The full width at half maximum (FWHM) of the emission is approximately $\Delta E \approx 2kT$ [7]. Thus, at a given temperature, $\Delta\lambda/\lambda$ scales with $2kT/E_{\mathrm{g}}$ or $\Delta\lambda$ increases with λ^2. The linewidth can be increased by using high doping levels or having graded compositions in the active region of the LED. The emission linewidth is an important parameter for near-infrared LEDs for optical fibre transmission systems due to the dispersive nature of the fibre.

Light that is extracted through the top surface has to penetrate through only transparent material before reaching the semiconductor–air or –epoxy interface. A significant fraction of light is guided along the active layers and extracted at the die sidewalls. Along this path, the emission wavelength is changed by absorption, which affects mostly the short-wavelength part of the spectrum. This effect is shown in figure B1.1.4 for an AlGaInP LED. Here, the emission spectrum measured at the top-side (0°) differs substantially from the side emission (90°). While the effect is typical for all LEDs that employ band–band transitions, it is not present in LEDs which are based on impurity level transitions, such as

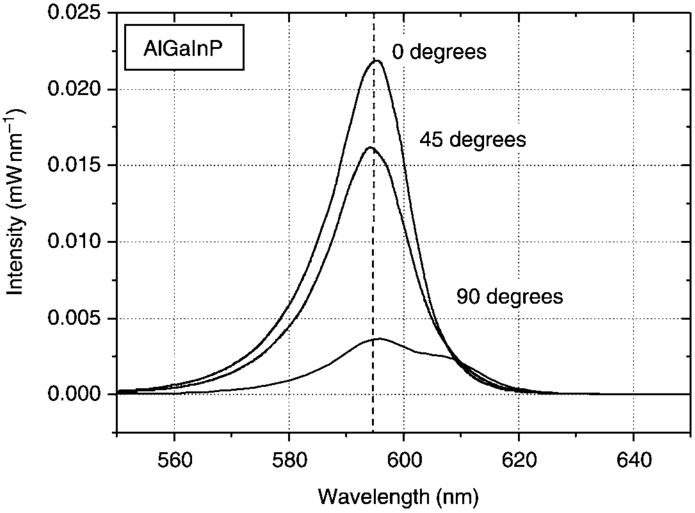

Figure B1.1.4. Spectrum of an AlGaInP LED for different directions of emission. 0° = normal surface emission, 90° = side emission.

used in GaP-based devices. Figure B1.1.14 shows the emission spectra of a GaP:Zn,O LED which is essentially independent of the emission direction.

Light extraction

Although light can be efficiently generated inside an LED ($\eta_{qi} > 90\%$) only a few per cent of the generated photons can actually escape from the semiconductor material. Due to the large difference in the refractive index between the semiconductor ($n = 3-3.5$) and the surrounding medium ($n = 1-1.5$), the interface acts as a perfect mirror for most of the generated photons and prevents them from leaving the diode. The major contribution to the high reflectivity is total internal reflection which occurs at all angles larger than the critical angle ϑ_c. According to Snell's law, this angle is

$$\vartheta_c = \arcsin\left(\frac{n_m}{n_s}\right) \tag{B1.1.16}$$

where n_s and n_m are the refractive indices of the semiconductor and the surrounding medium. All angles are measured to the direction normal to the interface. Only rays of light with $\vartheta < \vartheta_c$ can escape from the diode. In 3D-space this range of angles forms a cone, which is frequently called the 'escape cone'. If the semiconductor chip (e.g. GaAs, $n = 3.5$) is surrounded by air ($n = 1$), the critical angle ϑ_c is 17°, in the case of epoxy encapsulation with a refractive index of $n = 1.5$, ϑ_c becomes 26°. The fraction of escaping photons to the total number of generated photons is then given by

$$\eta_{ext} = \frac{2\pi(1 - \cos\vartheta_c)}{4\pi} = \frac{1}{2}(1 - \cos\vartheta_c) \tag{B1.1.17}$$

which is the ratio of the surface subtended by the spherical escape cone divided by the surface of the full sphere. Even for light that is incident perfectly normal to the chip surface some of the photons are reflected by Fresnel reflection:

$$R_{\mathrm{Fresnel}} = \frac{(n_{\mathrm{m}} - n_{\mathrm{s}})^2}{(n_{\mathrm{m}} + n_{\mathrm{s}})^2}. \tag{B1.1.18}$$

This relation describes the reflection at normal incidence. The correct angular dependence is described by the so-called Fresnel formulae which were first derived by Fresnel in 1823 [8]. For reasons of simplicity we approximate the Fresnel reflection within the light extraction cone by equation (B1.1.18). Then the total extraction efficiency is

$$\eta_{\mathrm{extr}} = \frac{1}{2}(1 - \cos\vartheta_{\mathrm{c}})\left(1 - \frac{(n_{\mathrm{m}} - n_{\mathrm{s}})^2}{(n_{\mathrm{m}} + n_{\mathrm{s}})^2}\right). \tag{B1.1.19}$$

For a GaAs-based LED the fraction of light that escapes the material is as low as ≈ 2% or ≈ 4% for air or epoxy as surrounding medium, respectively. Internal reflection is therefore a major obstacle for the fabrication of high efficiency AlGaInP/GaAs or AlGaAs/GaAs-based LEDs.

The typical destiny of a totally reflected photon is to be reflected a couple of times before finally being absorbed either in the active region or someplace else in the LED structure. Even without the presence of absorption, the angles of reflection in a typically cube-shaped LED die will continue to reproduce themselves, without ever falling inside an escape cone (figure B1.1.5). A straightforward remedy for LEDs on TSs is to give the entire die a geometrical shape which is more suitable for light extraction. The ideal solution would be a spherical or hemispherical chip with small active area in the

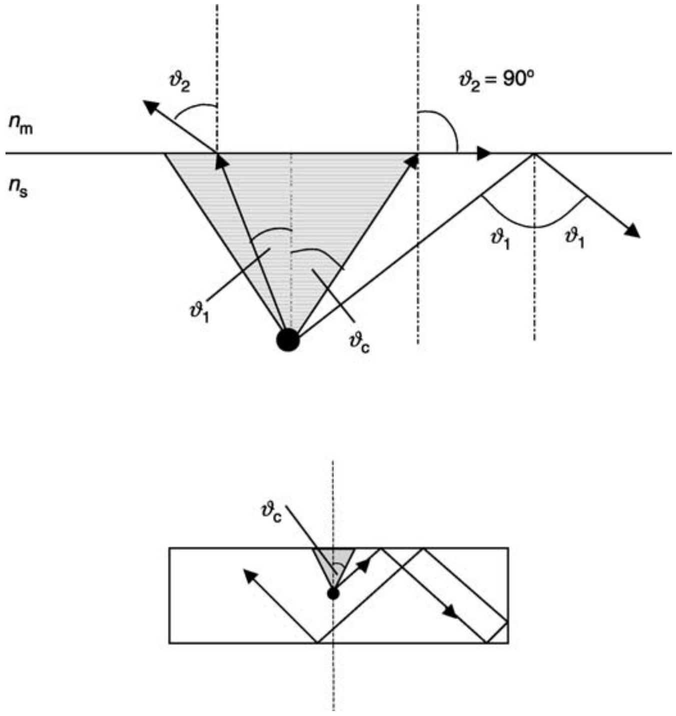

Figure B1.1.5. Top: Total internal reflection and 'escape cone' at the semiconductor–air interface. Bottom: Reproduction of reflection angles in a cubically shaped LED die.

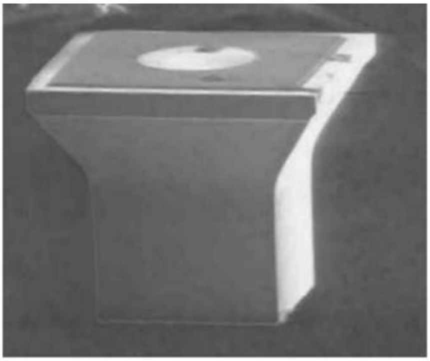
centre. Other geometries are LEDs with hemispherically shaped top side, inverted cones, truncated spheres or truncated cones. Already, in the early sixties, die shaping for high efficiency LEDs was extensively investigated [9, 10]. At that time, the technology of more or less individually shaped dies turned out to be not practical, mostly because of the associated high costs. However, more than 30 years later, high brightness LEDs with geometrically shaped dies have now entered the market: the truncated inverted pyramid AlGaInP LED (see section B1.1.4) and the InGaN/SiC 'Aton' LED, offered by Lumileds and Osram-OS, respectively. A photograph of the Aton-chip is shown in figure B1.1.6. Light is generated in the GaN-based structure on the SiC-substrate. Because the refractive index of SiC is larger than the index of GaN, light rays which enter the SiC material can only cover an angular range of 0–68°, according to Snell's law. Since most of this light would be totally reflected at the SiC–air interface in a cube-shaped die, the side facets are inclined by 30°. This increases the angular range of extracted light rays appreciably and results in an almost doubled brightness compared to the standard rectangular die [11].

From a fabrication point of view, planar LED structures with the shape of a rectangular parallelepiped are favourable. One way to increase the efficiency of planar LEDs is to increase the thickness of the transparent layers above the active layer, until the escape cones parallel to the active layer are fully utilized. This is schematically shown in figure B1.1.7. If the window layer thickness *d* is



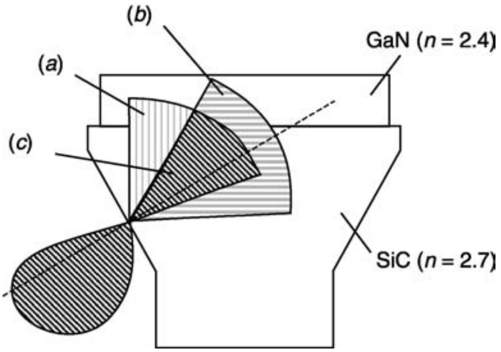


Figure B1.1.6. Above: InGaN 'Aton' chip with inclined facets. Below: Principle of light extraction in the 'Aton'-die: (*a*) range of angles coupled from GaN into SiC, (*b*) range of angles that can transmit the SiC–air interface, (*c*) fraction of light in SiC that can be extracted.

big enough, light generated in the centre and emitted into the side escape cone can escape if:

$$d_{\text{window}} = \frac{w}{2} \tan \vartheta_{\text{c}} \tag{B1.1.20}$$

where w is the lateral size of the die. For an encapsulated GaP LED with $n_{\text{s}} = 3.4$ and $n_{\text{m}} = 1.5$, the critical angle ϑ_{c} is 26°. If the chip width is $w = 300$ μm, the optimum window layer would be $d_{\text{window}} = 74$ μm. If the substrate is transparent, it is theoretically possible to extract the escape cones from all six sides of the cube, which would give 24% extraction efficiency for an encapsulated LED. In case of an AS, the bottom cone and the bottom half of the four side cones are lost, leaving an extraction efficiency of 12%, if the window layer complies with equation (B1.1.20). This is of course only a very crude model to estimate the effect of transparent windows and substrates because important effects like multiple pass reflection, absorption and re-emission are neglected. Real LEDs with TS and thick window layer can achieve up to 32% external efficiency [12] exceeding even the theoretical value of 24% using the simplified model.

Bragg mirror—About half of the emission of an LED is directed towards the substrate. If the substrate is not transparent, this light is basically lost by absorption resulting in a substantial reduction in extraction efficiency. This loss can be partly reduced by the introduction of a Bragg mirror between the active layer and the AS. A Bragg mirror consists of a stack of layer pairs with different refractive indices, where each layer has the thickness of a quarter optical wavelength. In such a stratified layer structure, each interface provides a certain reflectivity, depending on the contrast in refractive index. The Fresnel reflectivity at each interface is given by:

$$R_{\text{Fresnel}} = \frac{(n_{\text{low}} - n_{\text{high}})^2}{(n_{\text{low}} + n_{\text{high}})^2}. \tag{B1.1.21}$$

Here, n_{low} and n_{high} are the refractive indices of the layer with higher and lower index, respectively. Because all layers have the thickness of a quarter wavelength, all reflections in that direction add in phase so that the total reflection for perpendicular incidence can be very high. If the number of layer pairs is m, the mirror reflectivity is:

$$R_{\mathrm{DBR}} = \left[\frac{1 - \left(\frac{n_{\mathrm{low}}}{n_{\mathrm{high}}} \right)^{2m}}{1 + \left(\frac{n_{\mathrm{low}}}{n_{\mathrm{high}}} \right)^{2m}} \right]^2 . \qquad \text{(B1.1.22)}$$

This shows that a high mirror reflectivity can be achieved even for low index contrast materials, if the number of layer-pairs m is high enough. However, besides the practical drawback of growing large number of layer pairs, a low index contrast also results in a very narrow reflection bandwidth both in terms of wavelength and angular range. Therefore, Bragg mirrors are only of practical use if the material system offers a ratio $n_{\mathrm{high}}/n_{\mathrm{low}}$ sufficiently larger than 1.

In an LED, the Bragg mirror should be tuned to a maximum power reflectivity integrated over a range of angles within the escape cone. Note, that this situation is typically not achieved with a Bragg mirror optimized for perpendicular incidence. By shifting the centre reflectivity of a DBR towards longer wavelength, the reflectivity for off-axis light rays is enhanced and, since the solid angle with a given angular increment in these directions is much larger, a significantly higher integral reflectivity is obtained. If we take a 630 nm AlGaInP-LED, with a 20 period $Al_{0.5}Ga_{0.5}As/AlAs$ DBR, the integral reflectivity for a centre wavelength at 630 nm is in the order of 50%, whereas it is close to 75% if the mirror is tuned to 670 nm.

Surface structuring—Another approach to enhance the extraction efficiency of LEDs on ASs is to texture the surface [13]. Figure B1.1.8 shows a schematic drawing of a commercial surface-structured high-brightness AlGaInP-LED. The light extraction structure is etched into the window layers above the pn-junction. The basic idea is to inject the electrical current only along the edges of the die so that most of the light is generated close to the edge. The surface structure is then optimized for the extraction of light generated below the electrical contacts. An additional benefit of this approach is that the light is generated far away from the bond pad, which would otherwise shadow a substantial fraction of the emission. Other approaches for high extraction efficiency are discussed in section B1.1.4.

Radiation patterns

If external factors such as reflection, absorption or re-emission are excluded, the spontaneously generated photons in an electronic transition are emitted isotropically into all directions. The radiant

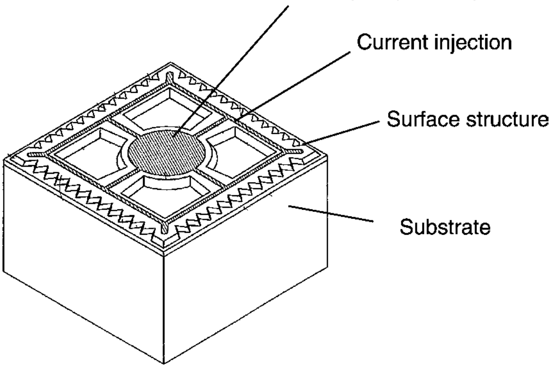

Figure B1.1.8. Sketch of a surface structured LED, with an etched light-extraction structure along the contacts at the chip edges.

intensity I_e of an LED is the divergence of optical power at a defined angular direction. In the case of ideal isotropic emission, the radiant intensity I_e would have the same value of $I_e = P_{out}/\Omega = P/4\pi$ in all directions. The solid angle Ω of a full sphere has the value $\Omega = 4\pi$. In the non-isotropic case, I_e is defined as the integral of $dP_{out}/d\Omega$ over all angles. Ideal isotropic radiation can only be achieved with point light sources and without the presence of internal reflection. In a real semiconductor diode, however, light is generated in an active region with the lateral extension of the die and is extracted through the semiconductor–air interface. In this case, the radiant intensity can be described by a cosine dependence:

$$I_e(\vartheta) \approx I_0 \cos(\vartheta). \tag{B1.1.23}$$

This is the Lambertian cosine law of radiation which applies to most planar LEDs. LEDs with TSs such as GaP- and AlGaAs/AlGaAs-LEDs or wafer-bonded AlGaInP/GaP devices, have enhanced side emission. Some novel types of LEDs show totally different emission patterns. Examples are LEDs with shaped dies such as the truncated inverted pyramid LED [14] or the 'Aton LED' [15]. Other examples are resonant-cavity LEDs, where the radiation pattern is given by the built-in optical resonator [16] (figure B1.1.9). Besides the properties of the LED die, the radiation characteristics of encapsulated LEDs is strongly influenced by the used package.

B1.1.2.2 Electrical properties

Electroluminescence

In a semiconductor diode, an electrical current composed of a flow of electrons and holes, is injected into the active region. A forward bias across the pn-junction reduces the potential barriers for electrons and enables them to spill over into the p-region (figure B1.1.10). Similarly, the forward bias reduces the potential barrier which blocked the flow of holes into the n-region. The overlapping concentration of electrons and holes allows spontaneous recombination.

The most simple diode structure is a pn-homojunction LED, where the p- and n-doped regions of a semiconductor material form a pn-junction. Examples of homojunction LEDs are blue GaN-LEDs where the pn-junction is created during the eptiaxial growth of n- and p-type GaN layers. Better carrier confinement is achieved, if the pn-junction is formed by two semiconductors having different bandgaps. Single heterojunction (SH) LEDs typically involve an n-type semiconductor with a narrow bandgap and a p-type semiconductor with a wider bandgap. SH active regions were first employed for LEDs in the AlGaAs system. Even better injection efficiency of electrons and holes and improved carrier confinement can be achieved if two heterojunctions are used to form the active region. Double heterostructure active regions of LEDs use a narrow bandgap semiconductor, sandwiched between two wide bandgap materials (figure B1.1.11) [17, 18]. In semiconductor lasers, the narrow bandgap layer has a thickness of a few ten nanometres, whereas in LEDs it can be up to some micrometres thick. High-brightness AlGaInP- and InGaN-LEDs employ double heterostructure active regions.

If A_{pn} and d_{pn} are the area and thickness of the active region, the generation density of carriers is

$$G = \frac{I_a/q}{A_{pn} d_{pn}} = \frac{J_a}{q d_{pn}} \tag{B1.1.24}$$

with $J_a = I_a/A_{pn}$ as the current density. If the generation rate of carriers equals the recombination rate in the active layer of the LED, the system has reached an equilibrium:

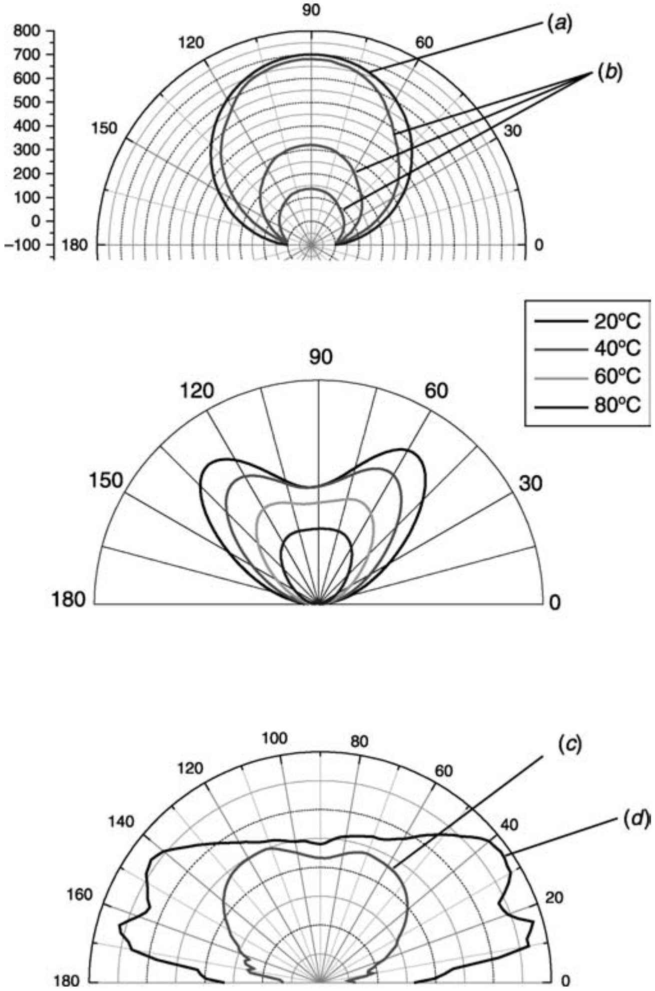

Figure B1.1.9. Emission pattern of different LED dies: top: ideal Lambertian radiator (*a*), AlGaInP LED at different current (*b*), middle: 650 nm resonant cavity LED, bottom: conventional SiC/InGaN LED (*c*) and InGaN 'Aton' die (*d*).

$$G = \frac{J_\mathrm{a}}{q d_\mathrm{pn}} = An + Bn^2 + Cn^3. \tag{B1.1.25}$$

The right-hand side of equation B1.1.25 is the total recombination rate for a given density of injected electrons n. The coefficient A in the linear term accounts for surface recombination, as well as recombination via defect levels. For typical, undoped III–V materials, A is in the order of $10^8\,\mathrm{s}^{-1}$. The quadratic term includes the bimolecular recombination coefficient B and accounts for radiative transitions. The cubic term is the Auger recombination.

According to equation (B1.1.25), the radiative recombination rate increases with the square of the carrier density, whereas the non-radiative recombination is basically a linear function of the carrier density (neglecting Auger). As the carrier concentration in the active region increases, the radiative

process starts to dominate over the non-radiative process and the internal efficiency of the device will increase. High carrier density in the active layer is usually achieved with a double heterostructure, where the active layer is sandwiched between large-bandgap barrier layers. The number of carriers that spill over the barriers is exponentially dependent on the barrier height, as well as on the temperature. Thus, to minimize this carrier leakage, the heterobarriers should be as high as possible, at least a few kT. While some alloy systems, such as AlGaAs/GaAs or InGaN/GaN, offer the possibility to realize high potential barriers, some other systems, like AlGaInP, lack large direct bandgap compositions.

The typical ternary and quaternary III–V alloys used for LEDs consist of solid solutions of binaries with direct (GaAs, InP) and indirect (GaP, AlP) bandgaps. As the fraction of indirect materials is increased, the bandstructure can change from direct to indirect. The closer the composition of an active region is to the so-called 'cross-over' point, where the indirect conduction band minimum (X) becomes lower than the direct minimum (Γ), the more carriers are leaking into the X-minimum. The Γ–X transfer of carriers is a non-radiative loss mechanism which substantially limits the internal efficiency of yellow and green emitting devices (see section B1.1.3).

Current–voltage characteristics

The current–voltage characteristic of pn-junctions is described by the Shockley equation [19, 20], which is given by:

$$I(V) = I_\mathrm{s}\left(\exp\frac{qV}{kT} - 1\right) \tag{B1.1.26}$$

where I_s is the current obtained with a reverse bias (V negative). I_s is called the saturation current and is controlled by the number of minority carriers which diffuse to the pn-junction. In this (ideal) case, the current density, I_s/A, can be calculated according to:

$$\frac{I_\mathrm{s}}{A} = \frac{qD_\mathrm{p}p_\mathrm{n0}}{(D_\mathrm{p}\tau_\mathrm{p})^{1/2}} + \frac{qD_\mathrm{n}n_\mathrm{p0}}{(D_\mathrm{p}\tau_\mathrm{n})^{1/2}} \tag{B1.1.27}$$

where A is the cross-sectional area of the diode junction, D_n and D_p are the electron and hole diffusion constants, n_p0 and p_n0 are the equilibrium electron and hole concentration on the p- and n-side, respectively. Under forward bias for $V > 3kT/q$ the current rises exponentially with V.

To describe real diodes, with a series resistance R_s, and in the presence of recombination centres in the active material, the Shockley equation has to be modified:

$$I(V) = I_\mathrm{s}\left(\exp\frac{qV - qR_\mathrm{s}I}{\alpha kT} - 1\right). \tag{B1.1.28}$$

The factor α is the so-called ideality factor. In the case of an ideal diode, α becomes 1, and, in the case of recombination only via defect states in the depletion region, α becomes 2. Since in real diodes both processes take place, the ideality factor α will take a value between 1 and 2. The series resistance R_s is typically of the order of a few ohms and can be neglected at small currents <1 mA. However, at higher currents R_s has an important influence on the $I(V)$ characteristics and on the energy efficiency.

A typical current–voltage characteristics of an AlGaInP-LED at room temperature is shown in figure B1.1.12. A linear current scale is used for the upper half of figure B1.1.12, whereas the lower part uses a logarithmic scale. At currents in the microampere region and below, non-radiative transitions dominate the recombination mechanisms and the ideality factor α is 2. For currents between approximately one microampere and one milliampere, more carriers are injected into the active region and the non-radiative transitions become saturated with carriers. At those currents, the desired radiative recombination can compete successfully with the transitions via non-radiative centres and the ideality factor α reduces to 1.3–1.5. At currents above some milliamperes, the series resistance of the LED eventually determines the slope of the current–voltage characteristics.

B1.1.2.3 Efficiencies

In an ideal LED, every injected electron generates one photon with an energy of $h\nu = E_\mathrm{g}$. In this case, the number of injected carriers I/q equals the number of generated photons and the efficiency of this process is 1. However, in reality, not all injected electrons reach the active region, not all electrons in the active

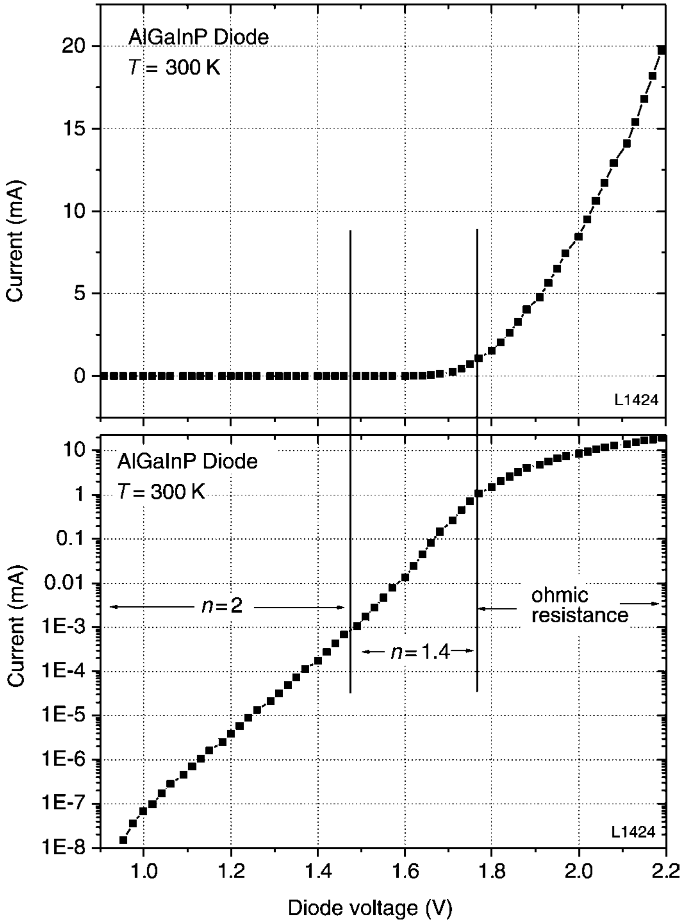

Figure B1.1.12. Current–voltage characteristics of an AlGaInP diode at room temperature on a linear (top curve) and logarithmic (bottom curve) current scale.

region can generate photons and not all photons can escape from the semiconductor. Therefore, all involved processes like carrier injection, carrier recombination or photon extraction are more or less efficient. Their efficiencies can be expressed either as quantum efficiency in terms of the number of photons and electrons involved or as power efficiency in terms of the optical or electrical power of all carriers involved.

In real LEDs, some of the electrical current is lost, e.g. due to conductive channels along the surfaces of the die or at crystal defects in the vicinity of the pn-junction. The fraction of current which is actually reaching the active region is:

$$I_a = \eta_{inj} I_0. \tag{B1.1.29}$$

The ratio $\eta_{inj} = I_a/I_0$ is called the injection efficiency.

At the pn-junction, the carriers recombine, either via radiative or non-radiative transitions. The internal quantum efficiency η_{qi} is defined as the number of generated photons per unit time over the number of electrons injected per unit time. In some cases, it is more convenient to express η_{qi} in terms of radiative and non-radiative recombination rates (equation (B1.1.13)) or the corresponding carrier lifetimes

$$\eta_{\mathrm{qi}} = \frac{R_{\mathrm{r}}}{R_{\mathrm{r}} + R_{\mathrm{nr}}} = \frac{\tau_{\mathrm{nr}}}{\tau_{\mathrm{r}} + \tau_{\mathrm{nr}}}. \tag{B1.1.30}$$

Only photons that leave the semiconductor chip are useful. Since only a small portion of photons generated in the die can be extracted, we have to define an extraction efficiency $\eta_{\mathrm{extraction}}$ as the number of extracted photons over the total number of generated photons.

The external quantum efficiency of an LED is the product of the internal quantum efficiency and the extraction efficiency:

$$\eta_{\mathrm{ext}} = \eta_{\mathrm{qit}}\eta_{\mathrm{extraction}}. \tag{B1.1.31}$$

This is the ratio of the number of photons emitted from the LED per unit time to the number of injected electrons into the LED per unit time. The number of emitted photons from the LED is obtained by dividing the measured optical energy by the photon energy $h\nu$. The number of electrons per unit time is the injected electrical current divided by the elementary electron charge q. Thus, the external quantum efficiency, η_{ext}, can be calculated according to

$$\eta_{\mathrm{ext}} = \frac{\left(\dfrac{P_{\mathrm{out}}}{h\nu}\right)}{\left(\dfrac{I_0}{q}\right)} = \frac{P_{\mathrm{out}}q}{h\nu I_0}. \tag{B1.1.32}$$

In an ideal diode, the forward voltage, V_{f}, of the device equals the bandgap energy divided by the elementary electron charge E_{g}/q. In real LEDs, however, the device structure contains additional series resistances and potential barriers which will increase the forward voltage. Therefore, we can define an external power efficiency or ‘wall-plug efficiency’ as

$$\eta_{\mathrm{wp}} = \frac{P_{\mathrm{out}}}{I_0 V_{\mathrm{f}}}. \tag{B1.1.33}$$

The ‘wall-plug’ efficiency is the most important parameter for LED applications. It can be expressed in terms of several efficiencies defined above:

$$\eta_{\mathrm{wp}} = \eta_{\mathrm{inj}}\eta_{\mathrm{qi}}\eta_{\mathrm{extraction}}\frac{h\nu}{qV_{\mathrm{f}}}. \tag{B1.1.34}$$

The different definitions are summarized in table B1.1.1.

B1.1.3 Material systems for visible LEDs

B1.1.3.1 GaP and GaAsP

The evolution of ternary III–V alloys started with the development of epitaxial growth methods like LPE or VPE. Binary alloys like GaAs or GaP were first available as bulk crystals and could be used as substrate materials. If P is added to an epitaxial layer of GaAs, the emission is shifted from the infrared to the visible spectrum (figure B1.1.13) and the lattice constant becomes larger than that of GaAs. For low P-fractions up to about 0.45 in $\mathrm{GaAs}_{1-x}\mathrm{P}_x$, the bandstructure remains direct and direct red emission is achieved [21]. However, the more P is added to the alloy, the larger the lattice mismatch to

Table B1.1.1. Summary of different definitions of internal and external efficiencies. The last expression for the extraction efficiency is valid for LEDs with a planar structure.

	Quantum efficiency	Power efficiency

I_0, total injected current; I_{a}, current flow into the pn-junction; R_{rad}, radiative recombination rate; R_{nr}, non-radiative recombination rate; τ_{r}, radiative carrier lifetime; τ_{nr}, non-radiative carrier lifetime; P_{out}, optical power emitted from the LED; V, applied voltage; ϑ_{c}, angle of total reflection; n_{s}, refractive index of the semiconductor material; n_{m}, refractive index of the surrounding medium; #, number.

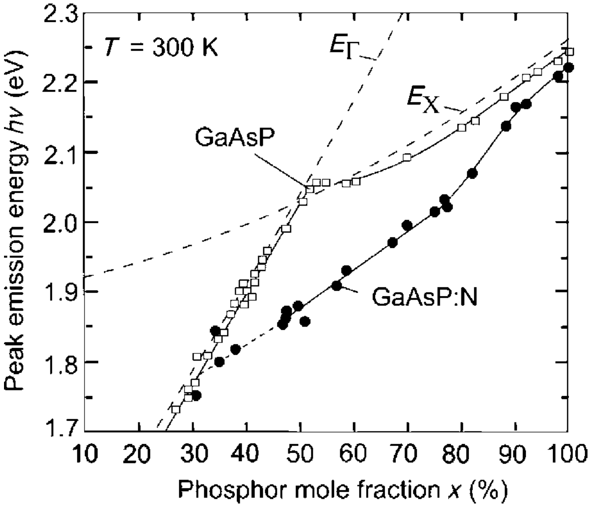

Figure B1.1.13. Emission energy versus phosphorous mole fraction of GaAsP and GaAsP:N LEDs. The solid lines are obtained from fits to experimental data at $5\,\mathrm{A\,cm^{-2}}$. The dashed lines are calculated data for the direct and indirect bandgap [21].

GaAs becomes and the more misfit dislocations are generated. The external efficiency of a GaAsP LED decreases by about a factor of 10 as the P-fraction is increased to the direct–indirect crossover point at $x = 0.45$. Fortunately, the human eye response increases in this wavelength range by more than a factor of 50 so that the product of LED efficiency and eye sensitivity reaches a maximum at $x = 0.4$ ($\approx$ 650 nm, red). The fabrication process of these LEDs is rather simple. It includes a selective Zn-diffusion step into an n-type layer to form the pn-junction and subsequent contact formation.

The emission properties are significantly changed if the material is doped with an isoelectronic impurity such as nitrogen. As a group V-element, nitrogen does not produce additional carriers as standard dopants do, but introduces a carrier trapping level approximately 100 meV below the conduction band. Trapped electrons become localized in space which causes a large spread in the allowed momentum of the electron. Matching the momentum of holes in the valence band enhances dramatically the probability for radiative recombination and thus the generation of light. The problem of lattice-mismatch-induced dislocations is, of course, still present and limits the efficiency for higher P-fractions in GaAsP [22]. On the other hand, isoelectronically doped LEDs do not suffer from re-absorption to the same extent as intrinsic devices, which is a substantial advantage for higher efficiency. Consequently, the light extracted in different directions from the die does not show the variation in the wavelength spectrum that is observed in high-brightness LEDs (figure B1.1.14).

Doping GaP simultaneously with the two group V-elements N and O also enhances the efficiency of GaP-LEDs. Introduced together in similar quantities, the two dopants tend to form complexes after proper annealing, and these function as isoelectronic traps. The Zn–O complex level lies deeper in the GaP band gap (approximately 0.3 eV below the conduction band) than the N-level and produces red photons at a wavelength of 700 nm. The low sensitivity of the human eye at 700 nm and the rapid saturation of the Zn–O centres with increasing current density limits the luminous efficiency to values below $0.5\,\mathrm{lm\,W^{-1}}$.

Table B1.1.2 summarizes some characteristic features of the most common GaAsP and GaP-based LEDs. One property of transitions via impurity levels is, that the recombination rate saturates as more carriers are injected, which limits the maximum applicable current to the diode. The brightness of

$GaAs_{0.14}P_{0.86}$:N	GaAs	Yellow	585	0.2	1
GaP:N	GaP	Green	565	0.4	2.5
GaP:Zn–O	GaP	Red	700	2	0.4

isoelectronically doped LEDs, such as green GaP:N devices, is still sufficient for many applications such as indoor signs, indicators or illumination of small displays. However, although such LEDs are still sold in quantities of billions of devices per year, the performance is not sufficient for high brightness applications.

B1.1.3.2 AlGaAs/GaAs

The first high-brightness LEDs on the market were red $Al_xGa_{1-x}As/GaAs$ devices. The ternary alloy $Al_xGa_{1-x}As$ is a solid solution of AlAs ($E_g = 2.168\,\mathrm{eV}$) and GaAs ($E_g = 1.424\,\mathrm{eV}$). Since AlAs ($a = 5.66\,\mathrm{\AA}$) and GaAs ($a = 5.65\,\mathrm{\AA}$) have basically the same lattice constant, AlGaAs is conveniently lattice matched to a GaAs substrate for the entire composition range. While GaAs is a direct bandgap material, AlAs has an indirect bandstructure. The bandgap of AlGaAs is direct for an Al-fraction up to 45% and indirect for higher values. This limits the efficient emission of visible light to the red spectral range above 620 nm. The composition dependence of the Γ- (direct gap) and the X-minima (indirect gap) of the Brillouin zone can be calculated according to reference [23]:

$$E_{g\Gamma}(x) = 1.424 + 0.247x \ \ \mathrm{eV} \quad 0 \le x \le 0.45 \tag{B1.1.35}$$

$$E_{g\Gamma}(x) = 1.424 + 0.247x + 1.147(x - 0.45)^2 \ \ \mathrm{eV} \quad 0.45 \le x \le 1 \tag{B1.1.36}$$

$$E_{gX}(x) = 1.9 + 0.125x + 0.143x^2 \ \ \mathrm{eV} \quad 0 \le x \le 1.0. \tag{B1.1.37}$$

The energies of the AlGaAs conduction band minima of the Γ-, X- and L-bands, are shown in figure B1.1.15 as a function of the Al-mole fraction. The band discontinuity at an AlGaAs/AlGaAs heterojunction splits in a ratio of roughly 60:40 between the conduction and valence bands [24]. Typical doping elements for p-type AlGaAs are zinc, carbon, beryllium and magnesium, while n-doping can be achieved with silicon, selenium or tellurium. The electrical conductivity of the material decreases rapidly with increasing Al-content.

Today, AlGaAs is a mature material system, readily fabricated using LPE or MOVPE growth [25]. High brightness visible LEDs emitting between 650 and 660 nm are routinely produced and are used worldwide. High performance AlGaAs-LEDs utilize an active layer with a double heterostructure confinement layer. Grown on absorbing GaAs substrates, these devices achieve luminous performances around $3\,\mathrm{lm\,W^{-1}}$. The material system offers the possibility to grow thick (100–150 μm) epi-layers by LPE on GaAs substrates. With these very thick AlGaAs layers, it is possible to remove the original GaAs substrate by, e.g. selective etching, leaving a transparent ‘substrate’ LED structure. Such TS AlGaAs LEDs are roughly twice as bright as devices on GaAs substrates with luminous performances of $8\,\mathrm{lm\,W^{-1}}$. One major drawback of AlGaAs is its tendency to oxidize in the presence of oxygen or

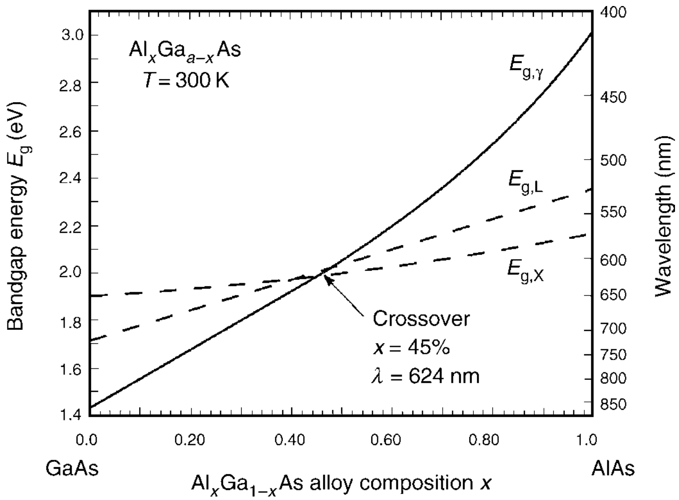

Figure B1.1.15. Composition dependence of the AlGaAs conduction band minima at the Γ-, X- and L-point.

moisture. Because the standard epoxy materials cannot seal the LED die efficiently, the oxidation is also present after polymer encapsulation. The process is accelerated at elevated temperatures. Although visible AlGaAs LEDs are still used in large quantities, it is anticipated that they will be replaced in many outdoor applications by the more robust AlGaInP LEDs.

B1.1.3.3 AlGaInP/GaAs

The alloy system $(Al_xGa_{1-x})_yIn_{1-y}P$ is a direct semiconductor material that covers the range of colours from red (650 nm) to yellow-green (560 nm). For higher brightness applications, it has widely replaced the indirect bandgap emitters GaP:N and GaAsP:N. The quaternary alloy AlGaInP can be regarded as a mixture of three binary materials, AlP, GaP and InP. The first two binaries have nearly the same lattice constant, which is appreciably different from the third involved material InP (figure B1.1.16). In order to obtain lattice matching to GaAs, the In mole fraction is fixed at about 0.48, whereas the Al mole fraction x can be varied widely without affecting the lattice constant (figure B1.1.17).

As usual for zinc blende type lattices, the band structure of the material has a single conduction band, with minima at the Γ-, X- and L-points, and three valence bands with degenerate heavy and light hole bands at the Γ-point. For low Al-content the bandgap is direct, but becomes indirect, with X being the lowest conduction band level for increasing Al-content. The bandgap energies have been determined by various methods [26], yielding slightly different results. A commonly accepted relation for the bandgap variation with composition at room temperature is:

$$E_{g\Gamma}(x) = (1.900 + 0.61x)\ \text{eV} \tag{B1.1.38}$$

$$E_{gX}(x) = (2.204 + 0.085x)\ \text{eV}. \tag{B1.1.39}$$

These values indicate that the Γ–X crossover takes place for $x = 0.58$, corresponding to an energy of 2.25 eV or a wavelength of 550 nm. As the crossover composition is approached from the low-energy side, the radiative efficiency of the material decreases drastically due to transfer of electrons from the Γ- to the X-valley, determining the maximum accessible range of wavelengths for LEDs. The conduction L-valley has not been seen directly in any experiment, but from measurements involving hydrostatic

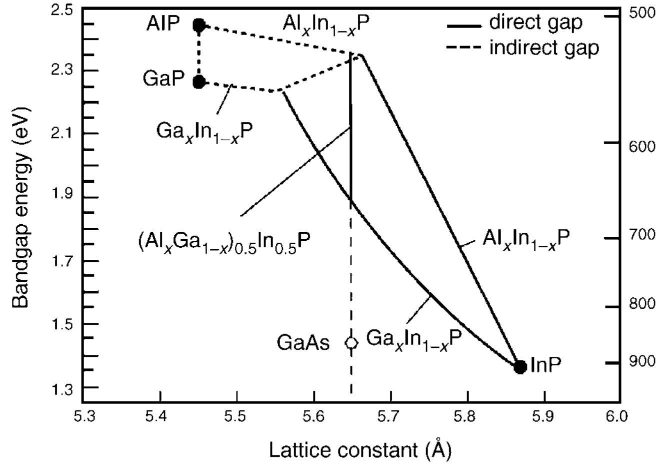

Figure B1.1.16. Bandgap versus lattice constant for the quaternary AlGaInP-system.

pressure [26], it has been estimated to be at least 125 meV above Γ_c. Although some theoretical work indicates a closer proximity to Γ_c [27], there are negligible effects on the performance of luminescent devices.

Various data indicate that the common 60:40 rule for the conduction and valence band offsets is also applicable in AlGaInP material [28]. The X-minimum of the conduction band changes accordingly, leading to a maximum band offset of about 200 meV in the conduction band. This conclusion has been nicely confirmed by transport experiments on n–i–n heterostructures [29].

For the active material, a double heterostructure design or a multiple quantum well (MQW) structure, embedded between larger bandgap layers, is used to optimize the carrier confinement. As the Al-concentration in the active region is increased to achieve shorter wavelength emission, electrons are thermally transferred from the Γ-minimum to the X-minimum, generating an additional non-radiative

recombination channel. Beyond the Γ–X-crossover, the radiative efficiency drops to zero. Closed-form expressions for the non-radiative losses through Γ–X-transfer have been derived under certain approximations [28] but a fit to experimental data requires additional assumptions, specifically a reduction of carrier lifetimes with Al-concentration. While this assumption is reasonable (the residual oxygen incorporation, e.g. increases with the Al content), electron leakage and, to a minor extent, hole leakage across the barriers follow a similar relationship on current and temperature, making it difficult to distinguish between the mechanisms in simplified models.

Simulations of the device efficiency show that, in the red colour range, the internal quantum efficiency is solely determined by non-radiative processes [30]. For emission wavelengths below 600 nm on the other hand, carrier leakage supersedes the non-radiative losses. Carrier leakage can be minimized by using larger active layers. Lower carrier densities in the active layer lead to higher effective barriers. At the same time, however, non-radiative processes become more favourable. Thus, as in many cases, the optimum configuration is determined by the material quality and different results have been obtained by different research groups [12, 13]. Another way of suppressing the carrier leakage is to increase the barrier heights. The barriers are maximized by using doped AlInP for the confinement layers. Even larger barriers can be obtained by thin layers of AlInP, with tensile strain or multiple quantum barrier (MQB) structures [31]. In the latter case, a combination of barrier layer and short-period strained superlattice (SPSS) is used, such that the lowest SPSS miniband accessible for electrons tunneling out of the active layer is above the largest conduction band energy of any of the constitutant materials.

An important issue for the fabrication of optoelectronic devices is the tendency of the material to form ordered phases. Depending on the growth conditions, atomic ordering of In and Al/Ga along the (111) planes can occur on the group-III sublattice [32]. The modified crystal structure leads to a significant reduction of the bandgap energy, which has been measured to be up to 160 meV in partially ordered material [33] and is estimated to be as large as 471 meV for completely ordered material [34]. Moreover, in photoluminescence experiments, it has been found that peaks can be split and broadened [35] and luminescence intensities are decreased [36], possibly due to the formation of piezoelectric fields and non-radiative recombination centres at domain boundaries. Therefore, disordered material is more favourable for most LED devices, in particular when short wavelengths are needed. Generally, the use of misoriented substrates, e.g. (100) tilted towards the $\langle 110\rangle$ or the $\langle 111\rangle_A$ direction, and the proper choice of growth conditions and doping profiles allows the complete suppression of ordering in the material [37]. More details about the AlGaInP alloy system can be found in the literature [28, 30, 38].

B1.1.3.4 InGaN

The group-III nitrides are the only III–V system that allows the generation of UV, blue and green photons. (Al)InGaN alloys can be described as a solution of the three binaries AlN, GaN and InN, with a very restricted solid miscibility due to thermodynamic constraints [40]. All three materials are direct semiconductors with band gaps of 6.2, 3.4 and 1.9 eV, respectively [41]. By adding In to GaN, the emission wavelength is shifted from the UV (365 nm) to the visible spectrum. Theoretically, the (Al)InGaN-system can cover a wide wavelength range up to 630 nm. The practical limit today, however, is somewhere in the green spectral range (≈ 550 nm).

The alloys can crystallize in two different modifications, either in a cubic zinc blende structure or in a hexagonal wurzite structure with the latter being considered as thermodynamically more stable. Since neither GaN nor AlN are available as bulk crystals, the system lacks a suitable semiconductor substrate for epitaxial growth (figure B1.1.18). The most common substrate today is sapphire, with a lattice mismatch of 16% to GaN. Although this large mismatch causes a very high dislocation density between 10^7 and $10^9\,\mathrm{cm}^{-2}$ in the epitaxial films [42], the system is still capable of producing highly efficient LEDs,

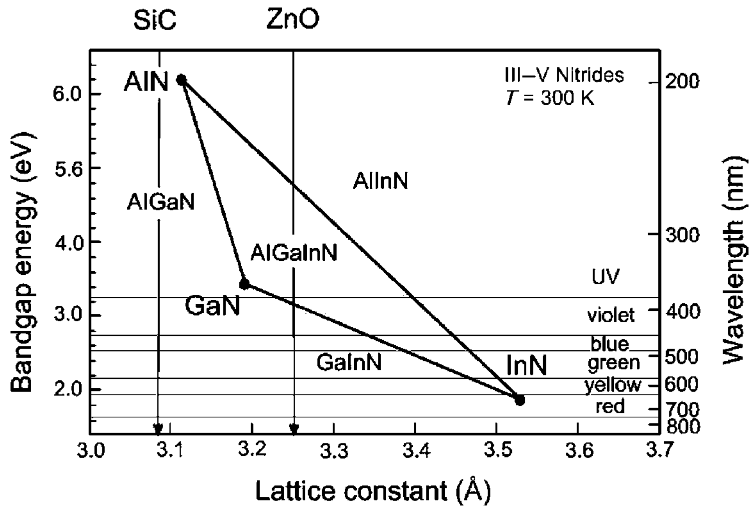

Figure B1.1.18. Bandgap energy versus lattice constant for III–V alloy systems of InGaN. The bowing parameters for the energy bands of AlGaN and InGaN are assumed to be 1.0 according to [39].

for reasons that are not fully understood. Obviously, the dislocations that must occur do not act as efficient recombination centres, which, together with the low diffusion length of holes, do not appreciably affect the radiative recombination efficiency. An alternative substrate is SiC which has a lower lattice mismatch to GaN and offers a number of additional advantages such as good electrical and thermal conductivity or a high electrostatic discharge hardness [43, 44]. Compared to sapphire, SiC is about ten times more expensive and less transparent. Also, its refractive index is less suitable for light extraction.

It has been found that the growth of a GaN, AlN or AlGaN buffer layer is essential for the growth of high-quality layers on both mismatched substrates SiC and sapphire. This buffer is usually grown at low temperatures (500–600°C), before the temperature is raised to 1000–1100°C for the growth of the device structure. On sapphire substrates, the buffer layer is necessary to achieve a smooth surface morphology and good optical and electrical properties despite the large lattice mismatch [45–47]. On SiC-substrate, the buffer layer reduces the voltage drop across the SiC–GaN interface. Also, the buffer thickness directly impacts the quality of the subsequently grown layers. Maximum Hall mobility in n-type GaN is achieved with 20 nm thick GaN-buffer layer thickness [47]. From the different temperature dependence of the Hall mobility with GaN- and AlN-buffer layers, it might be concluded that the GaN-buffer reduces the effect of ionized impurity scattering [48].

Nominally undoped GaN is n-type, with a high residual electron concentration. P-doping is very difficult to achieve in III-N-alloys. The lack of p-type material, and hence of pn-junctions, has been a blocking point for the fabrication of light-emitting devices for a long time. A lot of the early work was done with Zn as acceptor [49, 50], but today the preferred material for p-doping is magnesium [51]. After the epitaxial growth, the acceptors are passivated by the formation of some sort of Mg–H complexes [52]. P-conductivity can be obtained after a post-growth treatment by thermal annealing or using low-energy electron irradiation (LEEBI), but also ‘in situ’ by a suitable growth and cooling-down procedure. The activation energy of Mg acceptors in GaN, deduced from temperature-dependent Hall measurements, is assumed to be around 160 meV. In InGaN and AlGaN-alloys, the activation of Mg

Table B1.1.3. Material properties of binary III-nitrides and their potential substrates. GaAs and Si are listed as reference. Note that the thermal conductivity of SiC is anisotropic. The value in brackets gives the value in a different crystallographic direction.

acceptors is dependent on the composition. Silicon or germanium is used for n-type doping. The donor activation energy of Si in GaN is around 33 meV.

As a consequence of the high ionicity of the nitrides, their refractive indices are relatively small. The values for the binaries are listed in table B1.1.3. The index of (Al)InGaN can be changed appreciably by changing the composition and thus the bandgap. The refractive index is an important parameter for light extraction from the diode chip. Another favourable property of the III-nitrides is their high thermal conductivity. Some of the values are listed in table B1.1.3. The common substrates such as sapphire and 6H-SiC have thermal conductivities of 0.439 and 4.9 $\mathrm{W\,cm^{-1}\,K^{-1}}$, respectively.

The first blue emitting LEDs were homotype pn-junction GaN devices. The electroluminescence spectrum consists of a narrow acceptor-band emission in the UV (around 370 nm) and a broad band-acceptor line at 420 nm. Better carrier confinement and thus more efficient recombination are achieved in double heterostructure devices. By adding Al to GaN, the bandgap is increased while the addition of In shifts the bandgap to lower energies. Thus, typical DH-devices involve AlGaN confinement layers around GaN or InGaN active layers. Due to the large difference of lattice constant between AlN and InN, the range of usable composition and layer thickness is limited. Similar to the impurity related transitions in GaP, simultaneous doping of InGaN with Zn and Si can generate relatively efficient donor–acceptor emission in the violet to green spectral range [53, 54]. Using active material of quantum wells with a well thickness below the critical thickness the quality of the LED structure is improved significantly, which enables the use of band–band or near band–edge transitions as major recombination process [55]. As long as mismatch-induced strain and the quantum well thickness do not exceed the critical limits, the emission wavelength can be readily adjusted with the In-mole fraction. Nakamura *et al* reported emission from violet to yellow for In-fractions between 0.15 and 0.7 [56].

B1.1.4 High efficiency LEDs and novel technologies

The traditional design of an LED chip is a semiconductor die, with a planar metal contact at the bottom and a circular or square electrode at the top (figure B1.1.19). Very simple devices use a homostructure pn-junction as active region, the more advanced ones include a single- or double-heterostructure. Several factors limit the external efficiency of such LEDs: total internal reflection, shadowing by the metal electrodes and absorption in the semiconductor material. With the exception of GaP-based LEDs and some AlGaAs-devices on TSs, a substantial amount of light is lost by absorption in the substrate material. Therefore, even with an efficient internal process of current-light conversion, the external efficiency of standard LEDs hardly exceeds a few per cent. This frustrating situation has stimulated a lot of work on ways to increase the efficiency of LEDs such as:

- fabrication of dices that are as transparent as possible, by the use of very thick transparent layers and a TS;
- die-shaping to enhance the extraction efficiency;
- fabrication of substrate-less LEDs, to avoid substrate absorption;
- modification of the spontaneous emission by using optical cavities.

Each approach tackles the problem of light extraction in a different way. The first one applies rigorously the principle of extracting light from as many escape cones as possible. Die shaping is a step towards the ideal solution, that of a point light source in the centre of a spherical semiconductor die. Most of such ideas are almost as old as the LED itself, but practical devices have not been generated until very recently. For obvious reasons, die shaping works best on LEDs with TSs. The (absorbing) substrate can be removed entirely, if the LED layers are transferred to a new carrier such as a semiconductor wafer or other materials such as metal or ceramic. If metal soldering is used to combine the LED structure with the carrier, the metal also acts as mirror. Because the reflected light has to pass through the entire layer structure, the efficiency of LEDs with such an integrated reflector is very sensitive to internal absorption (table B1.1.4).

A completely different idea for high extraction efficiency is to change the fundamental process of spontaneous emission. Placing light generating material in an optical resonator, with spatial dimensions in the order of the emission wavelength, can change the spontaneous generation of light significantly

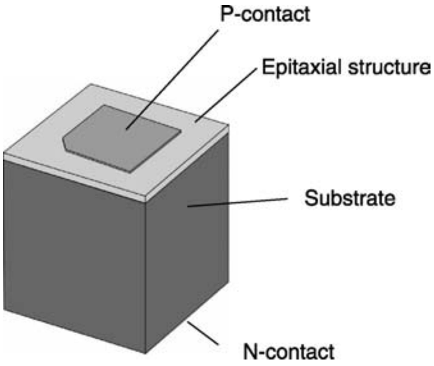

Figure B1.1.19. Conventional LED die on a conductive substrate. Typical dimensions are a chip area of $200 \times 200\ \mu m^2$ and a height of $200\ \mu m$.

Table B1.1.4. Summary of LEDs with the highest reported efficiencies. Listed are the material system, the technology used, the colour range of emission and the status (productive or demonstrator). The different LEDs are described in more detail in the text.

Device	Material system	Technology	Colour range (nm)	Status
Transparent substrate LED	AlGaInP/GaAs	Direct wafer bonding	590–650	Prod.
Truncated inverted pyramid LED	AlGaInP/GaAs	Direct wafer bonding, die shaping	590–650	Prod.
Thin-film LED	AlGaInP/GaAs	Wafer soldering	590–650	Prod.
Surface textured thin-film LED	AlGaAs/GaAs	Epitaxial lift-off, surface roughness	850–980	Demo.
LED with tapered waveguide	AlGaAs/GaAs	Etched lateral taper	850–980	Demo.
	InGaAlP/GaAs		650	Demo.
Resonant Cavity LED	AlGaAs	Standard technology	850–980	Demo.
	AlGaInP/GaAs		650	Prod.

[57, 58]. The ultimate micro-cavity LED would allow only one single optical resonator mode which could be extracted as efficiently as the optical modes in a laser. While such ideal LEDs are still far from any practicably manufacturable device, some aspects of micro-cavity LEDs have already found their way into commercial LEDs, e.g. red emitting (650 nm) RCLEDs.

B1.1.4.1 Transparent substrate AlGaInP LEDs

The extraction efficiency of LEDs with TSs is substantially higher than that of LEDs on ASs. Examples of LEDs on TSs are the early GaP-devices or AlGaAs-LEDs fabricated on thick LPE grown transparent layers. Due to the large lattice mismatch to GaP, high-brightness AlGaInP must be grown on absorbing GaAs-wafers, which strongly reduces the extraction efficiency. In order to overcome this fundamental limitation, Kish *et al* developed a technique to remove the absorbing GaAs substrate and to transfer the AlGaInP-LED layers to a transparent GaP wafer [59]. Direct wafer bonding allows the combination of various semiconductor materials more or less independently of their crystallographic lattice constant. In the case of AlGaInP–GaP, wafers with up to 3 inch diameter are bonded [60], the limit set by the diameter of the available GaP-wafers. The clean surfaces of both wafers are brought into contact under uniaxial pressure and heated up to temperatures of 750°C or more [61]. Under such conditions, and with proper crystallographic alignment, the two materials form a semiconductor heterointerface with covalent bonds between the two materials [60]. The interface is optically transparent and conducts both heat and electrical current. Excellent control over this complex process is required, in order to ensure low-resistance electrical contact over the entire bonded area. The feasibility of the AlGaInP–GaP wafer bonding process for the fabrication of an LED has been demonstrated by Hewlett-Packard and is now routinely used in high-volume production. The new class of AlGaInP LEDs is named TS LEDs to distinguish them from AS LED on GaAs-wafers.

With the very thick GaP current spreading layer on top of the AlGaInP active region and the transparent GaP-wafer below, the TS-LEDs achieve record high levels of light extraction. Very high efficiencies of up to 32% at 630 nm have been reported [12]. In terms of luminous efficiency, a maximum value of 74 lm W^{-1} has been achieved at shorter wavelengths (615 nm). The extraction efficiency of TS-LEDs can be further enhanced, if the die is shaped into cones, pyramids or spheres [62]. The highest reported efficiencies of AlGaInP LEDs are achieved with wafer-bonded TS-material which is cut into dices with the shape of a truncated inverted pyramid [14]. Light is generated at the base of the inverted pyramid and is extracted after a reduced number of reflections and with a low average photon path length within the semiconductor. The truncated inverted pyramid LED achieves a luminous efficiency of 102 and 68 lm W^{-1} at wavelengths of 610 and 598 nm, respectively. A peak external efficiency of 55% was measured at 650 nm.

B1.1.4.2 Wafer-bonded thin-film LED

A viable alternative to direct wafer bonding is to solder wafers with an intermediate metal layer. This is well established in silicon technology and is commonly used for the fabrication of micro mechanical components. In the context of AlGaInP-LEDs, the idea is to transfer the epitaxial structure at wafer level to a new carrier by soldering followed by GaAs removal [63]. This process generates a new wafer, with a metal layer buried between the epitaxial LED layers and the carrier material. Both the high reflectivity of the metal–semiconductor interface and the possibility to form ohmic contacts are favourable for the functionality of the LED.

The process flow is shown schematically in figure B1.1.20. After epitaxial growth, Au and AuSn are deposited on the AlGaInP-LED structure and the carrier wafer, respectively. Carrier and LED-structure are then brought into contact and soldered at 350°C. Then the original GaAs substrate is removed by selective wet chemical etching. Processing of the 'new wafer' is then finished using standard LED processing technology.

Figure B1.1.21 shows the basic principle of a thin-film LED. The metal layer below the active layer serves both as a reflector and as the anode. Light which is not directly extracted is reflected either by total reflection at the semiconductor–air (or epoxy) interface or at the metal mirror. Extraction is significantly enhanced if the reproduction of reflection angles is suppressed by surface roughness. Other critical parameters for high efficiency are a sufficiently thin active layer for reduced self-absorption and a power reflectivity of more than 90% at the metal–semiconductor interface. Although metals like Au, Al or Ag offer a very high reflectivity on AlGaInP or AlGaAs, the reflectivity is greatly reduced if the metals are alloyed to form good electrical contacts. Even on highly doped semiconductors contact alloying is

necessary to reduce the contact resistance. For the thin-film LED, this problem is solved by locally separating areas with high reflective mirrors from areas with good electrical contacts to the semiconductor. A thin dielectric layer, such as Si_2N_3 or SiO_2, is deposited between the semiconductor and the metal layer(s). Openings in this dielectric film define the electrical contacts, whereas the rest of the area serves as a dielectric/metallic mirror. The layer system can be alloyed in order to lower the contact resistance, without significantly changing the optical properties of the mirror area.

An attractive feature of wafer soldering for LEDs is the possibility to structure one of the surfaces before bonding. Geometrical shapes, such as cones, prisms or spheres, might be transferred into the AlGaInP-structure (or the carrier surface) by etching before they are covered with metal and embedded inside the LED structure. Generally, most of the geometries that have been used to shape dices, in order to enhance the extraction of light [62], can also be buried at the bonded interface of a thin-film LED. An example for an LED with an embedded array of cone-shaped micro reflectors is shown in figure B1.1.22. Truncated cones are etched through the active layer and electrically contacted at openings in the dielectric layer at the soldered interface. The fact that the localized current injection leads to a preferred generation of light in the centre of the etched cones is used to design the actual shape of the microstructure. Light rays that are totally reflected at the metal mirror along the cones are directed upwards towards the LED surface where they are extracted. The path length from the active layer to the top of the LED structure is only a few micrometre and does not include any absorbing material such as the active layer so that the effect of self-absorption inside the device is greatly reduced.

Figure B1.1.23 (left) shows the top view of a 615 nm device with a structured interface. Although the array of micro reflectors is located underneath the planar top-layers, it is clearly visible from the top.

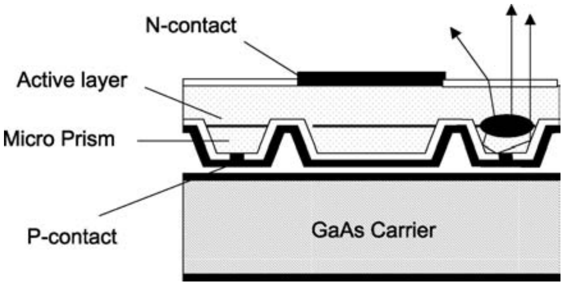

Figure B1.1.22. Schematic cross-section of a thin-film LED with buried micro reflectors.

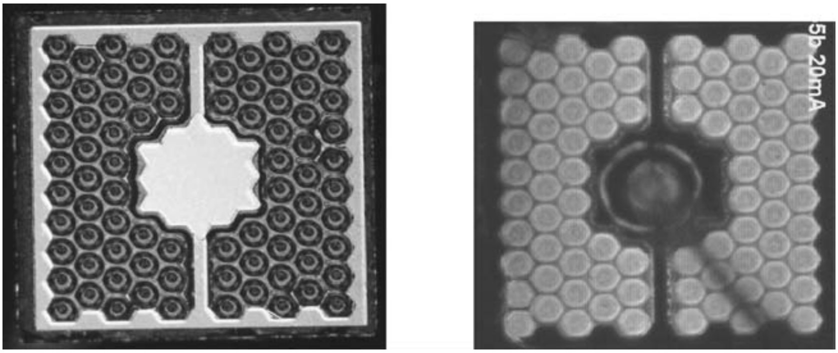

Figure B1.1.23. Top view (left) and illumination pattern (right) of a 615 nm thin-film LED.

Current injection is facilitated from the isolated bond pad and the connected square frame along the edge via the top n-contact layer to the individual p-electrodes in the centre of the individual reflectors. As shown in the illumination pattern (figure B1.1.23, right) light is generated and extracted around the micro reflectors, confirming the principle of operation. Figure B1.1.24 depicts the optical characteristics of the device. Driven at a dc-current of 100 mA, the LED emits up to 9.7 lm, corresponding to an optical power around 32 mW. In the range of 10–20 mA of operation current, the luminous performance is above 50 lm W^{-1}, with a peak value of 53 lm W^{-1} at 10 mA. One of the advantages of the thin-film technology is the low ohmic resistance that can be achieved. Operated at a dc-current of 10 mA, the forward voltage of the 615 nm LEDs is still below 2.0 V.

Thin-film LEDs are also very attractive as large-area chips for high-current application. Contrary to most other high-brightness LEDs, they do not need a thick window layer for light extraction. Because the thickness of these GaP or AlGaAs window layers is directly related to the chip size (equation (B1.1.20)), an increase of chip area usually results in a reduced extraction efficiency. The output characteristics of two large-area thin-film LEDs with 700 and 1000 μm chips are shown in figure B1.1.25. Up to a drive current of several hundred mA, the efficiency of both devices is comparable. Only at very high currents, the output power of the smaller chip begins to roll over due to thermal problems. The 1 mm LED achieves 64 lm at 1 A.

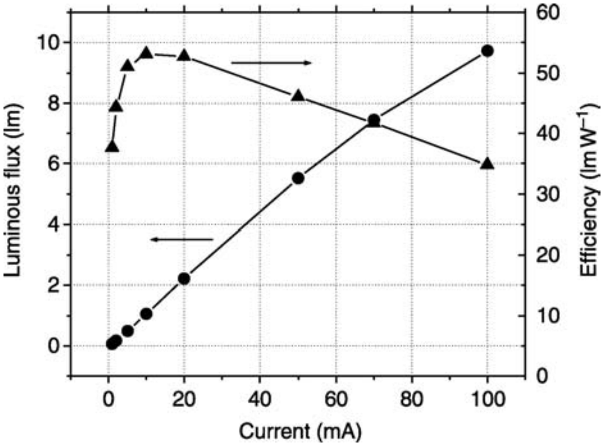

Figure B1.1.24. Optical performance of a 615 nm thin-film LED operated under dc-conditions.

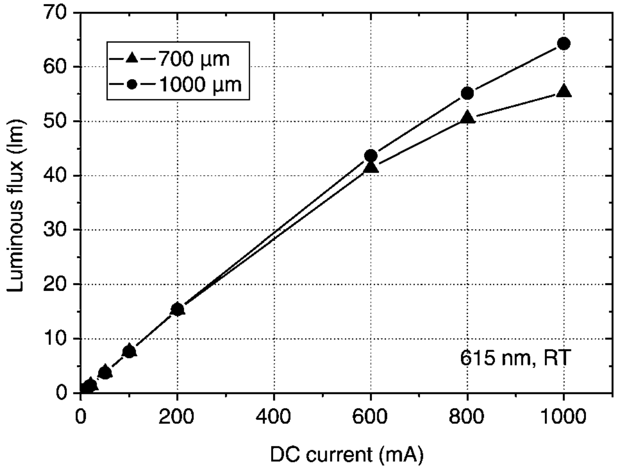

Figure B1.1.25. Light-output characteristics of a 1 mm thin-film chip emitting at 615 nm. The samples are mounted in a package for high-current operation.

The possibility of shaping the LED surface before bonding offers a whole range of new opportunities to optimize or tailor the device performance by combining novel micro-structures for light extraction with new schemes for current injection, heat dissipation or emission profiles. Figure B1.1.26 shows the performance of a 637 nm thin-film LED with a modified reflector structure. At 50 mA, the device emits a power of 34 mW corresponding to a quantum efficiency of 36%. The maximum values of quantum and wall-plug efficiency are 39.5 and 38%, achieved at a drive current of 10 and 2 mA, respectively.

A different approach to fabricate thin-film AlGaInP-LEDs is to bond the epitaxial structure to an isolating wafer. In this case, two top electrodes are required. Horng *et al* fabricated 600–620 nm AlGaInP LEDs on Si-wafers coated with SiO_2 [64, 65] using a metal combination of Au and AuBe for bonding. Despite the intermediate dielectric layer, the LEDs benefited from the good thermal properties

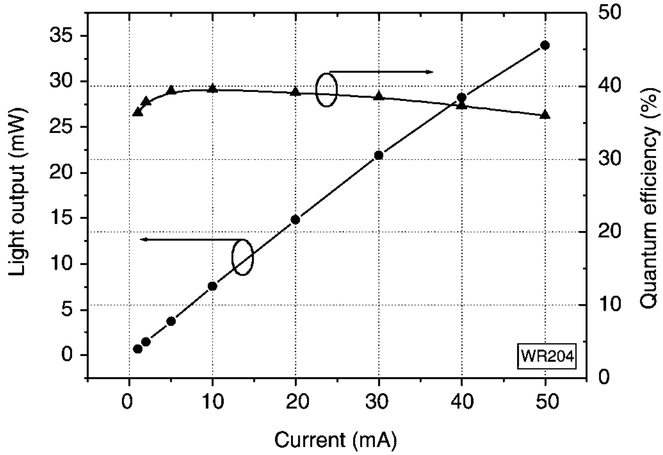

Figure B1.1.26. Characteristics of a 637 nm thin-film LED. The device gives 34 mW of output power at 50 mA dc-current. Maximum values of quantum- and wall-plug efficiency are 40% (10 mA) and 37.7% (2 mA), respectively.

of Si. A luminous intensity of 90 and 205 mcd (620 nm) was demonstrated at 20 and 50 mA of operation current, respectively.

Obviously, the thin-film approach is not restricted to a specific material system. Recently, a 460 nm InGaN thin-film LED was reported achieving an external quantum efficiency of 25% [66]. The device structure was grown on a sapphire and subsequently bonded to a GaAs wafer. A laser lift-off process was used to remove the original sapphire substrate.

B1.1.4.3 Surface-textured thin-film LED

The idea of surface-textured thin-film LEDs dates back to the early 1990s, when Schnitzer *et al* demonstrated an external efficiency as high as 72% with an optically pumped thin-film LED [67] and, shortly later, an electrically driven diode with an external efficiency of approximately 30% [68]. The devices are based on two new techniques for LEDs: 'epitaxial lift-off' (ELO) [69] and surface roughening by 'natural lithography' [70]. The idea of the ELO process is to insert a sacrificial layer, typically some 10 nm of AlAs, between the LED structure and the substrate. A selective wet chemical etching process removes the sacrificial layers and separates the epitaxial layers from the GaAs substrate. Subsequently, the thin epitaxial film is transferred to a new wafer by van der Waals bonding [71]. A metal film on the carrier serves as a highly reflective back mirror for the LED. Surface roughening is achieved by depositing a monolayer film of randomly ordered polystyrene spheres on the LED wafer. Then the random pattern is transferred into the semiconductor surface by dry etching.

The principle of operation is to randomize the angles of totally reflected light at the top surface with the high reflectivity of a metallic back mirror on the bottom side (figure B1.1.21). Light that is not extracted through the surface is reflected back and forth between the back mirror and the rough surface. For high efficiency devices, the losses per round-trip through the LED structure have to be minimized by (i) reducing the thickness of all absorbing layers including the active layer and (ii) optimizing the reflectivity of the back mirror. Both can be achieved easily in the AlGaAs/InGaAs/GaAs material system. The band structure offers a sufficiently high carrier confinement to use only a few nanometres of active material for efficient light generation. Additionally the reflectivity of common metals like Au, Ag or Al is very high in the infrared regime.

The combination of epitaxial lift-off and surface roughening has been optimized by Windisch *et al* on near infrared (850 nm) LEDs [72, 73]. A schematic layout of the device is shown in figure B1.1.27*a*. The LED employs a mesa structure, with a selectively oxidized current aperture to prevent the generation of light under the metal contact. Current injection is facilitated via an annular top-side p-contact and a lateral n-contact around the mesa. In order to extract some of the laterally guided light, not only the surface on top of the mesa but also the area between mesa and bottom contact was roughened. Very high quantum efficiencies of up to 43 and 54% were achieved before and after encapsulation, respectively [74]. Current densities up to 1000 A cm^{-2} were applied. Similar devices at 650 nm emission wavelength resulted in 24% external quantum efficiency (31% after encapsulation) [75]. Due to relatively high forward voltages, the wall-plug efficiency of the red LEDs ranges between 10 and 15% at 1 mA of operation current.

B1.1.4.4 LED with tapered waveguide

A device that extracts solely the laterally guided modes inside the epitaxial structure is the LED with a radial tapered output coupler [76] shown in figure B1.1.27*b*. The circular device structure comprises a central top contact, a circular symmetric out-coupling taper with the shape of a shallow truncated cone and a ring-contact along the taper perimeter. Light extraction occurs through the bottom side, where the GaAs substrate has been removed by wet chemical etching.

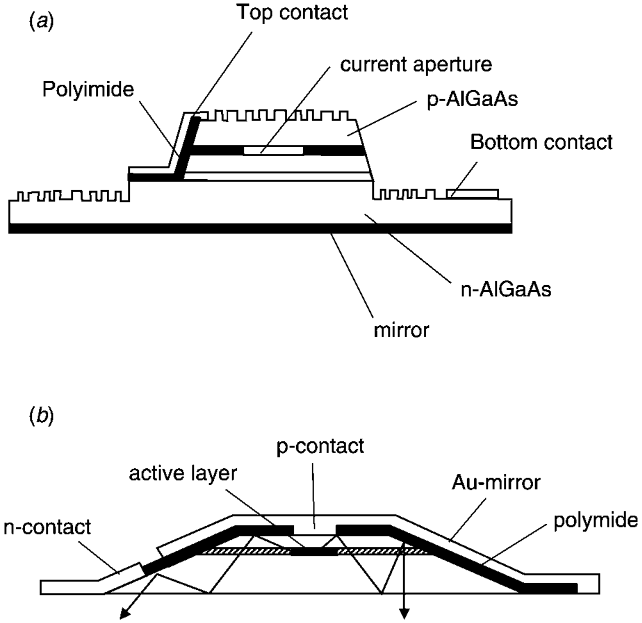

Figure B1.1.27. (*a*) Non-resonant LED with metallic back mirror and roughened surface. (*b*) LED with a radial tapered waveguide.

The principle of operation is to generate light in a small active area, defined by the geometry of the p-contact and to guide it radially towards the tapered area. The dimensions are chosen such that the light rays that hit the taper surface have a small azimuthal wave vector component which is an essential design parameter for efficient light extraction. Light that is reflected at the out-coupling surface is reflected again at the metal mirror on the taper and returns under a more favourable angle of incidence. The procedure is repeated until finally the angle of incidence falls within the escape cone. Absorption inside the waveguide layers which include unpumped active material and a reflectivity below 100% at the metal mirror on the taper limit the efficiency of this device.

With one and two InGaAs/GaAs compressively strained quantum wells as active material, Schmid *et al* demonstrated 45% quantum efficiency at 980 nm on encapsulated devices [77]. Maximum efficiency was reached at 2 mA injection current and a forward voltage around 2 V. This resulted in a wall-plug efficiency of 30 and 44%, before and after encapsulation, respectively. The first attempt to apply the same technology to 650 nm GaInP/AlGaInP devices resulted in an external efficiency of 13%.

B1.1.4.5 Resonant-cavity LEDs

The resonant-cavity LED or RCLED consists of a light-emitting active region between two Bragg mirrors which form an optical resonator. If the distance between the Bragg mirrors is set to a small multiple of half the optical wavelength, the cavity is in resonance with the emission and becomes transparent. In 1946, Purcell discovered that the spontaneous emission properties of an atom can be influenced by placing it inside a small (micro-) cavity [78]. The local strength of the electromagnetic modes and the density of states might then change the angular distribution as well as the emission rates. Schubert *et al* [79] proposed in 1992 to use a one-dimensional resonant cavity with a thin active layer inside as LED and to apply the cavity to manipulate the spontaneous emission.

The cavity determines the optical properties of the RCLED. It can be designed to direct more spontaneous emission into the escape cone than in the case of isotropic emission. This results in a higher intensity emitted in the surface normal direction as shown in figure B1.1.28. The different wavelengths within the emission linewidth fulfil the resonance conditions of the cavity at different angles of incidence at the top surface. Therefore, the RCLEDs spatial emission pattern contains every individual wavelength within the material linewidth in a specific angular direction. If the emission is spatially filtered, e.g. by coupling it into an optical fibre, also the range of emitted wavelengths is filtered, resulting in a narrow fibre coupled emission linewidth. However, when integrating over the entire half-sphere around the device, the measured emission linewidth is the same as that of the active material without the resonator.

A comprehensive introduction into the physics of RCLEDs can be found in the review of Benisty *et al* [80, 81]. Here, we will summarize only a few of the most important rules for the design of RCLEDs:

(1) The cavity order should be as low as possible. Even if the spacing between the Bragg mirrors is one half or one wavelength, the penetration depth of light into the Bragg layers increases the effective cavity length. Hence, the index contrast should be as high as possible.

(2) The quantum-well active layer should be placed in a maximum of the standing wave in the cavity.

(3) The emission of the active material should be tuned to a shorter wavelength than the resonance wavelength of the cavity. This compensates for a possible wavelength shift as the temperature rises and enhances the fraction of extracted light. The latter is due to the fact that the shorter wavelengths

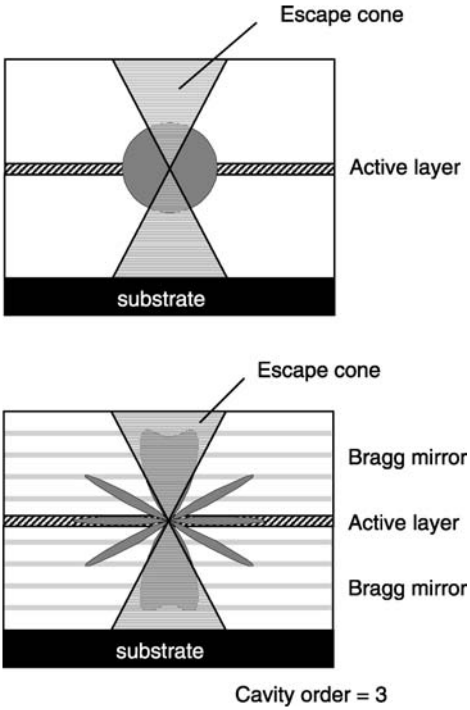

Figure B1.1.28. Spontaneous emission in a conventional LED (top) and in an RCLED (bottom). Because the spontaneous emission in the resonant cavity is no longer isotropic, the cavity can be designed to launch more emission into directions where the light is extracted (escape cone).

are resonant in off-axis directions with a much larger solid-angle element than the exactly tuned wavelength.

Contrary to conventional LEDs, many properties of RCLEDs such as the temperature dependence of intensity, the radiation pattern or the coupling efficiency into some kind of optical system can be designed. The key parameter here is the wavelength tuning of the cavity resonance, given by the thickness between the two mirrors and the emission wavelength. According to point 3, it is usually favourable to have the active material emitting at a few nanometres shorter than the on-axis cavity resonance wavelength. As the temperature is increased, the emission wavelength is shifted towards the resonance and increases the amount of light extracted in the surface normal direction. This is schematically shown in figure B1.1.29. Thus, for example the amount of fibre coupled light can increase with increasing temperature. At even higher temperatures, the emission will shift from the resonance to longer wavelengths and the surface normal intensity will decrease again. The wavelength tuning also affects the spatial radiation pattern of RCLEDs. If the peak intensity of the active layer emission is shifted to shorter wavelength than the cavity resonance, more light is extracted in off-normal directions.

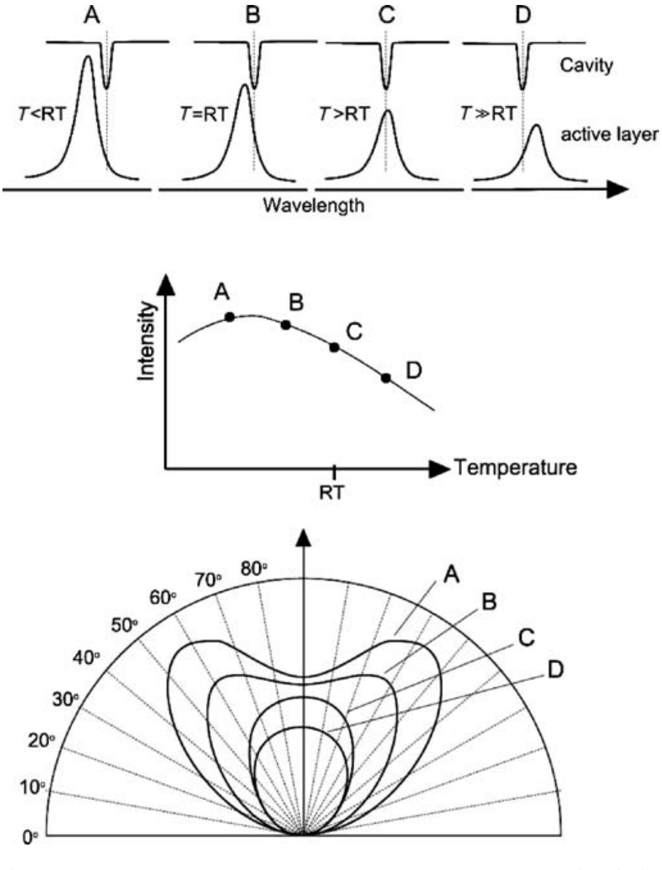

Figure B1.1.29. Effect of cavity tuning in RCLEDs. Top: emission wavelength of the active layer and cavity resonance at different temperatures. Middle: Emitted Intensity versus temperature. Bottom: Radiation pattern for the four temperatures A–D.

A two-dimensional-cross section of the resulting radiation pattern shows the typical double-lobe shape as shown in figure B1.1.29.

RCLEDs have been fabricated mostly for the infrared spectral range, often with the intention to use them as efficient light source in fibre communication systems. For this application, the RCLED has to compete with vertical cavity lasers, which are even more suitable for high-speed communication. However, a few groups continued to optimize RCLEDs and achieved remarkable results using, e.g. metal-mirrors or fully oxidized Al_xO_y/GaAs DBRs [82]. An external quantum efficiency above 20% was achieved by De Neve *et al* [83] with a bottom emitting 980 nm RCLED using an AlGaAs/GaAs-DBR and a metallic Ag-mirror. Also visible RCLEDs based on the AlGaInP/GaAs system have been demonstrated [16, 84, 85].

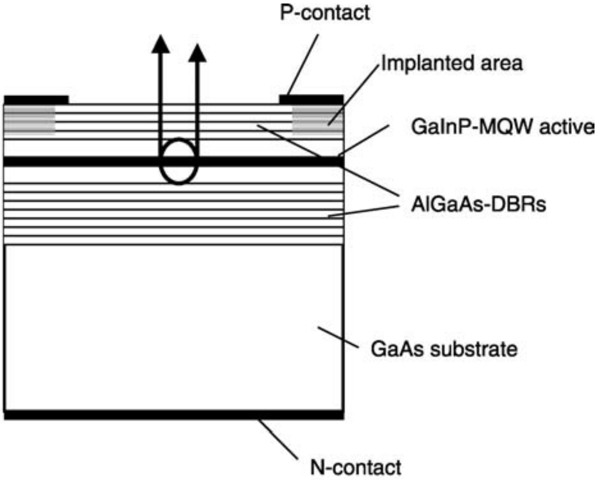
Only in the dark red around 650 nm, RCLEDs have made it to commercial products. At this wavelength there is a need for medium speed light sources for plastic fibre communication. RCLEDs are attractive because the directional output yields in a high fibre coupling efficiency and, due to the above-mentioned spatial filtering effect, in a narrow spectral linewidth in the fibre. Even with small devices and active diameters of less than 100 μm, levels of fibre coupled power well above 1 mW are achievable. If operated at some 10 mA of electrical current, the radiative carrier lifetime is reduced mainly by the high current density to rise- and fall-times of a few nanoseconds [86, 87]. Figure B1.1.30 shows the structure of a commercial 650 nm RCLED. It consists of two $Al_{0.5}Ga_{0.5}As/Al_{0.95}Ga_{0.5}As$ Bragg mirrors and an active layer of compressively strained GaInP quantum wells inside the $1-\lambda$-cavity [88]. For high-modulation speed, the material is processed to devices with an 80 μm light opening within an annular p-electrode (bottom of figure B1.1.29), but also conventional LED contact layouts are used. Large area devices achieve wall-plug efficiencies around 12% at 20 mA and 1.75 V forward voltage (figure B1.1.31). The high-speed devices are less efficient (9.5%), mainly due to the lack of photon recycling [89].

B1.1.4.6 Photonic bandgap approaches

Similar to the electronic bandgap, photonic bandgaps are defined as frequency bands over which all electromagnetic modes and spontaneous emission are suppressed [90–92]. They are a feature of periodically patterned materials with a strong dielectric constant contrast, so-called photonic crystals. The realization of photonic bandgap structures at optical frequencies requires the modulation of the dielectric constant on a nanometre scale, which is a challenging task for semiconductor processing technologies. In the context of optoelectronic device design, photonic bandgap structures are discussed as novel approaches for light confinement but their optical diffraction properties are also interesting.

Photonic bandgap structures can be employed for LEDs in different ways. One is to confine the photons in the device in two or three dimensions by using a periodic pattern in the semiconductor active material. This can be used to create waveguide structures with unique features on a very small scale but also to fabricate micro-cavities. The spontaneous emission in such a micro-cavity can be controlled if at least one dimension of the cavity is in the order of the emission wavelength. Ultimately, the vision is to realize single-mode LED emission or threshold-less micro-cavity lasing operation [92, 93]. In micro-cavities with metallic mirrors, two-dimensional photonic bandgap structures are used to create bandgaps for propagating surface waves or surface plasmon polaritons [94, 95]. Unlike three-dimensional photonic crystals, two-dimensional structures are easier to fabricate and therefore may be more interesting for practical applications.

Similar to grating output couplers on top-emitting in-plane lasers [96, 97], a two-dimensional photonic bandgap structure can be used to redirect laterally guided light inside an LED towards the surface normal direction. Photonic crystal light extractors have already been used in a number of different devices where the photonic bandgap structure was either etched into the top layer or all the way through the active LED structure. Erchak *et al* demonstrated a sixfold enhancement of PL-intensity at



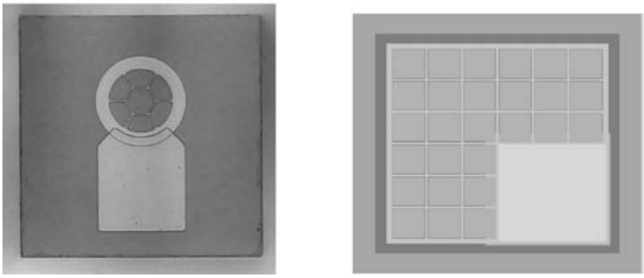


Figure B1.1.30. Top: Layout of a 650 nm RCLED with annular top contact and proton implanted current confinement. The distance between the AlGaAs-Bragg mirrors corresponds to one optical wavelength ($1 - \lambda$ cavity). Bottom: top view of two commercial RCLEDs. The chip dimensions are $(200 \times 250)\,\mu\text{m}^2$ and $(260 \times 260)\,\mu\text{m}^2$ for the left and right device. The smaller die has a light-emitting area with a diameter of 80 μm.

925 nm using a two-dimensional photonic bandgap in the upper cladding of an asymmetric LED structure [98]. Rattier [99] proposed a device where an unstructured LED-area for direct microcavity emission is surrounded by a deeply etched photonic bandgap for guided mode outcoupling. In both approaches, an oxidized Al_xO_y/GaAs Bragg reflector is used as bottom mirror, which offers a sufficiently high index contrast but is electrically isolating.

In order to combine an enhancement of the spontaneous emission rate with a mechanism for efficient light extraction, light can be generated in a thin film of active material and guided in a surface plasmon polariton mode [95]. These are guided optical modes that may exist at the interface between a dielectric and a metal and consist of an oscillating electromagnetic field coupled to an oscillating surface charge density. The rate of spontaneous emission can be increased by the coupling of the emitter to the enhanced electric fields associated with the guided modes (Purcell effect). A two-dimensional periodic photonic bandgap structure is used to create Bragg scattering and to couple the mode into useful radiation. A significant enhancement of PL extraction efficiency was demonstrated with optically pumped LEDs based on a thin-slab photonic crystal [100] and external quantum efficiencies of $>70\%$ were predicted with such a structure [94]. Most of the efficiency increase was associated with the improvement of Bragg extraction and to a minor increase in the Purcell enhancement.

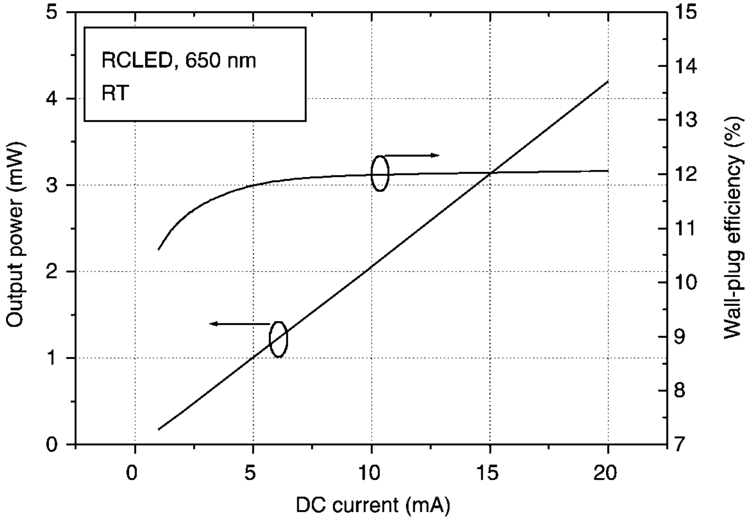

Figure B1.1.31. Wall-plug efficiency and optical output power of a 650 nm RCLEDs. The die size is 700 × 700 μm^2. At 20 mA, the device emits 4.2 mW.

The potential performance of LEDs using surface plasmon polariton modes is difficult to estimate. Apart from all the technical problems of realizing such devices, there are still a number of open questions to answer. Dissipative losses related to the propagation of light along a dielectric/metal interface will affect the performance and must be circumvented. Also it is not obvious if an effective extraction of the guided mode can be achieved with a structure that efficiently couples the emitter to the surface plasmon polarity mode [101].

B1.1.5 White LED

With the availability of wide-bandgap InGaN-based semiconductors, it became possible to produce not only efficient ultraviolet, blue and green diodes but also white emitting LEDs. Before that, the lack of white light has been a major barrier for LEDs in a wide range of applications. With LEDs covering the full colour spectrum including white, the ultimate goal of LED-based illumination and lighting became possible.

B1.1.5.1 White light

It is important to define what is meant by ‘white’ light, as it has to be compared with some kind of standard. The most fundamental model for white light is the solar spectrum shown in figure B1.1.32, but even then the sunlight changes with daytime and season of the year. It is usually therefore ‘idealized’ by using an equivalent black body radiation spectrum. According to Wien’s law, the peak maximum of the black-body spectrum is only a function of the temperature:

$$\lambda_{\text{peak}} = \frac{2880}{T}\ \mu\text{m K}. \tag{B1.1.40}$$

As the temperature increases from room temperature to thousands of degrees kelvin, the peak wavelength of the black body radiation moves from infrared to visible wavelengths. In the chromaticity

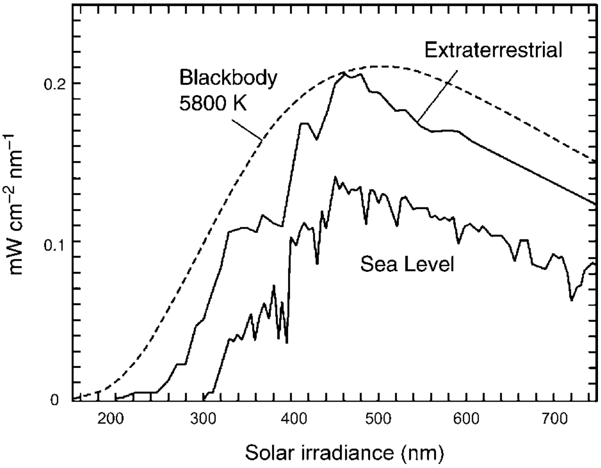

Figure B1.1.32. Spectrum of sunlight. The solid lines show the solar spectrum before and after transmitting the earth's atmosphere. The dashed line is the blackbody radiation at 5800 K.

diagram, this is represented by a line from the red towards the centre of the white colours (see appendix A). Consequently, assuming true black-body radiation, it is sufficient to use only one parameter, the *colour temperature*, to specify the spectral properties. The Commission Internationale de l'Eclairage (CIE) defined several standards for the so-called white, illuminants. The most commonly used standard for white light is the Illuminant C, describing overcast sunlight at a colour temperature around 6770 K.

Besides the colour temperature, the quality of white light can also be measured by the so-called *colour-rendering index* R_a. R_a describes the colour of objects illuminated with the light source as compared to the illumination with a reference light source. The CIE defined eight different sample objects, again using sunlight as reference. At first, eight special values R_a are deduced from these objects and then the average R_a is calculated as the arithmetic average [102]. By definition, sunlight has $R_a = 100$, incandescent bulbs achieve R_a up to 100, fluorescent lamps $R_a = 85$ and Na-vapour lamps $R_a = 20$. A selection of some application-specific requirements on R_a is given in table B1.1.5. The colour rendering index is a relative parameter and does not describe the real appearance of illuminated objects

Table B1.1.5. Colour rendering index required for different applications.

Application	R_a
Indoor/retail	90
Indoor office/home	80
Indoor work area	60
Outdoor pedestrian area	≥ 60
Outdoor general illumination	≤ 40

Source: ODIA workshop on LEDs for solid state lighting, October 26–27, 2000, Albuquerque, NM.

or the true colour of the light source. Therefore, even bluish or reddish light sources can achieve the ideal value of 100. Table B1.1.6 summarizes the values of R_a for a selection of conventional and LED-based white light sources. Note that the colour rendering index is very important for all illumination purposes, but is irrelevant for many other applications such as white signals or signs.

B1.1.5.2 Phosphor-converted white LEDs

The first commercial white LEDs introduced by Nichia, used the same principle as white-emitting high pressure mercury lamps, that of adding a 'colour-correcting' phosphor to the bulb to convert part of the primary emission into yellow. These LEDs mixed the residual blue emission from the LED chip with the complementary yellow luminescence from phosphor. The first phosphor-converted white LEDs were developed by the Fraunhofer Institute for Solid State Physics (IAF) in Germany. Blue emitting GaN LEDs were used in conjunction with organic colour convertors. The luminescent dyes, dissolved in the epoxy resin, absorbed the blue light and re-emitted luminescence at different colours [103]. Using the same principle of luminescence conversion, the blue GaN emission could also be used to fabricate green, yellow and red LEDs [104].

Today, white LED light is usually achieved by the use of an efficient inorganic phosphor and a single blue LED [105, 106]. The resulting emission spectrum, together with the human eye sensitivity is shown in figure B1.1.33. The most common phosphors are based on yttrium aluminium garnet (YAG) doped with one or more rare earth elements or rare earth oxides. Optically active rare earth elements such as neodymium (Nd), erbium (Er), cerium (Ce) or thorium (Th) are widely used in light sources like lasers, light amplifiers or fluorescent tubes. A very common and extensively studied phosphor for blue-yellow conversion is YAG:Ce ($Y_3Al_5O_{12}:Ce^{3+}(4f1)$) [107]. Within the packaging procedure, the YAG phosphor powder is suspended in the epoxy and deposited directly on or around the LED die [108]. Colour temperature and colour rendering index of such a single-chip white LED can be adjusted by the amount of phosphor suspended in the epoxy and the emission wavelength of the LED die. From a production point of view, the packaging step is critical for maintaining consistency in the colour characteristics, because subtle variations in concentration or spatial distribution of the phosphor coating changes the tint of white light between a more yellowish- or bluish-white.

Typically, the emission of such devices appears as a bluish or cold white due to the low level of absorption in the phosphor. Because the emission of the blue LED is directional, while the phosphor converted light radiates over a 2π solid angle, the appearance of white changes for an observer looking

Table B1.1.6. Colour rendering of different LED-based and conventional white light sources [111].

Technology	R_a
Blue LED + yellow phosphor	75–80
Blue LED + green + red phosphors	≥ 90
UV LED + blue + green + red phosphor	≥ 90
Red + blue + green LED (610/470/560 nm)	60
Blue + yellow LED (500/595 nm)	40
Halogen W-filament incandescent lamp	100
Fluorescent lamp	85
Na vapour lamp	20–65
Hg vapour lamp	35–55

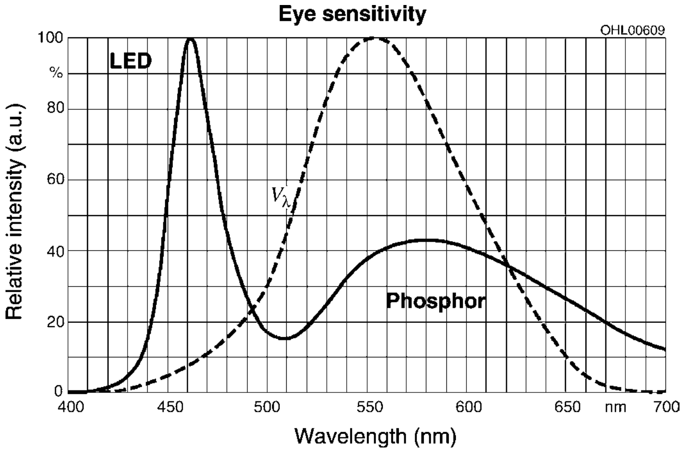

Figure B1.1.33. Spectral emission of a white LED based on phosphor conversion. Also shown is the human eye sensitivity with its maximum at 555 nm (green).

from the side. Compared to other approaches, phosphor converted LEDs have lower fabrication costs and offer a good control over quality and colour. Colour rendering with R_a around 75 is typically achieved at effective colour temperatures around 5000 K. The energy conversion efficiency of a single phosphor is below 60%, which is still rather low. Another drawback is the lifetime of the encapsulating materials which can degrade in the presence of the near-UV radiation tail from the blue LED die.

White light can also be generated by the combination of a near-UV (380–400 nm) LED and a two- or three-colour phosphor. The generation of white light by UV-pumped three-colour phosphors is widely used in fluorescent tubes and phosphors for the emission of the gas-discharge process at 254 nm are readily available. The overall efficiency of such an LED is given by the efficiency of the UV-LED, the degree of absorption in the phosphors and the efficiency of the wavelength-conversion process. Despite the challenging material constraints in the AlGaN/InGaN system [109], UV LEDs with remarkably high quantum efficiencies of up to 32% at 390 nm and output power levels of 21 mW at 20 mA have been reported [110]. Although less efficient than these record values, UV InGaN-LEDs with a few mW of output power are already commercially available. The UV absorption in the phosphors is still an issue for optimization and much effort is dedicated to either developing LEDs that match the absorption of existing phosphors or developing appropriate phosphors absorbing at wavelengths where the LED is most efficient. However, even with 100% UV-absorption, a substantial amount of energy is lost in the actual wavelength conversion processes which markedly limits the overall luminous performance of such devices.

A potential advantage of the UV-pumped phosphor-based LED is that the visible emission is solely originated by phosphorescence with a broad spectral output. The superposition of three broad lines at red, green and blue (e.g. 610, 560 and 470 nm) results in white light with excellent CRI values (>90). Also, the white point in the CIE chromaticity diagram is independent of the LED characteristics. Thus, in terms of colour rendering and colour stability the UV pumped phosphor-based LED is the most attractive source for white lighting.

B1.1.5.3 Multi-chip white

By definition, the addition of two complementary colours produces white. Hence, white light can also be generated by mixing the emission of two different LEDs with complementary colours. In the chromaticity diagram, the positions of complementary colours lie on opposite sides of the achromatic point with $x = y = 0.3333$. All white points along this line are accessible by adjusting the power ratio of the two monochromatic colours at the perimeter of the chromaticity diagram. An example for white light generated by a mixture of blue (490 nm) and amber (590 nm) is shown in figure B1.1.34. LED-based white light sources using two discrete colours are very efficient in terms of luminous performance ($\mathrm{lm\,W^{-1}}$) and costs/lumen. The main problem, however, is the very limited colour rendering which excludes this solution for general lighting applications. Despite this drawback, two-chip white LEDs are commercially available and used, e.g. as map lights in the interior of automobiles. The luminous output of such lamps can be increased by using several LEDs of each colour within the same package.

White with a better spectral distribution is generated by the mixture of three discrete colours of three different LED chips. The three-chip white LED has the advantage of providing no inherent loss mechanisms due to wavelength conversion to the emission from the primary sources. In the CIE chromaticity diagram, the three monochromatic colours span a triangle in which all mixed colours including white are accessible by the adjustment of the power ratios of the corner point colours. Figure B1.1.38 shows an arrangement of three LEDs (blue, green and red) in a single package. With individually addressable dices, such a multi-chip full colour LED lamp is capable of producing various mixed colours, including a range of whites. As a white light source, the multi-chip LED achieves relatively good colour rendering, colour temperatures between 3000 and 7000 K, and high efficiencies in terms of luminous performance [112]. Unlike single-chip white LED, the colour characteristics of multi-chip white LEDs can be altered after the packaging step. Used only as a source of white light, the multi-chip LED might be too expensive, but it is ideally suited for applications where variable-colour pixels are required. Commercial multi-chip LEDs are offered with three or even five dices of discrete colour in one lamp.

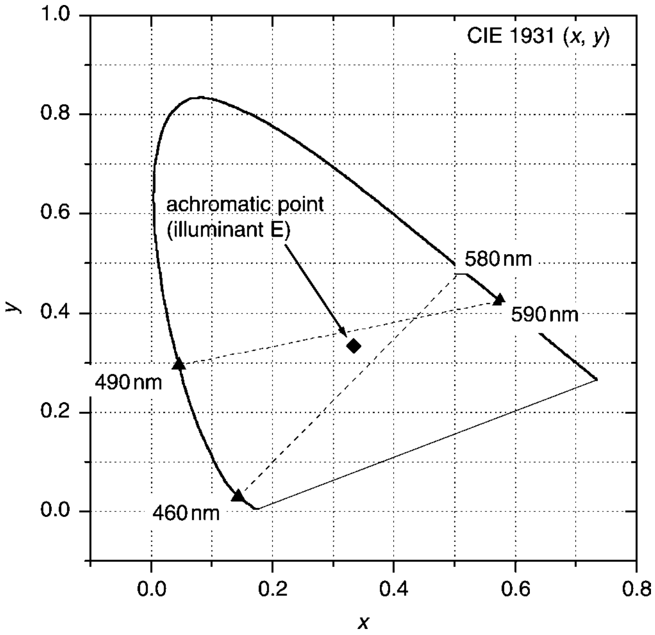

Figure B1.1.34. Examples for complementary colours in the CIE chromaticity diagram. The line between 490 and 590 nm is used for two-chip white LEDs. The 460–580 nm line is an example for white from phosphor-converted blue.

B1.1.6 Applications

B1.1.6.1 Packaging

The packaging technology is becoming increasingly important for the performance of LEDs in many current and future applications. Some of the older, conventional packages today are inadequate for the rapidly improving high brightness AlGaInP or InGaN dices. Novel packages must consider better optical, electrical and thermal performance. The demand for high reliability puts stringent requirements on the chemical and thermal stability of the packaging, die attach and encapsulating materials as well as the selected processes. Devices with light converting phosphors such as white LEDs have to take additional care of the efficiency and stability of the phosphor materials. The best monochromatic LEDs today achieve $>100\,\mathrm{lm\,W^{-1}}$ and the goal to achieve this and better efficiencies within the entire visible spectrum and, most importantly, in white LEDs will depend not only on the dices but also on the package used for assembly.

A simple radial LED package is shown in figure B1.1.35. It was originally designed for low current indoor applications and has a thermal resistance of max. $280\,\mathrm{K\,W^{-1}}$ (R_{thjs}, thermal resistance at junction solder point), limiting the electrical input power to some hundred mW. The die has typically a lateral dimension of 200–300 μm. It is attached to the metal lead frame with epoxy-based conductive glue, so that the lead frame can act as electrical contact to the outside. This metal is shaped in a way that it can act as a mirror cup as well as heat sink for the die. A separate metal pin is connected to the bond-pad on the chip and acts as second electrode. Chip and lead-frame are encapsulated by epoxy which has the form of a dome in order to achieve a certain radiation characteristics. The epoxy almost doubles the extraction efficiency due to its favourable refractive index around 1.5 and the non-planar epoxy–air interface. Standard diameters of the epoxy dome are 3 and 5 mm and the package is also named simply '5 or 3 mm-LED package'. About two-thirds of all high brightness LEDs are shipped in radial housings.

Packages for LEDs, like for most electronic components, can be divided into two categories: through hole and surface mount. Through hole components like the radial package are loaded to a PC-board from one side and soldered from the other. Surface mount devices (SMDs) are loaded and soldered on the same side. This has several benefits for industrial production such as faster placing in automatic machines, smaller size, less parasitic effects and lower costs. In particular, in applications where space is limited such as in mobile phones, the surface mount technology (SMT) is superior. Figure B1.1.36

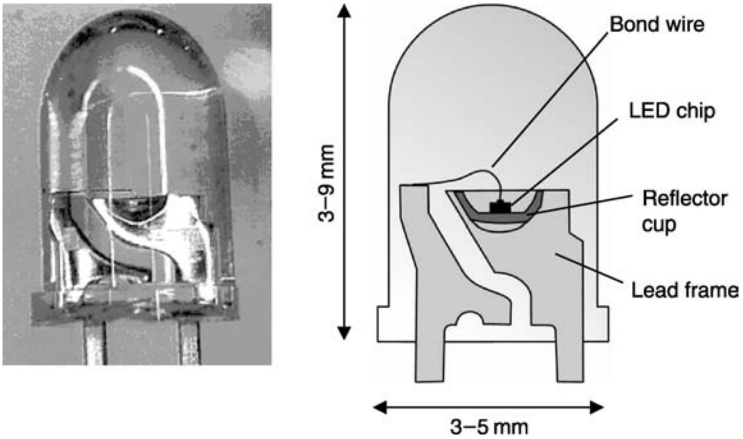

Figure B1.1.35. Radial LED lamp.

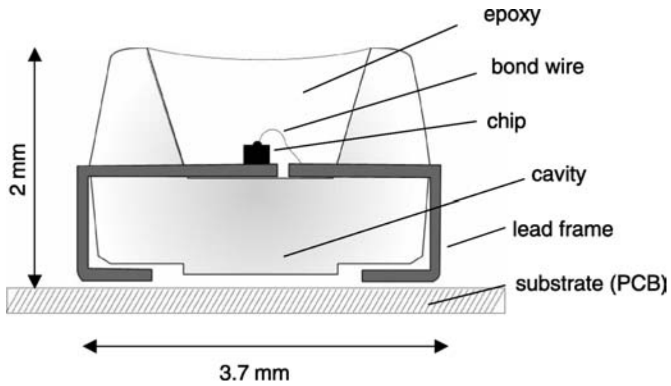

Figure B1.1.36. Schematic drawing of a surface mount LED package (TOPLED).

shows a standard SMT-package for LEDs with the lateral dimensions of $3.4 \times 3.0\,\mathrm{mm}^2$ and a height of 2.1 mm. The die is attached to the lead-frame with the pre-moulded housing of plastic (A-model). A bond wire connects the die's top electrode to the other part of the lead-frame. Finally, the housing is filled with encapsulating resin and, if necessary, one or more phosphor converters. The flat epoxy–air interface of SMT-packages results in a 10% lower extraction efficiency compared to radial packages with epoxy domes. However, for applications with the need for narrower emission profiles or more directionality, a transparent lens can be integrated (see figure B1.1.37).

Depending on the application, the leads are folded either outwards or inwards under the housing. Some packages use specially bent leads so that the LED can disappear in a hole in the PC-board while still being soldered from the top. SMT packages can be made very small. The smallest devices are 0.5–1 mm wide and high, which is just a little more than the dimensions of the die. The thermal resistance of SMT packages ranges from 300 to $500\,\mathrm{K\,W^{-1}}$. This limits the maximum applicable current to 100–150 mA. SMT packages can also house several chips, e.g. for the generation of white light or as multiple-colour LEDs. An example for a multi-chip SMT package is shown in figure B1.1.38.

High-flux LEDs are designed for operation currents of 1 A or even more. For this current range, the package has to be capable of dissipating thermal powers of 1–2 W. High power packages, like the one shown in figure B1.1.39, include a deep reflector and heat sinking metal base. The package can also include a lens-shaped epoxy dome to optimize the radiation pattern.

B1.1.6.2 Applications

For a long time, LEDs were low cost, low brightness devices suitable for single colour, low power applications, e.g. to illuminate switches, indicators, small signs or to transmit information. With the availability of high brightness yellow and red AlGaInP LEDs and the development of blue and green InGaN-LEDs, the full colour spectrum could be covered and a whole range of new applications opened up. A good example is signs and displays, where originally LEDs were only applied for monochromatic indoor numerical or text displays. Today, LED-based single or full colour outdoor signs can be found as variable message signs on motorways or large area video panels for entertainment arenas and sports stadiums. One of the largest high resolution outdoor panels is the outer skin of the NASDAQ-building at New York's Time Square, which consumes 18 million LEDs. The LED sign market accounts for about one-third of the total market for high brightness LEDs (2000: $1.22 billion).

LCD backlighting—The rising market for cellular phones has also opened up new opportunities for LEDs. Here, LEDs are used to illuminate both the LCD display as well as the keypad. In 2000 about 400

Micro SIDELED SmartLED

Figure B1.1.37. Examples for SMT packages. Note the small size of, e.g. the SmartLED: 0.8 × 1.2 and 0.6 mm height.

million cellular phones were sold worldwide with an average number of approximately ten LEDs per unit. This application is still dominated by standard-type low brightness GaP yellow-green LEDs, but the use of high-brightness devices, in particular white, is growing rapidly. The arguments for LEDs here is mainly their small size but also the low power consumption, which helps to prolong the battery lifetime. White LEDs are also increasingly used to illuminate other types of LCD displays such as digital camera displays, handheld computers or, maybe in a longer perspective, even large area LCD screens.

Traffic lights—Traffic lights are a typical example for an application, where LEDs as efficient monochromatic light sources can favourably compete with conventional solutions. A tungsten bulb with a red filter provides about 4 lm W^{-1} compared to more that 50 lm W^{-1} of a high-brightness AlGaInP-diode. The motivation to use LEDs is mainly driven by energy savings and reduced requirements for replacement. After the initial hurdles of standards and regulations were taken, high brightness AlGaInP-(red and yellow) and InGaN-LEDs (green) have an impressive degree of market penetration, especially in the US. In 2000 about 14% of all red and 6% of all green traffic signals in the US had been converted to high-brightness LEDs [113].

LEDs for automotive applications—Another application which increasingly consumes high numbers of LEDs is the interior and exterior illumination of automobiles. Inside a car, LEDs are used not onlly to backlight the dash panel, push buttons and indicator lamps but also LCD-displays, e.g. for the navigation system. Primarily, LEDs are used for dashboard illumination because their lifetime is

significantly longer than that of conventional incandescent bulbs. Despite the higher price for LEDs, cost savings can be achieved, because no replacement has to be considered, but also because surface mount LED packages allow for cost efficient automated dashboard assembly. In total, the number of LEDs inside a car can easily sum up to several hundred pieces per car.

The first application in the exterior was the centre high mounted stop light (CHMSL), which is still a steadily increasing market for AlGaInP red LEDs. While the CHMSL was for many years the only exterior LED application for automobiles, LEDs have now also started to penetrate other areas such as stop- or tail-lights and indicators. The benefits of LEDs here are their ruggedness, small size, low power consumption and the high reliability. They also offer a much faster turn-on time compared to incandescent bulbs, which is an important safety aspect for stop-lights and CHMSLs. Sometimes, LEDs are clustered in modules of 70 or 80 red and amber LEDs that combine the functions of stop-, tail- and indicator lights. So far only a few car manufacturers have started to equip some high-end car models with LED-based exterior functions, but it is expected that the number of LEDs in the exterior of automobiles and trucks will grow rapidly over the next years.

General lighting—The ultimate goal for the future of white LEDs is, of course, general lighting. This market is valued to approximately $12 billion and represents a huge potential market for LEDs. In order to make this happen, LEDs do have to face a number of issues that are relevant to the lighting industry. The efficiency of LEDs as well as the light-output generated per device or module has to be raised to the level of conventional lighting systems. In terms of efficiency, the target for white LEDs is somewhere between 100 and 150 $\mathrm{lm\,W^{-1}}$, the total generated flux should come up at least to levels of incandescent bulbs (1700 lm for a 100 W bulb). For indoor lighting, the colour rendering index R_a describing the appearance of colours when illuminated with LED light, should be higher than 80. The colour temperature of LED-white should at least replicate the values of fluorescent or incandescent (2850 K) lamps. Colour variations in different directions of radiation or variations from device to device have to stay within the acceptable ranges of conventional sources. The colour stability of phosphor-converted white LEDs is mainly an issue for the packaging process, whereas multi-chip LEDs require very reproducible intensity ratios or an active adjustment of the colour point. A long device lifetime is important to reduce the overall operating costs including replacement and maintenance. The crucial part for high reliability is the package including encapsulating and converter materials. Even if the diode chip alone has a lifetime of many ten thousand hours, the encapsulating materials tend to degrade faster in the presence of UV-photons. Finally, it is of paramount importance to reduce the cost for white LED light to competitive levels.

Acknowledgment

I would like to thank all colleagues at Osram Opto Semiconductors who contributed to this chapter. In particular, I thank the AlGaInP R&D team: Norbert Linder, Ralph Wirth, Walter Wegleiter, Reiner Windisch, Peter Stauss, Christian Karnutsch, Wolfgang Schmid, Ines Pietzonka, Simone Thaler, Gertraud Huber, Monika Mändl, Kornelia Kruger and Monika Kuttenberger.

Appendix A

A.1 The CIE colour system

In 1931, the Commission Internationale de l'Eclairage (CIE) produced the 'Colour Standard Table' in order to create an objective method of determining colours [114]. As a basis for standardization, the CIE chose the response of the three sets of colour receptors in the eye. Colours are measured by comparison with an additive mixture of three elementary colours and specified by the tristimulus values X, Y and Z. The next task was to find a way for a two-dimensional representation of colours in a colour map, similar to geographical maps. This was achieved by calculating a new set of variables, the colour-masses x, y and z from the measured tristimulus values by dividing each of them by their total sum: $x = X/(X + Y + Z)$, $y = Y/(X + Y + Z)$ and $z = Z/(X + Y + Z)$. With this conversion, only two values, e.g. x and y, remain independent and can be used as coordinates in a two-dimensional chart. A representation with the x-values on the horizontal axis and the y-values on the vertical axis is called the CIE chromaticity diagram. The saturated colours are located on the locus of the chromaticity diagram. A straight line, the 'purple line' joins the red and violet ends of the spectral locus to form a closed diagram. The colours on the purple line are mixtures of the spectral colours 770 and 400 nm on the right- and left-hand side. All existing colours lie within the tongue shape delineated by the line of spectral colours and the purple line (figure A1).

The CIE defined the colour coordinates of several illuminants to describe commonly used white light sources (table A1).

The special point E with the coordinates $x = y = 1/3$ is denoted 'equal energy' and locates the achromatic point representing greys and white. Complementary colours lie on opposite sides of the achromatic point. An important definition for the colour of LEDs is the *dominant wavelength*. It is defined as the spectral colour that is perceived to be the same as the colour of the LED. In the chromaticity diagram, the dominant wavelength can be determined by drawing a straight line from the achromatic point through the point representing LED colour (figure A2). The intersection of the

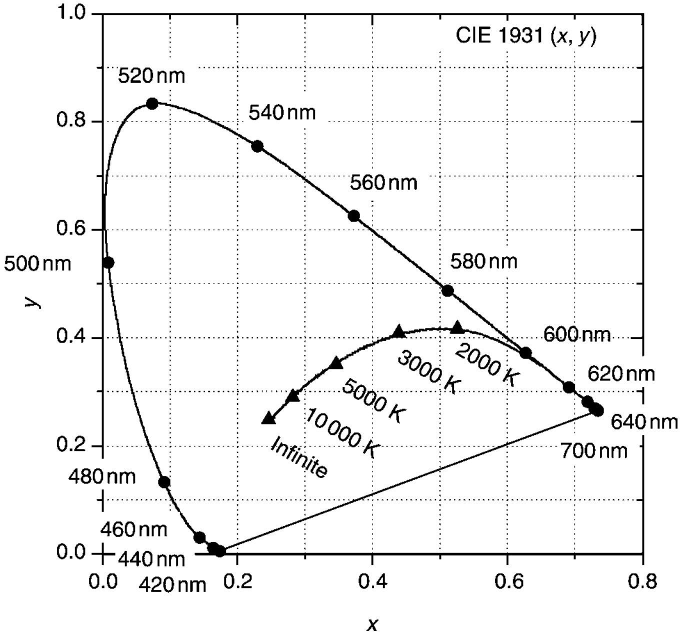

Figure A1. 1931 CIE diagram of colours. The solid line gives the black body radiation at temperatures from 1000 K to infinite.

prolonged line with the perimeter of the diagram gives the spectral colour that defines the dominant wavelength. This concept is also used to define the colour purity of a light source. *Colour purity* is a measure of how close the colour point lies to the perimeter of the CIE diagram. It is defined as the ratio of the distance of the colour point to the perimeter, weighted with the distance of the achromatic point to the same intersection point. Thus, the purity of a colour ranges from 0 for the achromatic point to 1 for saturated colours at the perimeter.

The human eye sensitivity has been defined and standardized by the CIE in 1924. Usually two response curves V_λ and V'_λ for day and night vision (photopic and scotopic vision) are used (figure A3). In daylight vision, yellowish-green light at 555 nm stimulates the eye more than blue or red light. At this wavelength, the human eye can detect about 10 photons s^{-1} or a radiant power of 3.58×10^{-18} W. At blue (450 nm) and red (650 nm), the eye detection limits are 214 and 126 photons s^{-1}, respectively [115].

Table A1. Colour coordinates and colour temperature of CIE Illuminants. Illuminant E is an imaginary colour with equal values for *x*, *y* and *z*.

	Illuminant	*x*	*y*	*T* (K)
Incandescent lamp	A	0.4476	0.4074	2856
Direct sunlight	B	0.3484	0.3516	4870
Overcast sunlight	C	0.3101	0.316	6770
Daylight	D_{65}	0.3128	0.32932	6504
Equal energy	E	0.3333	0.3333	

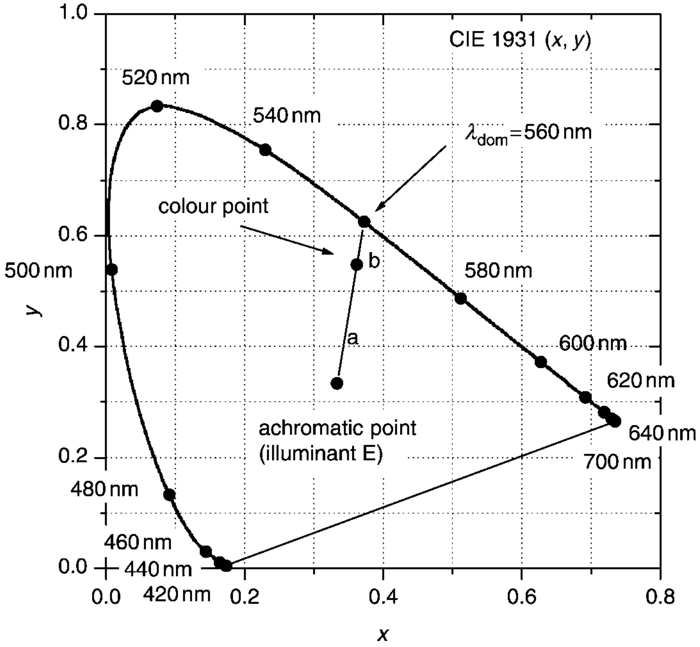

Figure A2. Dominant wavelength and spectral purity of a light source. The colour purity is defined as $a/(a+b)$.

A.2 Photometric and radiometric units

Radiometry is the measurement of electromagnetic radiation at all frequencies, whereas photometry is restricted to the measurement of visible light. The difference between the two methods is that in photometry everything is weighted by the human eye sensitivity.

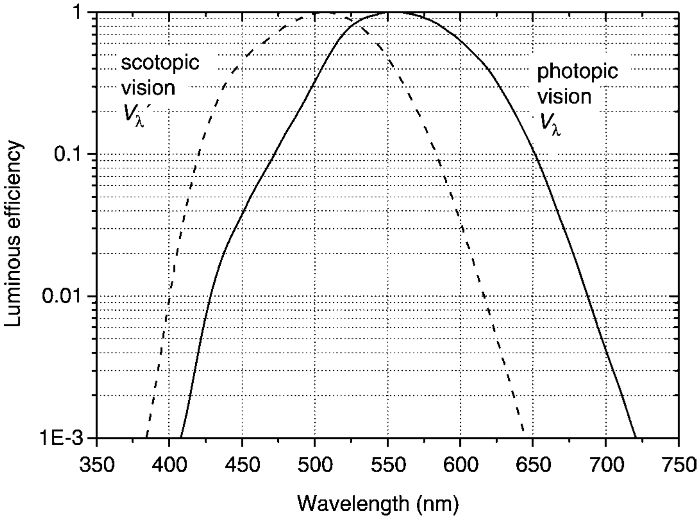

Figure A3. Spectral eye sensitivity curves V_λ and V'_λ for light-adapted (photopic) and dark-adapted (scotopic) vision. The peak of V'_λ is shifted 43 nm towards shorter wavelength.

Table A2. Radiometric and photometric units. Symbols for the radiometric quantities have the subscript e, and photometric quantities have the subscript v. The SI unit watt is suffixed with 'opt' and 'el' in order to denote the units of optical and electrical power.

Radiometric units		Photometric units	
Radiant flux ϕ_e	W_{opt} (watt)	Luminous flux ϕ_v	lm (lumen)
Radiant efficiency	W_{opt}/W_{el}	Luminous efficiency	lm/W_{el}
		Luminous efficacy	lm/W_{opt}
Radiant intensity I_e	W_{el}/sr	Luminous intensity I_v	lm/sr = cd (candela)
Radiance L_e	$W_{el}/sr\,m^2$	Luminance L_v	cd/m^2

W_{opt}, unit of the radiant flux (watt); W_{el}, unit of electrical power (watt); sr, SI unit of the solid angle (steradian).

In radiometry, the power flux of electromagnetic radiation is measured in watts (W). This flux is called the *radiant flux* ϕ_e of a light source. The photometric pendent to the radiant flux is the *luminous flux* ϕ_v and has the SI unit lumen (lm). The definition of lumen is related to the CIE eye response curve where 1 W of radiant flux at 555 nm wavelength is defined to have a luminous flux of 683 lm.

$$\phi_v = 683 V_\lambda \phi_e. \tag{A1}$$

Luminous efficiency is the ratio of luminous flux measured in lumen and the electrical power used to generate this flux measured in watt. One very confusing thing here is that watt as the general SI unit for power is used for optical and electrical measurements. Thus another term, the *luminous efficacy K* defined as the ratio of luminous flux and radiant flux has the same unit $\mathrm{lm\,W^{-1}}$.

$$K = \frac{\phi_v}{\phi_e}. \tag{A2}$$

Luminous efficiency is inevitably lower than the luminous efficacy, because some of the input power is lost in form of heat and does not appear as emitted radiant power. The efficiency of converting electrical power into radiant flux is measured by the *radiant efficiency* with the unit $\mathrm{W\,W^{-1}}$.

The total radiant or luminous flux does not indicate how the LED output varies with direction. For many applications, it is important to know how much power in watts or lumen is concentrated within a narrow angular range in a particular direction. This is measured by the *radiant intensity* I_e or the luminous intensity I_v of the LED in that direction. The units for *luminous intensity* are $\mathrm{W\,sr^{-1}}$ (sr = steradian) and $\mathrm{lm\,sr^{-1}}$, respectively. The latter unit, $\mathrm{lm\,sr^{-1}}$ is called candela (cd) and is equal to $1\,\mathrm{lm\,sr^{-1}}$.

The concept of radiant and luminous intensity applies only to point sources. Sources with an extended light-emitting area are characterized by the luminance, defined as luminous intensity per unit light-emitting area. The unit of *luminance* is $\mathrm{cd\,m^{-2}}$. Since light sources that emit the same luminous intensity from a smaller emitting area appear brighter, the term luminance is correlated with the qualitative term 'brightness'. The radiometric counterpart to luminance is *radiance*, which is the radiant flux per steradian per square metre of emitting surface area (table A2).

B1.2
Semiconductor lasers

Jens Buus

B1.2.1 Introduction

The semiconductor laser is now by far the most commonly used laser type, with several millions now being produced every month. It is also the most versatile laser type, allowing a variety of performance parameters to be optimized for specific applications: For example, the lasing wavelength can be tailored by the use of different materials and compositions, the spectral properties can be optimized, and lasers can be designed for high power levels.

Semiconductor lasers operating at visible wavelength around 650 nm (red) are widely used in pointers, bar code readers and DVD players. Lasers with wavelengths around 800 nm (just outside the visible part of the spectrum) are used in CD players and CD-ROM drives. The lasers for these applications have comparatively simple structures, making it possible to manufacture packaged laser assemblies for prices of the order of $1. Lasers used as transmitters in fibre optic communication systems, on the other hand, can cost several thousand dollars. These lasers usually work at wavelengths around 1300 nm (where the dispersion in standard fibres has its minimum) or 1550 nm (where the fibre loss has its minimum). Devices with a variety of performance characteristics, and prices, are available for different types of communication systems.

The widespread use of semiconductor lasers is due to a number of inherent advantages, including:

- simple electrical pumping merely by passing a current through the device;
- possibility of direct modulation by varying the pump current;
- high efficiency, over 50% conversion efficiency has been achieved;
- robustness and reliability;
- small size, typically 0.3 mm by 0.3 mm, i.e. a density of about 1000 per cm^2 is possible;
- amenable to automated mass production;
- large degree of freedom for optimization for specific applications.

The semiconductor laser differs from other laser types in many respects. A main reason for these differences is that the lasing transition occurs between electronic states in relatively broad *energy bands*, rather than between *discrete energy levels*. Another important difference is that very high gain coefficients (well over $100\,\mathrm{cm}^{-1}$) are possible. This in turn means that the laser cavities can be very short, and the end reflectivities can be quite low.

In this chapter, the basic principles and properties of semiconductor lasers will be outlined (sections B1.2.2–B1.2.6), and examples of some of the various semiconductor laser types will be given (sections B1.2.7–B1.2.12). The various sections are intended to be relatively independent, and the sections on the specific examples can be read without studying the more theoretical parts (sections B1.2.4–B1.2.6 in particular) in detail. For papers describing the historical development of semiconductor lasers, the reader is referred to [1, 2].

B1.2.2 General principles and basic structures

Nearly all semiconductor lasers are based on the *double heterostructure*. (We note in passing that Alferov and Kroemer shared half the 2000 Nobel Prize in physics for their work on heterostructures.) In this structure, a material with a relatively narrow bandgap—*the active layer*—(normally undoped) is sandwiched between a pair of n-type and p-type materials with wider bandgaps—*the confinement layers*. When this structure is forward biased, *quasi-Fermi levels* are formed, and electrons and holes are injected into the active layer from the n-type and p-type material, respectively. The Fermi level(s) is the energy where the probability of electron or hole occupation is 50%, and this (these) level(s) determine the energy distribution of electrons in the conduction band and holes in the valence band. *Population inversion*, and thereby gain, is achieved when the quasi-Fermi level separation exceeds the bandgap of the active layer, see figure B1.2.1.

If the bandgap difference is sufficiently large $E_{g_2} - E_{g_1} \gg k_B T$, where k_B is Boltzmann's constant and T the temperature. Then carriers injected into the active layer cannot escape over the heterobarrier, and carrier recombination can only take place in the active layer. Light generated in the active layer is not absorbed in the confinement layers, because semiconductors are transparent to light with a photon energy lower than the bandgap. The photon energy E is given by the product of Planck's constant h and the optical frequency ν, which is in turn equal to the speed of light in vacuum, c, divided by the wavelength, λ. Hence

$$E = h\nu = \frac{hc}{\lambda}. \tag{B1.2.1}$$

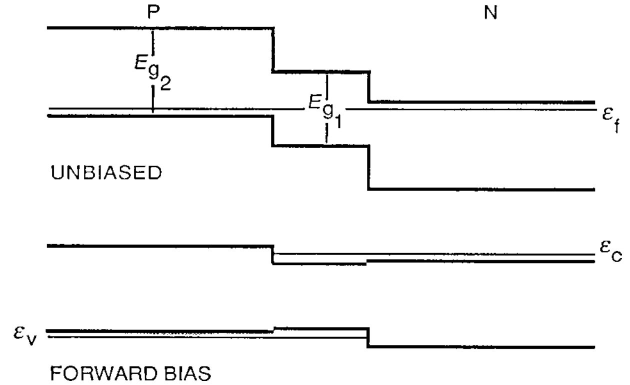

Figure B1.2.1. Double heterostructure formed in a material with a narrow bandgap E_{g_1}, placed between n-type and p-type materials with a wider bandgap E_{g_2}. Carriers cannot have energies that correspond to states within the bandgap. Without bias, the Fermi level ε_f is continuous. Under forward bias quasi-Fermi levels ε_c and ε_v are formed for electrons in the conduction band and for holes in the valence bands, respectively.

At a given optical frequency, a narrow bandgap semiconductor generally has a higher refractive index than a semiconductor with a wider bandgap. Consequently, the structure shown in figure B1.2.1 also forms a planar dielectric waveguide, with a high index core between a pair of low index cladding layers, analogous to an optical fibre. It is characteristic for a dielectric waveguide that only a part of the optical power is confined to the core, because the power distribution extends well into the cladding layers. The power fraction in the core is known as the *confinement factor*, and denoted by the symbol Γ.

The optical field distribution supported by the waveguide is known as a *mode*. The optical field propagates at a speed given by c/n_{eff}, where the *effective index*, n_{eff}, of the mode is higher than that of the cladding layers, but lower than that of the core.

The laser cavity forms a resonator, and the cavity length L and the effective index n_{eff} are related to the lasing wavelength λ by

$$n_{\mathrm{eff}}L = M\frac{\lambda}{2}. \tag{B1.2.2}$$

This states that the optical length of the cavity is an integer number of half wavelengths, where $M \gg 1$ is known as the (longitudinal) *modenumber*. The separation, also known as the *modespacing*, between two wavelengths (*longitudinal modes*) satisfying this condition (corresponding to modenumbers M and $M+1$) is

$$\Delta\lambda = \frac{\lambda^2}{2n_{\mathrm{eff}}L}. \tag{B1.2.3}$$

With an effective index of 3.5 and a cavity length 300 μm, the modespacing is about 0.2 nm for a lasing wavelength of 650 nm, and about 1 nm for a lasing wavelength of 1550 nm. Strictly, it is the *effective group index* which should be used in equation (B1.2.3) in order to account for dispersion.

The combination of amplification and feedback from the mirrors forms an oscillator, and oscillation takes place if the amplification balances the loss caused by light escaping through the mirrors. With a gain factor g, a cavity length L, and two mirrors both with a power reflectivity of R, this condition can be written as

$$\exp(gL)R\,\exp(gL)R = 1. \tag{B1.2.4}$$

Gain levels can be very high, this means that the lasing condition, as expressed in equation (B1.2.4), can be satisfied for low values of the reflectivity R, even for short cavity lengths (e.g. 300 μm as mentioned earlier). As semiconductors typically have refractive index values around 3.5, sufficient reflectivity (about 30–35%) can be obtained from a cleaved facet, and there is no need for special high reflectivity external mirrors as is the case for most other laser types.

It is important to note that the gain factor g in equation (B1.2.4) is the *net modal gain* experienced by the lasing mode. Taking internal optical losses, given by the *internal loss factor* α_{int}, into account, and noting that only the power fraction in the active layer, given by the confinement factor Γ, experiences gain, we have

$$g = \Gamma g_{\mathrm{act}} - \alpha_{\mathrm{int}} \tag{B1.2.5}$$

where g_{act} is the gain in the active layer.

If the two facet reflectivities are equal, as in equation (B1.2.4), equal amounts of power will be emitted from the two ends. This power balance can be changed by applying a facet coating to either increase the reflectivity (HR—high reflection coating), or to decrease the reflectivity (AR—anti-reflection coating). If, for example, the back facet reflectivity is increased to near unity, nearly all the light will be emitted from the front facet.

Light emitted from the ends can be accounted for by introducing an *end loss factor* α_{end}, which can be found by solving equation (B1.2.4) for the gain required to overcome the end losses. For the case of two equal facet reflectivities, we get

$$\alpha_{\text{end}} = \frac{1}{L}\ln\left(\frac{1}{R}\right). \tag{B1.2.6}$$

The condition for lasing is that the *available* gain, given by equation (B1.2.5), equals the gain *required* for lasing, given by equation (B1.2.6). This *lasing condition* can be written as

$$g = \Gamma g_{\text{act}} - \alpha_{\text{int}} = \alpha_{\text{end}}. \tag{B1.2.7}$$

The gain in the active layer, g_{act}, is an increasing function of the carrier density N in the active layer. As long as the carrier density is so low that the gain is insufficient to satisfy the lasing condition, the carrier density is related to the current I supplied to the laser by

$$I = \frac{eVN}{\tau} \tag{B1.2.8}$$

where e is the unit charge, V the volume of the active region and τ the *carrier lifetime*. (We should note here that the carrier lifetime may describe several recombination mechanisms, some of which in turn depend on the carrier density. Hence the carrier lifetime cannot necessarily be considered as a simple constant.)

We can now see that the laser is a threshold device. For low values of the current I, there is insufficient gain to satisfy the lasing condition, and only a small amount of light is generated by spontaneous emission. Lasing starts at the *threshold current* I_{th}, which is the current that gives a carrier density N_{th} that satisfies the lasing condition

$$\Gamma g_{\text{act}}(N_{\text{th}}) = \alpha_{\text{end}} + \alpha_{\text{int}} = g_{\text{th}} \tag{B1.2.9}$$

where N_{th} is referred to as the *threshold carrier density* and g_{th} is the *threshold gain*. For currents above the threshold, the gain does not increase any further and the carrier density remains at the threshold value. Stimulated recombination now takes place, and the amount of optical power emitted from the laser increases sharply. We describe this by introducing the *differential efficiency* η_{d}, which is the ratio of light 'lost' by emission through the facets to the total loss, hence

$$\eta_{\text{d}} = \frac{\alpha_{\text{end}}}{\alpha_{\text{end}} + \alpha_{\text{int}}}. \tag{B1.2.10}$$

The dependence of the carrier density and the emitted laser power as functions of the laser current are shown in figure B1.2.2.

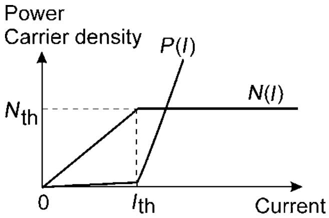

Figure B1.2.2. Carrier density N, and emitted laser power P, as functions of the current supplied to the laser. Below the threshold current there is only spontaneous emission, above the threshold the carrier density (and hence gain) remains fixed, and the power increases.

In order to work out the total power balance, we consider a laser operated at a current I, with an electrical resistance R', and a photon energy $h\nu$. Introducing the unit charge e, the voltage drop U across the laser is given by

$$U = IR' + \frac{h\nu}{e}. \tag{B1.2.11}$$

By multiplying this equation by the current I, we can write the power supplied to the laser as

$$IU = I^2R' + I_{\mathrm{th}}\frac{h\nu}{e} + (I - I_{\mathrm{th}})(1 - \eta_{\mathrm{d}})\frac{h\nu}{e} + (I - I_{\mathrm{th}})\eta_{\mathrm{d}}\frac{h\nu}{e}. \tag{B1.2.12}$$

The four terms on the right-hand side represent, respectively: ohmic losses, recombination losses, internal optical losses and emitted laser power (with one half of this power emitted from each end if the reflectivities are equal).

Example: For a facet reflectivity of 0.35 and a cavity length of 300 μm, the end loss, from equation (B1.2.6), is 35 cm^{-1}. If the internal optical loss is 20 cm^{-1}, and the confinement factor is 0.2, then equation (B1.2.9) gives the gain required in the active region as 275 cm^{-1}, and according to equation (B1.2.10), the differential efficiency is 0.64 (i.e. 0.32 per facet). We next assume that the width of the active region is 2 μm and its thickness is 0.1 μm. This gives an active volume of $60 \times 10^{-18}\ \mathrm{m}^3$. If the threshold carried density is $2 \times 10^{24}\ \mathrm{m}^{-3}$ and if the carrier lifetime is 2 ns, then, according to equation (B1.2.8), the threshold current is 9.6 mA.

As we have seen, the double heterostructure confines both carriers and light in the vertical direction. In order to reduce the volume of the active region (and hence, according to equation (B1.2.8), reduce the threshold current), there is also a need for lateral carrier confinement. The simplest approach is to limit the current injection to a narrow stripe along the length of the laser. However, there are problems associated with this: Firstly, there is still no well-defined carrier confinement, and, due to current spreading in the confinement layer and carrier diffusion in the active layer, the carriers will occupy a region much wider than the stripe, effectively giving a larger active volume. Secondly, there is no well-defined lateral optical waveguide, resulting in reduced beam quality and erratic optical behaviour.

These problems are partly solved by using the *ridge waveguide* (RW) structure shown in figure B1.2.3. The current is injected into a narrow ridge, and, due to the reduced thickness of the confinement layer outside the ridge, current spreading is reduced. In addition, the presence of the ridge creates a weak lateral optical waveguide, thus improving the optical confinement properties.

Strong lateral confinement of both carriers and light requires the active region to be completely surrounded by material with a larger bandgap. This is achieved in the *buried heterostructure* (BH) shown in figure B1.2.4. The improved performance of the BH lasers comes at a cost of a more complicated

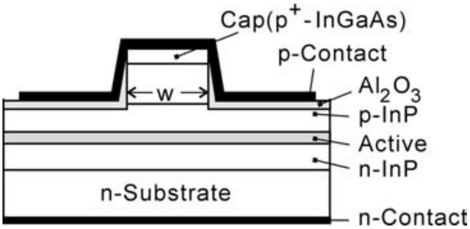

Figure B1.2.3. Schematic cross-section of an InP-based ridge waveguide laser. Due to current spreading, the effective active volume is somewhat wider than that corresponding to the ridge width w.

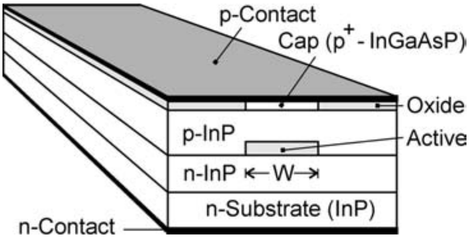

Figure B1.2.4. Schematic diagram of an InP-based buried heterostructure laser.

fabrication process. In order to fabricate a BH structure, multiple epitaxial growths, with intermediate stripe definition and etching processes, are necessary.

B1.2.3 Materials and fabrication technologies

Until now, almost all semiconductor lasers have been based on materials with a direct bandgap, usually using GaAs or InP substrates. In order to fabricate a double heterostructure, it is necessary to find materials that can be grown on these substrates, which have bandgaps different from the substrate material, and which have a lattice constant compatible with the substrate.

The simplest example is $Al_xGa_{1-x}As$, which consists of two group III elements (Al and Ga) and one group V element. The bandgap increases with the Al fraction (x), but the lattice constant remains nearly unchanged. A constant lattice constant is important in order to avoid the formation of defects during the growth of the material. A double heterostructure semiconductor laser is formed by having an active layer with a low Al content, and confinement layers with a high Al content. The difference in Al content must be sufficiently high to ensure sufficient carrier confinement. The photon energy for the laser is slightly higher than the bandgap of the active layer, and by changing the Al fraction in the active layer, this photon energy can be changed, resulting in lasers with wavelengths in the 800–900 nm range. We note that because the photon energy is higher than the bandgap of the substrate (GaAs), the lower cladding layer must be sufficiently thick to avoid absorption losses in the substrate.

More design flexibility is possible by using two group III and two group V materials. The prime example is $In_{1-x}Ga_xAs_yP_{1-y}$. Lattice matching to an InP substrate is achieved by having $x \approx 0.47y$, and the second degree of freedom in the composition can be used to vary the bandgap, and hence the wavelength. This makes it possible to fabricate lasers with wavelengths from around 1100 nm to nearly 1700 nm, covering the important 'telecommunications' wavelengths around 1300 and 1550 nm. Figure B1.2.5 shows the relation between bandgap and lattice constant. An alternative '*long wavelength*' material, also lattice matched to InP, is $(Al_xGa_{1-x})_yIn_{1-y}As$.

Lasing at visible wavelengths is convenient for applications such as bar code readers and pointers, and access to shorter wavelengths, with a smaller focused spot size potential, also makes it possible to achieve a higher information density on storage media such as DVDs. Lasers operating in the 600–700 nm range (red) can be fabricated using $(Al_xGa_{1-x})_yIn_{1-y}P$ compounds on GaAs substrates.

For even shorter wavelengths, corresponding to blue and green, ZnSe-based materials have been used, and there is currently a high level of activity on the development of short wavelength lasers based on $(Al_xGa_{1-x})_yIn_{1-y}N$ compounds.

For wavelengths around 2 μm antimony (Sb) containing materials have been used, and for even longer wavelengths there has been work on 'lead-salts' such as Pb(SSe), (PbSn)Te and (PbSn)Se.

It should be noted that, by using one or more very thin active layers, the lattice matching requirement can be relaxed making it possible to get access to an extended range of wavelengths.

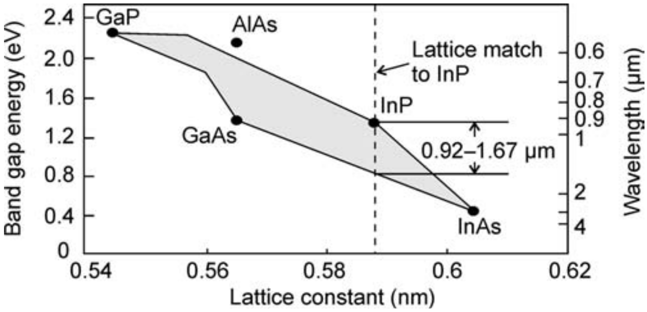

Figure B1.2.5. Bandgap energy, corresponding wavelength and lattice constant for InGaAsP compounds (and AlAs). Lattice matching to InP is indicated by the broken line. Notice the similarity of the lattice constants for GaAs and AlAs.

One example is lasers fabricated on GaAs substrates, with (InGa)As active layers and (AlGa)As confinement layers, operating at a wavelength of 980 nm for use as pump sources for Er-doped fibre amplifiers. This topic is discussed further in sections B1.2.5 and B1.2.9.

The growth and processing of layers with sub micrometre thickness, with high precision and a high degree of uniformity is technologically very demanding. The most commonly used technique for growth of heterostructures is *metal-organic chemical vapour phase epitaxy* (MOVPE). Hydrides such as arsine (AsH_3), phosphine (PH_3) and organometallics such as tri-methyl-gallium $Ga(CH_3)_3$ and tri-methyl-indium $In(CH_3)_3$ are carried by hydrogen and react on the surface of the wafer. The material composition is controlled by adjusting the flow rate of the various sources. Large wafers can be grown, and some reactors allow multi-wafer handling, making this technique suitable for large volume manufacturing. MOVPE requires very stringent safety measures due to the toxicity of the hydrides.

An alternative technology is *molecular beam epitaxy* (MBE). In this technique, beams of atoms or molecules impinge on a heated substrate. MBE is particularly suitable for high precision growth of very thin layers, but the requirement for ultra-high vacuum makes it very expensive. The fabrication of semiconductor lasers also requires high precision lithography and etching to form the active stripe, and some laser structures require multiple growths.

B1.2.4 Basic theory for gain in semiconductor lasers

The detailed calculation of the gain in the active layer of a double heterostructure is a rather lengthy procedure, and here we will only consider the main points of that procedure. For a more comprehensive and more accurate treatment the reader is referred to one of the standard texts, for example, reference [2] on the further reading list. Readers not familiar with basic solid state physics concepts may skip this section as it is not essential for the understanding of the remainder of this chapter.

In a semiconducting material, the electrons and holes do not move as free particles, so the relation between energy, momentum and mass is different from that of a free particle. However, in many cases, the relation between energy and momentum is still nearly parabolic, hence an *effective mass* can be defined. In most of the materials of interest for semiconductor lasers, we find that the effective mass for the electrons in the conduction band, m_c, is smaller than the effective mass for the holes in the valence band, m_v.

We consider the recombination of a hole and an electron, as shown in the band diagram in figure B1.2.6. Note that conservation of momentum corresponds to a vertical transition in such a diagram.

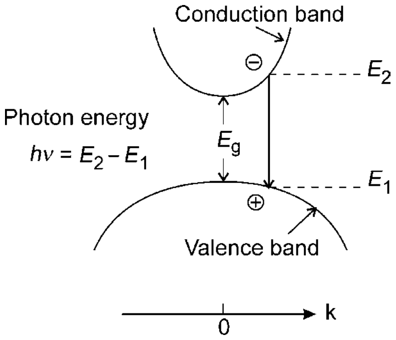

Figure B1.2.6. Band diagram of a semiconductor, where the effective mass for the electrons is smaller than the effective mass for the holes.

The energy of the photon emitted by the transition shown in figure B1.2.6 is given by

$$h\nu = E_2 - E_1 = E_\mathrm{g} + \frac{\hbar^2 k^2}{2m_\mathrm{c}} + \frac{\hbar^2 k^2}{2m_\mathrm{v}} = E_\mathrm{g} + \frac{\hbar^2 k^2}{2m_\mathrm{r}} \tag{B1.2.13}$$

where k is the wave vector, $\hbar k$ the momentum and $\hbar$ Planck's constant divided by 2π and the last equality serves as the definition of the *reduced mass* m_r. For vertical (i.e. momentum conserving) transitions we have, with $E = 0$ at the bottom of the conduction band

$$E_2 = (h\nu - E_\mathrm{g})\frac{m_\mathrm{r}}{m_\mathrm{c}} \quad \text{and} \quad E_1 = -E_g - (h\nu - E_\mathrm{g})\frac{m_\mathrm{r}}{m_\mathrm{v}}. \tag{B1.2.14}$$

We next need to know how many states are available corresponding to a given energy. This is given by the *density of states function,* which, for the case of parabolic bands, has a simple dependence on effective mass and energy. For the conduction band, we have

$$D_\mathrm{c}(E_2) = \frac{\sqrt{2}}{\pi^2 \hbar^3} m_\mathrm{c}^{3/2} \sqrt{(h\nu - E_\mathrm{g})\frac{m_\mathrm{r}}{m_\mathrm{c}}} \tag{B1.2.15a}$$

and for the valence band

$$D_\mathrm{v}(E_1) = \frac{\sqrt{2}}{\pi^2 \hbar^3} m_\mathrm{v}^{3/2} \sqrt{(h\nu - E_\mathrm{g})\frac{m_\mathrm{r}}{m_\mathrm{v}}}. \tag{B1.2.15b}$$

The *reduced density of states* at the transition energy is the reciprocal of the sum of the reciprocal densities of states given in equations (B1.2.15a) and (B1.2.15b)

$$D_\mathrm{r}(h\nu) = \frac{\sqrt{2}}{\pi^2 \hbar^3} m_\mathrm{r}^{3/2} \sqrt{(h\nu - E_\mathrm{g})}. \tag{B1.2.16}$$

Electrons and holes are *fermions*, and the probability that a certain energy state is occupied is therefore given by a *Fermi–Dirac distribution*. The number of occupied states with a given energy in the conduction band (unoccupied states, i.e. holes, in the valence band) is given by the product of the density of states in the conduction (valence) band, multiplied by the probability of occupation f_c (the probability of finding an empty state is $1 - f_v$). These probabilities are given by

$$f_c(E) = \frac{1}{1 + \exp\left(\frac{E - \varepsilon_c}{k_B T}\right)} \quad \text{and} \quad 1 - f_v(E) = \frac{1}{1 + \exp\left(-\frac{E - \varepsilon_v}{k_B T}\right)} \tag{B1.2.17}$$

where the Fermi level ε_c (ε_v) (cf figure B1.2.1) is found by requiring that the integral (over all energies) of the product of the density of states and the occupation probability is equal to the total number of electrons (holes). In the case of charge neutrality and no doping, the number of electrons must be equal to the number of holes. In equation (B1.2.17) k_B is Boltzmann's constant.

We can now write an expression for the increase of the optical energy density ρ, per unit time, at a given photon energy due to stimulated emission. This expression is the product of the reduced density of states, the occupation probability for the conduction band, the probability of having an empty state in the valence band and the transition probability (the Einstein B coefficient)

$$\frac{d\rho}{dt}(h\nu)_{\text{stim}} = D_r(h\nu) f_c(E_2)(1 - f_v(E_1))B\rho. \tag{B1.2.18}$$

The expression for absorption is similar, but the Fermi–Dirac factors have opposite roles, and there is a negative sign because absorption decreases the optical energy density

$$\frac{d\rho}{dt}(h\nu)_{\text{abs}} = -D_r(h\nu) f_v(E_1)(1 - f_c(E_2))B\rho. \tag{B1.2.19}$$

By adding these two expressions, we get the result for the net increase in the optical energy density per unit time

$$\frac{d\rho}{dt}(h\nu)_{\text{net}} = D_r(h\nu)(f_c(E_2) - f_v(E_1))B\rho. \tag{B1.2.20}$$

The factor preceding ρ on the right-hand side of equation (B1.2.20) is simply the gain per unit time.

It is simple to show that, in order to have a positive gain factor, the separation between the Fermi levels must exceed the transition energy, which in turn must exceed the bandgap

$$f_c(E_2) > f_v(E_1) \text{ for } \varepsilon_c - \varepsilon_v > h\nu = E_2 - E_1 > E_g. \tag{B1.2.21}$$

The transition probability B, can be found from *Fermi's Golden Rule*, which gives the probability in terms of the matrix element of the interaction Hamiltonian

$$B = \frac{\pi}{2\hbar}|H|^2. \tag{B1.2.22}$$

It now requires some more detailed solid state physics theory to find the matrix element, here the result is simply quoted, m_0 is the free electron mass, ε_0 the free space permittivity and n the refractive index

$$|H|^2 = \frac{2e^2\hbar^2}{m_0^2 \varepsilon_0 n^2 h\nu}|M|^2 \tag{B1.2.23}$$

with the approximate expression

$$|M|^2 \approx \frac{m_0^2}{12m_c} E_g. \tag{B1.2.24}$$

Finally, the gain per unit length is written as the gain per unit time divided by the group velocity of the light in the laser, given by c divided by n_g. The resulting expression consists of three parts. The first is material dependent but energy independent, the second contains the square root of the energy dependence from the density of states, and the last factor comes from the occupation probabilities

$$g \approx \frac{\sqrt{2}e^2 m_r^{3/2} n_g}{12\pi\hbar^2 m_c \varepsilon_0 n^2 c} \frac{E_g}{h\nu} \sqrt{h\nu - E_g}(f_c - f_v). \tag{B1.2.25}$$

It must be stressed that this gain calculation is somewhat simplified, for example, we have only considered vertical transitions in the energy diagram, i.e. strict conservation of momentum, or k. Nevertheless, the result is of the correct magnitude, and gives a nearly correct parameter dependence.

The gain depends on the carrier (i.e. electron and hole) density through the Fermi–Dirac factor $(f_c - f_v)$. With increasing carrier density, the Fermi levels ε_c and ε_v move further into the bands, and the function $(f_c - f_v)$ moves towards higher energies, as illustrated in figure B1.2.7.

The gain is positive for photon energies in the interval between E_g and $(\varepsilon_c - \varepsilon_v)$. For higher photon energies, the gain is negative, i.e. the material is absorbing, and for photon energies below E_g the material is transparent. We notice that the photon energy corresponding to the maximum gain increases with increasing carrier density (this is known as *bandfilling*).

It is a characteristic of semiconductor lasers that the gain can reach values of several hundred cm^{-1}, far higher than in any other laser type. This explains why the lasers can be short, yet still lase with low facet reflectivities, cf equation (B1.2.6) for the facet loss. Another characteristic feature of the gain curves is that they are very wide compared to other laser types. This is due to the fact that the lasing transition occurs between two bands of energies rather than between two discrete energy levels.

The expression for gain given by equation (B1.2.25) is too cumbersome for direct use in device design and modelling. It is often sufficient to describe the gain, at a given photon energy, as a simple linear function of the carrier density

$$g \approx a(N - N_0). \tag{B1.2.26}$$

The parameter a is called the *gain slope* and N_0 is referred to as the *transparency carrier density*.

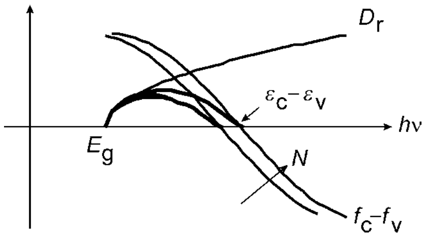

Figure B1.2.7. Fermi–Dirac factor $(f_c - f_v)$ for two different carrier densities. According to equation (B1.2.25), the gain is (apart from a numerical factor) mainly given by the product of $(f_c - f_v)$ and the reduced density of states D_r, which in turn varies as the square root of $(h\nu - E_g)$. This gives the gain curves for the two carrier densities, shown as bold curves.

In some cases, in particular, for quantum well lasers (see section B1.2.5), it is more appropriate to approximate the dependence of the gain on the carrier density by a logarithmic expression

$$g \approx g_0 \ln\left(\frac{N}{N_0}\right). \tag{B1.2.27}$$

B1.2.5 Structures with reduced dimensionality

In a semiconductor heterostructure, which is small in one or more dimensions, the carriers (electrons and holes) do not behave like particles. Instead, they start to display wave nature, and their behaviour must be treated according to the rules of quantum mechanics. By 'small' we mean that the size of the structure, in one or more directions, is of the order of the *de Broglie wavelength*, λ_d, which is given by

$$\lambda_\mathrm{d} = \frac{2\pi}{k} = \frac{h}{p} \tag{B1.2.28}$$

where k is the wave vector, h Planck's constant and p the momentum of the particle.

The case where the structure is 'small' in only one dimension, usually the thickness of the active layer, is known as a *quantum well*, and is one of the basic examples of the application of quantum mechanics. For a particle in an *infinitely deep* quantum well, the values for the wave vector are quantized according to

$$k_N = \left(\frac{\pi}{L_z}\right)N, \quad N = 1, 2, 3, \ldots \tag{B1.2.29}$$

where L_z is the *width* of the quantum well. By combining equations (B1.2.28) and (B1.2.29) with the relation between energy and momentum, we find that, with m being the mass (i.e. effective mass in the case of a semiconductor), the corresponding energy levels are given by

$$E_N = \frac{1}{8m}\left(\frac{hN}{L_z}\right)^2. \tag{B1.2.30}$$

For the case of a finite well depth, there are a finite number of energy levels, also known *as mini bands or sub bands*. If the well is sufficiently narrow (about a few nanometres), there will only be one possible energy level. For a more detailed treatment of quantum wells, the reader should consult, for example, reference [4] on the further reading list.

We note in passing that a quantum well is mathematically analogous to a waveguide: The different energy levels correspond to the modes of the waveguide; a 'small' waveguide supports one mode only; an infinitely deep quantum well is equivalent to a metallic waveguide.

Although a quantum well confines the carriers in one dimension, i.e. the carriers cannot move freely in the direction perpendicular to the well, there is no confinement in the other two dimensions, i.e. in the well plane, and the carriers can move freely in these two dimensions. The confinement changes the density of states function. We recall from equations (B1.2.15a) and (B1.2.15b) that, for bulk material the density of states varies with the square root of the energy

$$D(E) \propto \sqrt{E}. \tag{B1.2.31}$$

In a quantum well, the density of states associated with energy level N is given by a step function

$$D_N(E) = 0 \quad \text{for } E < E_N, \quad D_N(E) = \frac{m}{\pi\hbar^2 L_z} \quad \text{for } E > E_N \tag{B1.2.32}$$

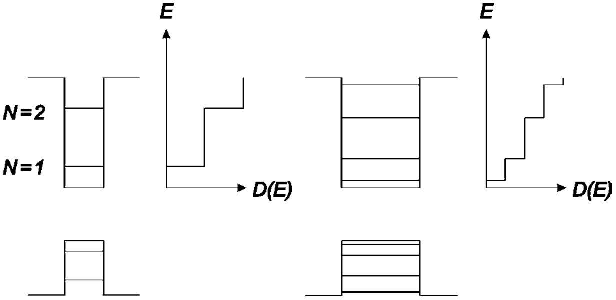

Figure B1.2.8. Energy levels in a 'thin' (left) and in a 'thick' (right) quantum well. Both the conduction bands and the valence bands are shown, assuming that the confinement energy is higher for the conduction bands than for the valence bands. It is also assumed that the effective mass is higher for the valence band than for the conduction band, leading to smaller energy level separations in the valence band. Because the quantum well has a finite depth, the positions of the energy levels deviate somewhat from the simple expression in equation (B1.2.30). The density of states functions for the conduction bands are also shown. The diagrams are schematic, and do not refer to a specific set of material parameters.

where again L_z is the width of the quantum well. As the value of the gain depends on the density of states function, cf equation (B1.2.20), the gain properties of a quantum well differ from those of bulk material. Very high gain coefficients are possible, but the gain tends to depend sub-linearly on the carrier density, as for example described by the approximation in equation (B1.2.27). In working out the details of the gain, a number of factors must be considered: All the subbands must be included, selection rules apply, so that transitions from a given subband in the conduction band are only allowed to the corresponding subband in the valence band, and the gain depends on the polarization of the optical field, see references [2, 4] on the further reading list for details.

According to equation (B1.2.30), the positions of the energy levels vary as the square of the level number. For a 'very thick' quantum well, the density of states summed over all the sub bands will therefore vary as the square root of the energy, thus recovering the result for bulk material given by equation (B1.2.31).

Figure B1.2.8 shows, schematically, examples of energy levels and density of states in quantum wells.

A single quantum well active region is too thin to provide efficient optical confinement, and it is normal to use a *separate confinement* structure, where the optical guiding is provided by a region which is much thicker than the quantum well. It is also possible to use more than one quantum well (see figure B1.2.9).

In a separate confinement structure, some of the important design considerations are de-coupled. For a given width of the quantum well(s), the optical confinement factor, defined as the overlap of the quantum well(s) and the optical field, is nearly completely determined by the design of the optical confinement region and almost independent of the quantum well(s). The quantum well properties, on the other hand, are determined by the combination of well width and depth. As the well width and depth determine the energy levels, these parameters partly determine the lasing wavelength.

A quantum well is very thin, typically less than 10 nm, and, although the gain in a quantum well can be high, the confinement factor is low, usually not more than a few percent per well. According to equation (B1.2.5) this gives a low value for the *modal* gain. As the gain increases sub-linearly with carrier density, it may be advantageous to have several wells, in spite of the fact that this increases the total

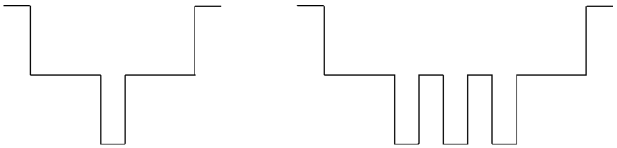

Figure B1.2.9. Band diagram (conduction band only) for separate confinement single (left) and multi (right) quantum well laser structures. Optical confinement is provided by the wide, low bandgap (high refractive index), optical confinement region. Carrier confinement is provided by the quantum well(s).

active volume. It is thus seen that, for a given threshold gain, it is possible to minimize the threshold current by optimizing the number of wells.

The degree of design freedom for the gain function in a quantum well structure also gives some scope for optimizing lasers for high-speed operation (see section B1.2.6 on laser dynamics).

We have previously mentioned that lattice matching is important to ensure a sufficient material quality. For a sufficiently thin layer, this condition is relaxed, because the misfit can be accommodated by strain without the formation of dislocations. For a single quantum well, the *critical thickness*, which is the maximum layer thickness that can be formed without dislocations, is approximately given by

$$t_\mathrm{c} \approx 0.2\left(\frac{\Delta a}{a}\right)^{-1}\ \mathrm{nm} \tag{B1.2.33}$$

where a is the lattice constant and Δa the lattice constant difference. As an example, this implies that a layer thickness of 20 nm is possible with a lattice mismatch of 1%. The lattice mismatch is accommodated by strain (tensile or compressive) of the quantum well layer.

The use of *strained quantum wells* makes it possible to use materials for which binary substrates are not available. An important practical result of this is that it gives access to new lasing wavelengths such as 980 nm, which is used for the pumping of fibre amplifiers (see also section B1.2.9). The strain also changes the band structure and hence the electronic properties of the material, and gives more flexibility for the optimization of laser performance.

By reducing the feature size(s) in one or two additional dimensions, *quantum wires* and *quantum dots* are formed. An important application of quantum dots is the fabrication of lasers operating at the 'telecom' wavelength of 1300 nm on GaAs substrates by using highly strained (InGa)As dots. In a quantum dot, the energy levels are discrete and the density of states function becomes a sum of δ functions. Consequently, some properties of these lasers become akin to those of gas or solid state lasers.

B1.2.6 Dynamics and noise

As mentioned in section B1.2.1, one of the major advantages of semiconductor lasers is that they can be directly current pumped. This also opens the possibility for *direct modulation* simply by varying the pump current. *Analogue modulation* can be performed by DC biasing the laser above threshold and superimposing an AC modulation current. In *digital modulation,* the laser is DC biased close to threshold, and a digital modulation current is superimposed.

In order to assess the modulation properties, we need to look at the dynamic behaviour of the laser, this behaviour is determined by the interaction of the carriers and the photons in the laser. As carriers (electrons and holes) are injected into the active region, they can either recombine spontaneously or by stimulated recombination brought about by the photon density in the active region. The photon density, on the other hand, is subject to both gain, due to the stimulated recombination of the carriers, and to losses, either internal losses, or losses due to photons being emitted from the end facets of the laser.

The interactions between the carrier density, N, and the photon density, S, are described by the so-called *rate equations* for the laser. In their simplest form, these equations can be written as

$$\frac{\mathrm{d}N}{\mathrm{d}t} = \frac{I}{eV} - \frac{N}{\tau} - v_\mathrm{g}\Gamma g_\mathrm{act}S \tag{B1.2.34}$$

$$\frac{\mathrm{d}S}{\mathrm{d}t} = v_\mathrm{g}\Gamma g_\mathrm{act}S - v_\mathrm{g}(\alpha_\mathrm{end} + \alpha_\mathrm{int})S + \beta\frac{N}{\tau}. \tag{B1.2.35}$$

Equation (B1.2.34) gives the time dependence of the carrier density. The first term on the right-hand side is the pump term, where I is the current supplied to the laser, e the unit charge and V the active volume of the laser. The second term accounts for spontaneous recombination with τ being the spontaneous lifetime. Finally, the last term accounts for stimulated recombination with Γg_act being the modal gain. Here Γ is the confinement factor, g_act the gain in the active region (cf section B1.2.2), and v_g the group velocity of the light in the laser. The group velocity appears because the rate equations describe the development of the carrier and photon densities in time, whereas the gain (and loss) describes the spatial evolution of the photon density.

The second rate equation (B1.2.35) describes the time dependence of the photon density. The first term on the right-hand side is recognized as the stimulated recombination term. The second term accounts for losses, with α_end describing facet losses and α_int being the internal loss coefficient. The final term occurs because a fraction β of the spontaneous emission events adds a photon to the lasing mode.

Under static conditions, the left-hand sides of equations (B1.2.34) and (B1.2.35) vanish, and if the current is below the threshold, the photon density is very small. Equation (B1.2.34) then reduces to the relation between current and carrier density, as given by equation (B1.2.8) in section B1.2.2. Under static conditions above the threshold, equation (B1.2.34) gives

$$S = \frac{I - I_\mathrm{th}}{eV}\frac{1}{v_\mathrm{g}\Gamma g_\mathrm{act}}. \tag{B1.2.36}$$

In order to translate the photon density S to optical power, we first multiply by the photon energy $h\nu$ to get the optical energy density, then by the active volume V to get the total optical energy in the laser, and finally by the facet loss rate $v_\mathrm{g}\alpha_\mathrm{end}$ to get the emitted power (from both ends of the laser). Hence

$$P = v_\mathrm{g}\alpha_\mathrm{end}Vh\nu S. \tag{B1.2.37}$$

Combining equations (B1.2.36) and (B1.2.37) and using the gain condition equation (B1.2.9) (or alternatively using equation (B1.2.35) for steady state with the last term neglected) gives the relation between optical power and current

$$P = (I - I_\mathrm{th})\frac{\alpha_\mathrm{end}}{\alpha_\mathrm{end} + \alpha_\mathrm{int}}\frac{h\nu}{e} \tag{B1.2.38}$$

in agreement with the results from section B1.2.2.

In writing the rate equations in the form given by equations (B1.2.34) and (B1.2.35), we have implicitly assumed that there was only one lasing mode. If several modes are lasing, there will be a photon density rate equation like equation (B1.2.35) for each mode, and the last term on the right-hand side of the carrier density rate equation, equation (B1.2.34), has to be summed over all lasing modes.

Before starting to derive results from the rate equations, some of the terms need to be discussed in more detail. Looking first at the second term on the right-hand side of equation (B1.2.34), we rewrite it as a polynomial expression

$$\frac{N}{\tau} = \frac{N}{\tau_{\mathrm{nr}}} + BN^2 + CN^3. \tag{B1.2.39}$$

In this expression, the first term accounts for *nonradiative recombination*, the second for *radiative recombination*, and the third term for *Auger recombination*. This latter is a higher order process which is particularly important at high carrier densities. It is seen that the carrier lifetime, τ, is not a constant, but depends on the carrier density.

Under conditions where the variations in the carrier density are small, it is convenient to introduce a *differential carrier lifetime*, defined by

$$\frac{1}{\tau'} = \frac{\mathrm{d}}{\mathrm{d}N}\left(\frac{N}{\tau}\right) = \frac{1}{\tau_{\mathrm{nr}}} + 2BN + 3CN^2. \tag{B1.2.40}$$

For the case where the three recombination term in equation (B1.2.39) are comparable, it follows that the differential carrier lifetime from equation (B1.2.40) is close to half the average carrier lifetime. Carrier lifetimes are typically in the range between one and a few nanoseconds.

In the last term in equation (B1.2.35) β is the fraction of the spontaneous emission events which add a photon to the lasing mode. Because the total number of modes is proportional to the laser volume V, it follows that β is proportional to the reciprocal of the volume. It is convenient to rewrite the spontaneous emission term as

$$\beta\frac{N}{\tau} = \frac{v_{\mathrm{g}}\Gamma g_{\mathrm{act}} n_{\mathrm{sp}}}{V} = \frac{R_{\mathrm{sp}}}{V} \tag{B1.2.41}$$

where n_{sp} is known as the *population inversion factor* and usually has a value between 1 and 2, with a value of 1 corresponding to complete inversion. Using equation (B1.2.41) in equation (B1.2.35), and comparing the first term with the third term, shows that we have VS photons due to stimulated emission in the laser and n_{sp} photons due to spontaneous emission. For operation close to, or above, the lasing threshold, the carrier density is close to or equal to the threshold carrier density, and we can replace Γg_{act} by g_{th} in equation (B1.2.41).

It turns out, that the rate equations in the form given by equations (B1.2.34) and (B1.2.35) do not agree fully with the observed laser behaviour. It is found that better agreement is obtained by including a nonlinear gain term, according to

$$g_{\mathrm{act}} \Rightarrow g_{\mathrm{act}}(1 - \varepsilon S) \tag{B1.2.42}$$

where ε is the *gain suppression parameter*. Such a nonlinear term may be somewhat surprising, because semiconductor lasers are usually regarded as being *homogeneously broadened*, i.e. a change in the carrier density (and hence the gain) due to stimulated recombination, will affect the gain over the whole spectral range. However, there is evidence that some degree of spectral hole burning (*inhomogeneous broadening*) is present, and carrier dynamics may also play a role.

The nonlinear gain gives rise to additional damping, and also explain why the spectrum is broader (i.e. contains more longitudinal modes) than might otherwise have been expected.

Because the rate equations are nonlinear, due to the dependence of the gain on the carrier density, they cannot in general be solved analytically, but a number of important results can still be derived from them. In the case of weak modulation, where the current I consists of a bias current plus a superimposed small signal modulation current, the rate equations can be linearized by expanding the current, the carrier density and the photon density around an operating point according to

$$X(t) = \overline{X} + \Delta X \exp(\,\mathrm{j}\omega t) \tag{B1.2.43}$$

with $X = I, N, S$ and $\Delta X \ll \overline{X}$. With a linear dependence of gain on carrier density, equation (B1.2.26), using equations (B1.2.40)–(B1.2.42), we eliminate the steady-state solution, and assume that the carrier density is close to the threshold carrier density. By discarding terms containing products of ΔX, it can be shown (see, for example [2] or [5] on the further reading list for details) that the laser modulation response has the form

$$\frac{\Delta S}{\Delta I} = \frac{1}{eVv_{\mathrm{g}}\Gamma g_{\mathrm{act}}} H(\omega), \quad H(\omega) = \frac{1}{1 + \dfrac{\mathrm{j}\omega\gamma}{\omega_{\mathrm{R}}^2} - \left(\dfrac{\omega}{\omega_{\mathrm{R}}}\right)^2}. \tag{B1.2.44}$$

The resonance frequency is given by

$$\omega_{\mathrm{R}} = \sqrt{v_{\mathrm{g}}^2 \Gamma a g_{\mathrm{th}} \overline{S}} \tag{B1.2.45}$$

where a is the gain slope from equation (B1.2.26), and g_{th} is the threshold gain from equation (B1.2.9). Because the photon density is proportional to the power, equation (B1.2.37), it follows that the resonance frequency increases with the square root of the power. It can be shown that the *damping rate* γ varies linearly with the square of the resonance frequency. The degree of damping is determined by spontaneous emission and by the nonlinear gain.

Resonance frequencies well in excess of 10 GHz can be achieved, and it is found that the resonance frequency is a reasonable measure of how fast the laser can be modulated. In the case of low damping, the 3 dB cut-off frequency is about 50% above the resonance frequency. For modulation frequencies above the resonance frequency, the laser response drops off rapidly. Ultimately, the 3 dB frequency will be limited by damping, because the damping increasing with increasing resonance frequency. Maximum modulation frequencies above 30 GHz have been reported. From equation (B1.2.45), it is seen that for achieving a high value of the resonance frequency, the laser should be operated high above threshold, and be designed to have a high value of the gain slope parameter.

Because the rate equations deal with the interaction of carriers and photons in the active region, other factors can influence the laser dynamics. *Parasitic elements*, such as the combination of a series resistance and a parallel capacitance, may reduce the achievable modulation frequency. *Carrier transport effects* can also lead to a roll off in the laser response at high frequencies. Other results that can be derived from the linearized rate equations include *harmonic distortion* and *intermodulation products* [3].

In general, an investigation of the large signal properties will require a numerical solution of the rate equations. An important practical case is the *turn on transient* when the current is changed from a value close to, or even below, threshold to an 'on' value well above threshold (see figure B1.2.10). The behaviour is explained as follows: Below threshold the photon density is very small, and the last term in the carrier density rate equation can be neglected. When the current is increased, the carrier density will increase and even exceed the threshold carrier density. As the gain is now above the lasing threshold, the photon density will increase rapidly, but when the photon density is sufficiently high, the carrier density will start to drop due to the stimulated emissions. When the carrier density drops back below the threshold carrier density, the photon density will start to fall, but when the photon density gets low, the carrier density will start to increase again. This process goes on until a steady-state situation is reached, with a photon density (and hence power) corresponding to the current. The frequency of the *ringing* in the turn on transient is equal to the resonance frequency corresponding to the 'on' level.

For digital modulation the *turn on* and *turn off* times are of importance. Analytical approximations for these times are given in [4].

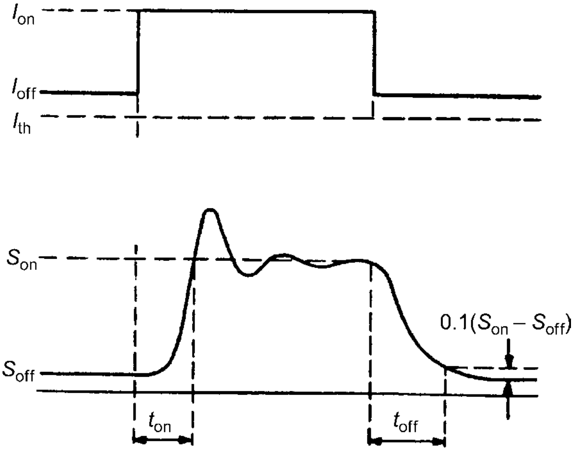

Figure B1.2.10. Digital modulation with the laser current being switched between 'off' and 'on' levels. The figure shows the turn on transient with the accompanying ringing, after [4].

$$t_{\mathrm{on}} = \frac{\sqrt{2}}{\omega_{\mathrm{R}}}\sqrt{\ln\left(\frac{S_{\mathrm{on}}}{S_{\mathrm{off}}}\right)} \qquad \text{(B1.2.46)}$$

$$t_{\mathrm{off}} = \frac{2\pi(\sqrt{2}-1)}{\omega_{\mathrm{R}}} + \frac{\varepsilon}{v_{\mathrm{g}}\Gamma a}. \qquad \text{(B1.2.47)}$$

The resonance frequency appearing in equations (B1.2.46) and (B1.2.47) is the one corresponding to the 'on' level. A careful balance must be found in setting the 'off' level. If it is too low, the turn on time will be long, and if it too high the *extinction ratio*, defined as the ratio between the 'on' and the 'off' levels will be too low.

Taking into account that spontaneous emissions do not occur at a constant rate, but are the result of a statistical process, it is possible to derive results for the laser *relative intensity noise* (RIN) of the laser power, and its spectral distribution. The frequency dependence of the RIN can be written as

$$\mathrm{RIN}(\omega) = |H(\omega)|^2 \frac{\left(\frac{1}{\tau'} + v_{\mathrm{g}}\Gamma a S\right)^2 + \omega^2}{\omega_R^4} \frac{2R_{\mathrm{sp}}}{VS} \qquad \text{(B1.2.48)}$$

where $\mathrm{RIN}(\omega)$ is the relative intensity noise per unit bandwidth around ω. The total relative intensity noise is found by integrating equation (B1.2.48) over the relevant bandwidth.

Readers should consult [5] on the further reading list for more details on modulation and noise properties of semiconductor lasers.

The *laser linewidth* (i.e. the spectral width of a single longitudinal mode) is also related to spontaneous emission. Photons added to the lasing mode by spontaneous emission events have a random phase relative to the optical field in the laser. This gives rise to phase fluctuations which can be quantified in terms of a finite laser linewidth. The laser linewidth can be shown to be proportional to the spontaneous emission rate R_{sp} and inversely proportional to the photon density. Typical linewidth values for a single frequency laser are a few tens of megahertz, but much lower values have been reported for optimized structures.

B1.2.7 Visible wavelength lasers

For many years, nearly all semiconductor lasers were based on GaAs substrates. This is convenient for forming heterostructures using $Al_xGa_{1-x}As$ compounds, with a relatively low Al content (if any) in the active layer, and a higher Al content in the confinement layers. In order to provide sufficient confinement of carriers, the Al fraction in the confinement layers must exceed that of the active region by about 20–30%, but, on the other hand, Al fractions above 40% cannot be used because these materials do not have a direct bandgap.

By varying the Al content in the active layer, lasing wavelengths can be achieved ranging from 880 nm (with no Al in the active layer) to about 750 nm. These wavelengths are just beyond the visible part of the spectrum, in the near infrared. Lasers operating around 780 nm are used extensively in CD players and CD-ROM drives.

For use in storage devices, it is an obvious advantage to operate at short wavelengths. Because the minimum features that can be resolved optically have a linear dimension of the order of the wavelength used, it follows that the recording density, which depends on the reciprocal of the focused spot area, is proportional to the inverse square of the wavelength. A reduction of the wavelength from 780 to 650 nm (used in DVD players) will increase the recording density by nearly 50%, and even higher densities will be possible by further reduction of the wavelength.

A possible material system is $(Al_xGa_{1-x})_yIn_{1-y}P$. A lasing wavelength in the 670–680 nm region is achieved using GaAs substrates, a GaInP active region, and having $y = 0.5$ and $x \approx 0.7$ in the confinement layers. Shorter wavelengths are possible by using quantum well (possibly strained) active regions.

Wavelengths in the 600–700 nm region lie within the visible part of the spectrum, and lasers operating in this range are of interest for applications such as bar code scanners and pointers, where they can replace HeNe lasers, which operate at 633 nm.

Even shorter wavelengths (i.e. green and blue) are possible, and currently there is a great deal of activity in developing lasers in the $(Al_xGa_{1-x})_yIn_{1-y}N$ system, based on GaN substrates. Blue emitting LEDs are already widely available. A particular problem with the nitride materials is that their crystal structure makes it more difficult to form good end facets by cleaving.

An interesting aspect of the development of short wavelength semiconductor lasers is that it gives access to the whole visible range, thus, for example, allowing fabrication of high brightness displays.

B1.2.8 GaAs-based VCSELs

In a *vertical cavity surface emitting laser* (VCSEL), the direction of lasing is perpendicular to the active layer, and light is emitted from the top or bottom surface of the chip. As this means that the active cavity is very short, it follows from equation (B1.2.6) that very high end-reflectivities are required. Such high reflectivities can be achieved by producing a stack consisting of a large number of layers of alternating high and low refractive index, each layer having a thickness corresponding to a quarter of a wavelength.

The *field reflection* for an interface between a layer of index n_1 and one of index n_2 is given by the *Fresnel formula*

$$r = \frac{n_1 - n_2}{n_1 + n_2} = \frac{\Delta n}{2n_{\mathrm{av}}}. \tag{B1.2.49}$$

The *power reflection* is given by the square of the field reflection. With each layer being a quarter of a wavelength in thickness, we introduce *the coupling coefficient*, κ, as the reflection per unit length (note that, by a quarter of a wavelength, we mean a quarter of a wavelength in the material)

$$\kappa = \frac{2\Delta n}{\lambda}. \tag{B1.2.50}$$

In a stack with N layer pairs, i.e. $2N$ layers, the total reflection (not including the final surface/air or surface/substrate interface) can be shown to be given by

$$r_{\mathrm{tot}} = \tanh\left(2N\frac{\Delta n}{2n_{\mathrm{av}}}\right) = \tanh(\kappa t) \tag{B1.2.51}$$

where the total thickness of the reflector stack is

$$t = 2N\frac{\lambda}{4n_{\mathrm{av}}}. \tag{B1.2.52}$$

See, for example [5] for more details. As an example, we consider a stack with 30 layer pairs, an index difference of 0.3 and an average index of 3.3. The power reflectivity, given as the square of the expression in equation (B1.2.51) is in this case 0.98.

The *reflection bandwidth* of a reflector stack depends on the wavelength and on the *index contrast*

$$\Delta\Lambda = \frac{\lambda}{2}\frac{\Delta n}{n_{\mathrm{av}}}. \tag{B1.2.53}$$

It is also useful to define an *effective length* of the stack, as a measure for how far the light 'on average' penetrates into the stack. This quantity is given by

$$L_{\mathrm{eff}} = \frac{1}{2\kappa}\tanh(\kappa t). \tag{B1.2.54}$$

For $\kappa t > 1$ we then have

$$L_{\mathrm{eff}} \approx \frac{\lambda}{4\Delta n}. \tag{B1.2.55}$$

Including both a top and a bottom reflector stack, we see that the effective cavity length of a VCSEL is much smaller than that of a conventional edge emitting laser, typically by a factor of between 10 and 100. Combined with the fact that in a VCSEL there is only gain in a part of the cavity, it follows that reflectivities of the order of 0.99 are necessary. A schematic of a VCSEL is shown in figure B1.2.11.

It is a considerable advantage of the short cavity of VCSELs that because of the resulting wide mode spacing, only one longitudinal mode has significant gain, cf equations (B1.2.2)–(B1.2.3). This means that a VCSEL is by its nature a single frequency laser. Other major advantages include: the possibility of matching the laser spot size to that of a fibre—making coupling simpler and more efficient, and the use of on-wafer testing in the fabrication process. See [6] for more details and a review.

The various advantages of GaAs VCSELs make them highly suitable as relatively low cost transmitters for short distance systems operating at relatively short wavelengths, such as data links. The technology for VCSELs based on InP and intended for operation at the 'telecoms' wavelengths of 1300 and 1550 nm has proved to be considerably more difficult.

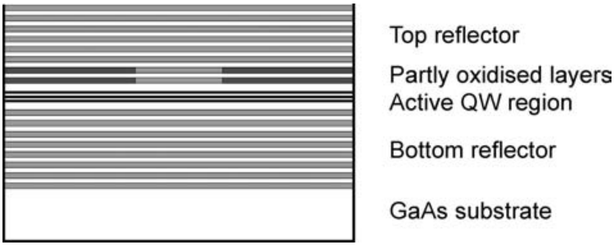

Figure B1.2.11. Simplified diagram of a VCSEL on GaAs substrate. In this case, the active material is based on InGaAs quantum wells (see section B1.2.9). The top and bottom reflectors consist of alternating layers of GaAs and AlAs. Some of the top AlAs layers have been partly oxidized, forming low index, nonconducting Al_xO_y, which gives both optical and electrical confinement. The actual number of layers in the reflector stacks is higher than shown.

For long wavelength materials, the index contrast that can be achieved in the mirror stacks is smaller than for shorter wavelength materials, hence more layers are needed. In addition, the electrical and thermal properties of the long wavelength materials tend to be inferior to those for the short wavelength material. In addition, higher order recombination processes, cf equation (B1.2.39) present more of a problem.

One possible way of overcoming some of these problems is the use of, for example, 980 nm lasers for optical pumping, as an alternative to direct electrical pumping. Other options for long wavelength VCSELs include the use of hybrid structures with dielectric (nonsemiconductor) reflectors, or the use of new semiconductor material combinations.

B1.2.9 High power pump lasers

In general, semiconductor lasers have very high efficiencies, i.e. a large fraction of the electrical input power supplied to the laser is converted to laser power. The overall efficiency, also known as the *wallplug efficiency* (defined as the ratio between the optical output power and the electrical power supplied to the laser), can exceed 50%. The combination of the high efficiency with the ability to design lasers to operate within a given spectral range, makes the semiconductor laser very attractive as a pump source for other lasers, because a high optical power can be delivered at a wavelength coinciding with a pump band in the other laser.

In section B1.2.2, we assumed that the two laser facets had the same reflectivity, R. In this case, equal amounts of power will be emitted from the two ends. This power balance can be changed by changing one or both end reflectivities, e.g. by coating. Equation (B1.2.6) in section B1.2.2 and equations (B1.2.37)–(B1.2.38) in section B1.2.6 still remain valid, provided we interpret R as the geometric mean of the two end reflectivities

$$R = \sqrt{R_{\text{front}} R_{\text{back}}}. \tag{B1.2.56}$$

It is easy to show that the power ratio is given by

$$\frac{P_{\text{front}}}{P_{\text{back}}} = \sqrt{\frac{R_{\text{back}}}{R_{\text{front}}}} \frac{1 - R_{\text{front}}}{1 - R_{\text{back}}}. \tag{B1.2.57}$$

By having a high back reflectivity and a low front reflectivity most of the power is emitted from the front. The facet reflectivities are subject to a design trade-off: A high value of R will give a low end loss, equation (B1.2.6), leading to a low threshold gain, equation (B1.2.9), and hence a low threshold current; but the differential efficiency, equation (B1.2.10), will be low. On the other hand, a low value of R will give a high efficiency, but also a high threshold current.

The limiting factor for high power operation is optical damage to the end facet. This occurs when the optical power density gets too high. By using proper facet coating technology, the power density can be of the order of $10\,\mathrm{MW\,cm^{-2}}$ before damage occurs. This implies a design trade-off for the waveguide in the laser: In order to have a well-defined beam, the waveguiding will have to be reasonably strong, but a strong waveguide will tend to give a small spot size, and may also make it possible to excite higher order modes. Single transverse mode, high power, lasers usually have spot sizes of a few square micrometres, giving power levels up to a few hundred milliwatts.

A very important practical example of the use of semiconductor lasers as a pump source is that intended to power the *erbium-doped fibre amplifier* (EDFA), which is used to provide amplification for wavelengths in the 1530–1560 nm range. The EDFA can be pumped at several wavelengths, the most commonly used being 980 nm (1480 nm is another possible pump wavelength).

Using conventional materials on GaAs or InP substrates, there are no material combinations which can be used to form a laser operating at 980 nm. However, strained InGaAs has a narrower bandgap than GaAs, so a possible structure consists of one or more strained $\mathrm{In}_x\mathrm{Ga}_{1-x}\mathrm{As}$ quantum well(s) (about 20% In, and a well width around 10 nm) in a separate confinement structure, cf figure B1.2.9, with a pair of GaAs layers providing carrier confinement, and with $\mathrm{Al}_y\mathrm{Ga}_{1-y}\mathrm{As}$ layers for optical confinement.

It is a characteristic feature of semiconductors, that the bandgap energy (and hence the wavelength region of gain) varies with temperature. If the lasing wavelength is not controlled a drift of about 0.4–0.5 nm per degree will occur in the peak wavelength of the gain, and hence of the laser. Consequently, lasing would only correspond to the EDFA pump band for a limited temperature range. In addition, fabrication tolerances on layer compositions and thicknesses give some variation in the lasing wavelength from device to device. These effects can be mitigated by using an external reflector with spectrally well-defined (and temperature stable) reflection properties. An example of a suitable reflector is a *fibre Bragg grating* (FBG) with a reflection of a few per cent, comparable to the reflection of the (anti-reflection coated) laser facet, and a reflection bandwidth of the order of 1 nm.

Semiconductor lasers are also widely used for pumping of solid-state crystal-host lasers, e.g. the Nd:YAG laser that has a pump band near 810 nm. Extremely high power levels (over 100 W) can be achieved in structures with a wide active region, or with multiple active stripes [7]. By forming a stack of such devices, power levels of as much as 1 kW for a $1\,\mathrm{cm}^2$ emitting area have been obtained.

B1.2.10 Fixed wavelength DFB lasers

The spectral width of the gain curve of semiconductor lasers, cf figure B1.2.7, exceeds the modespacing, given by equation (B1.2.3), by a large factor, leading to possible multimode lasing. For applications in fibre optical communication, this gives two problems: Firstly, the resulting spectral width of several nanometres leads to pulse broadening due to fibre dispersion, and secondly, the number of distinct channels that can be multiplexed on the same optical fibre is reduced.

In order to achieve single mode lasing, some form of spectral selectivity is necessary. The conventional way to achieve this is by incorporating a *periodic structure* (i.e. a *grating*) in the laser, as shown schematically in figure B1.2.12. In this structure, the grating provides internal reflections at a wavelength determined by the grating period. This type of laser is known as a *distributed feedback laser* or *DFB* in short.

The wavelength selected by the grating is given by

$$\lambda_{\mathrm{DFB}} = 2n_{\mathrm{eff}}\Lambda \tag{B1.2.58}$$

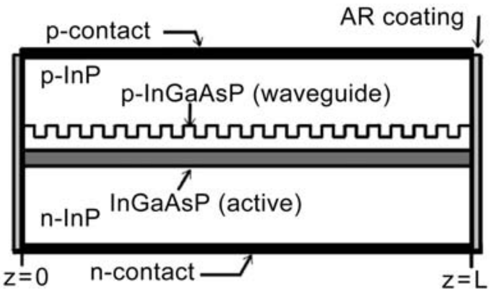

Figure B1.2.12. Outline of a DFB laser. The waveguide layer has a bandgap (and consequently a refractive index) between that of the active layer and InP.

where n_{eff} is the effective index and Λ the grating period. Because the grating only provides efficient internal feedback at wavelengths very close to λ_{DFB}, any wavelength different from λ_{DFB} will have a higher rate of loss through the end facets, and as a result lasing will occur at λ_{DFB}.

As the grating period, Λ in equation (B1.2.58), is equal to half a wavelength, the square grating shown in figure B1.2.12 is in fact similar to the quarter wave stack considered in section B1.2.8. However, in contrast to the situation shown in figure B1.2.11, it is only a part of the optical field that 'sees' the region where the refractive index varies. In other words, it is the *effective* (modal) refractive index that varies, and from perturbation theory, we find this variation to be

$$\Delta n_{\mathrm{eff}} = \Gamma_{\mathrm{g}}(n_1 - n_2) \tag{B1.2.59}$$

where Γ_{g} is the confinement factor for the grating (the ratio of the optical power in the grating relative to the total optical power) and n_1 and n_2 the refractive indices of the materials forming the grating.

In analogy with equation (B1.2.50) the coupling coefficient is

$$\kappa = \frac{2\Delta n_{\mathrm{eff}}}{\lambda}. \tag{B1.2.60}$$

The bandwidth of the grating is found from equation (B1.2.53), but with Δn replaced by Δn_{eff}.

As an example, we consider a wavelength of 1.55 µm, and an average effective refractive index of 3.3. For $(n_1 - n_2) = 0.1$ and $\Gamma_{\mathrm{g}} = 0.1$, we find $\kappa = 130\,\mathrm{cm}^{-1}$, a length of 200 μm gives $\kappa L = 2.6$, and the bandwidth is 2.3 nm. As seen in this example, the bandwidth is similar to the modespacing, so only a single mode will be selected by the grating.

The κL product in a DFB laser plays a role similar to the facet reflectivity in an ordinary laser, and a high value (i.e. strong feedback) will give a low threshold current, but also a low efficiency. As the lasing mode experiences gain from the active layer and, at the same time, feedback from the grating, the gain condition and the phase condition (equivalent to equations (B1.2.9) and (B1.2.2), respectively) are coupled in a DFB laser, and the wavelengths of the modes and their required gains are found by solving a complex transcendental equation.

The discrete (and nonselective) reflections from the end facets will interfere with the distributed reflection from the grating, and usually the reflection from the front facet is suppressed by applying an *anti-reflection* (AR) coating. The detailed theory for DFB lasers is rather involved, particularly if the facet reflections are included, and readers are referred to [6, 7] on the further reading list for more information.

Gratings can be fabricated by covering the waveguide layer with a photoresist, which is then exposed to an optical interference pattern, and the developed resist is used as an etch mask. After etching of the grating, the remaining layers in the laser structure are grown.

As mentioned in section B1.2.9, the bandgap energy of a semiconductor is temperature dependent, and the wavelength corresponding to the peak gain, will change by about 0.4–0.5 nm per degree. However, in a DFB laser the lasing wavelength is stabilized and determined by the grating rather than by the gain curve, so a smaller temperature coefficient due to refractive index change will apply. The refractive index of a semiconductor laser structure is still quite sensitive to temperature; so this will lead to a temperature dependence of the lasing wavelength. A typical value is about 0.1 nm per degree (corresponding to a change in the optical frequency of about 10 GHz per degree).

Whereas temperature tuning can be used to trim the wavelength to a given value, the temperature dependence also means that, in order to ensure that the lasing frequency is within 10 GHz of a given value, the laser temperature has to be stabilized to within 1 degree.

DFB lasers are often designed for direct modulation at data rates up to 2.5 Gbit/s. For higher data rates external modulation is used. An interesting option is to integrate, monolithically, a DFB laser and an *electroabsorption modulator* (EAM).

In systems using *wavelength division multiplexing* (WDM), signals from several lasers are multiplexed before transmission, and in order to ensure interoperability of equipment from different manufacturers, the International Telecommunications Union, ITU, has set a standard for optical transmission frequencies. This standard is based on a frequency grid with a 100 GHz spacing. Consequently, the range from 192.1 THz (corresponding to a wavelength of 1560.61 nm) to 195.9 THz (1530.33 nm) comprises 39 channels.

B1.2.11 Tunable lasers

The wide optical gain curve in a semiconductor laser makes it possible to achieve tuning of the lasing wavelength/frequency. As already mentioned, tuning is possible by changing the operating temperature. However, unless a large temperature variation is allowed, the tuning range will be limited to a few nanometres in wavelength (a few hundred gigahertz in frequency), and thermal tuning is comparatively slow (microsecond to millisecond range).

The fact that the refractive index depends on the carrier density can be used for tuning. However, in a simple structure (like figure B1.2.3 or B1.2.4), and also in DFB lasers, the carrier density is clamped to the value which is required to give sufficient gain to satisfy the lasing condition, and tuning by carrier density changes is not possible. This limitation can be overcome by using structures with two (or more) separate regions. One example is the *distributed Bragg reflector* (DBR), laser shown in figure B1.2.13. The tuning speed will be limited by the carrier lifetime in the tuning region (nanosecond range).

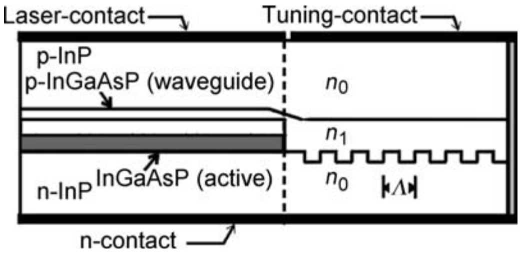

Figure B1.2.13. Two section DBR laser. The output power is controlled by the laser current supplied to the active region. The tuning current supplied to the Bragg reflector region controls the carrier density in that region, and hence its refractive index. This in turn tunes the wavelength at which the grating gives efficient reflection. Tuning ranges can be up to 10–15 nm, e.g. [8].

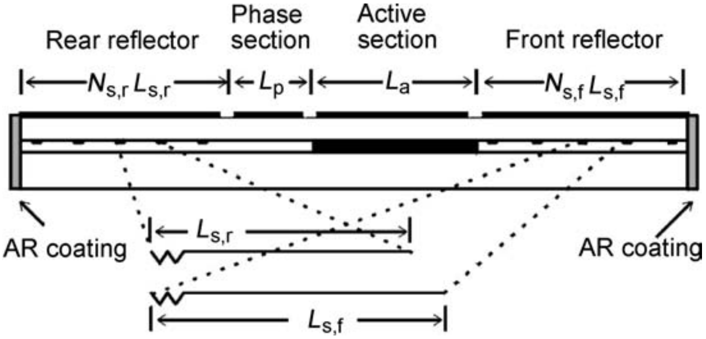

Figure B1.2.14. Sampled grating DBR. Instead of a continuous grating the two reflectors have sampled gratings. These gratings give reflection spectra that have a comb of reflection peaks with a spacing determined by the sampling period. By using two different sampling periods, two reflection combs with different periodicities are obtained.

It should be noted that the tuning of a DBR laser is not continuous, but shows jumps between the wavelengths that satisfy the resonance condition given by equation (B1.2.2).

In order to give separate control of the lasing wavelength, a phase section can be inserted between the active section and the DBR reflector. This section is similar to the DBR section, but it has no grating. Changing the carrier density, and hence the refractive index in this section, makes it possible to fine tune the lasing wavelength.

Whereas the tuning range of a two-section DBR laser is limited by how much the refractive index of the tuning section can be changed, wider tuning ranges can be achieved using somewhat more complicated structures. An example of such a structure is the *sampled grating DBR* (SGDBR) which is shown in figure B1.2.14.

A small change of the refractive index of one of the tuning sections gives a large change in wavelength, because a new pair of reflection peaks will coincide. This behaviour is recognized as the *Vernier effect*, see [9] for more details. This principle leads to greatly enhanced tuning ranges, with up to about 100 nm being reported. Similar tuning ranges have also been achieved by combining a tunable co-directional coupler with a sampled grating [10].

A particular problem with the tunable laser structures described earlier is that several control currents are required to set a specific combination of power and wavelength. Tunable lasers must therefore be characterized in sufficient detail to identify the current combinations required for various wavelengths. The laser driver electronics must contain this information in such a form that tuning can be achieved in response to simple external instructions.

Other semiconductor laser structures capable of very wide tuning include various forms of external cavity lasers. Ultimately, the tuning range is of course limited by the width of the gain curve. More details on different tunable laser types can be found in reference [8] on the further reading list.

Figure B1.2.15 shows an example of a widely tunable laser.

B1.2.12 Quantum cascade lasers

The *quantum cascade laser* is radically different from other semiconductor lasers. The lasing is based on inter-subband transitions, and involves only one type of carrier (the electrons); it is therefore also referred to as a *unipolar* laser.

The active region consists of a number of coupled quantum wells, and the possible energy states form a set of *minibands* and *minigaps*. An electrical field is applied to the structure and the electrons enter

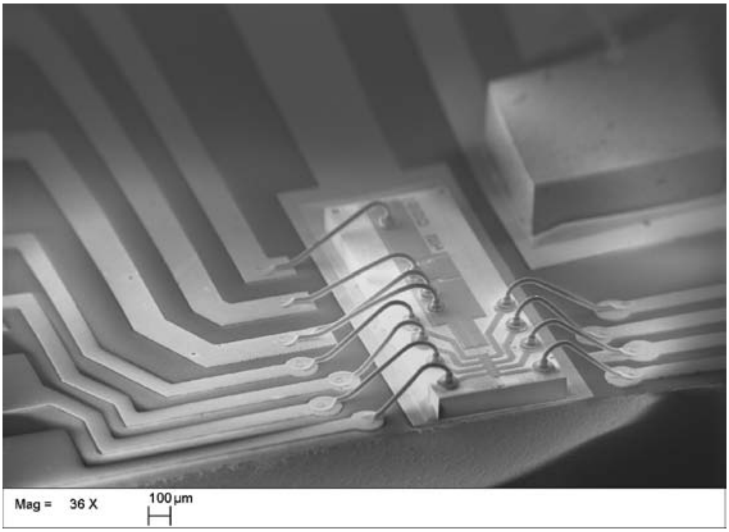

Figure B1.2.15. Micrograph of widely tunable laser from Bookham Technology. This particular structure, known as the 'digital supermode structure' has multiple individually contacted gratings in the front section. Courtesy Bookham Technology.

the active region from an *injector* region with aligned energy levels, creating a population inversion. A schematic diagram is shown in figure B1.2.16.

The successful fabrication of a quantum cascade laser requires a detailed design of the quantum well and barrier thicknesses, the material compositions and the doping levels, as well as a high level of

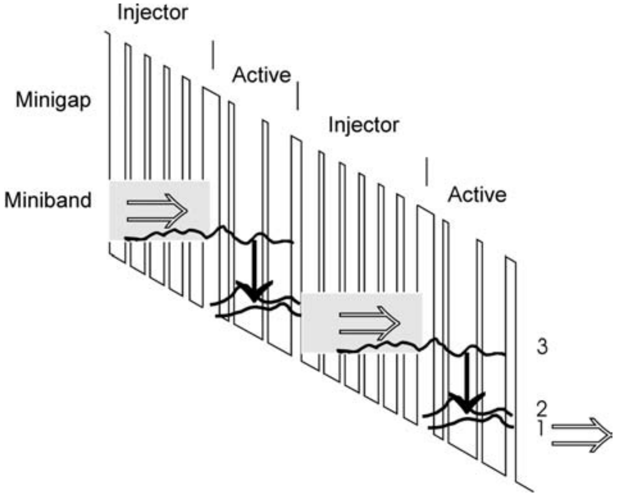

Figure B1.2.16. Basic principle of a quantum cascade laser. The figure shows the band edge for the conduction band subjected to an electrical field. Some of the electron wavefunctions are indicated, each with a baseline corresponding to the relevant energy level. As shown, the laser structure can have a number of stages, and by regarding the miniband in the injector as a pump band, the structure looks like a set of four level lasers in series. The total thickness of one injector region and one active region is about 50 nm, based on reference [11].

accuracy in the materials growth (i.e. use of MBE). A possible combination of materials is, for example, GaInAs for the quantum wells and AlInAs for the barriers.

Quantum cascade lasers have been made for operation at wavelengths ranging from a few micrometres to above 20 μm. Usually, they are either operated under pulsed conditions or at a low temperature, but examples of continuous operation at room temperature have also been reported. Whereas these lasers usually operate in several longitudinal modes, the spectral properties can be improved by the use of a grating to form a DFB laser (see section B1.2.10). Reference [11] contains a recent review of quantum cascade lasers.

B1.2.13 Concluding remarks

The main objectives of this chapter have been firstly to provide an introduction to the basic concepts related to semiconductor lasers, and secondly to show examples of semiconductor laser structures optimized for various functions and applications. In doing so, a number of details and other aspects have necessarily been left out, and the reader is encouraged to consult the further reading list for additional information. We note that somewhere around 40 books dealing exclusively or mainly with semiconductor lasers have been published to date, and there are whole books devoted to topics that have been covered on a single page in this chapter. In addition, some topics have not been covered at all in this chapter, including, for example, the use of modelocked lasers for short pulse generation, and the monolithic integration of lasers structures performing other functions such as modulation, detection, wavelength conversion, etc. Anyway, it is the hope of the author that this paper will serve a dual purpose as a basic reference, as well as a starting point for further study.

Acknowledgments

Some of the sections in this chapter are partly based on material used in the article: J Buus, ‘Optical Sources’ in *Wiley Encyclopedia of Telecommunications*, Editor J Proakis, to appear in 2002.

Optical detectors and receivers

Hidehiro Kume

B2.1 Introduction

This chapter describes the operating principles, construction and characteristics of major optical detectors.

Optical detectors (often called photodetectors) can be classified by their principle of light detection as shown in table B2.1. Typical optical detectors utilizing physical or chemical changes are photographic films, but these are now seldom used in photometric applications. Methods utilizing solid or gas ionization and scintillation are usually limited to detection in the x-ray and gamma-ray regions.

Optical detectors making use of photoelectric effects are widely used as UV to IR sensors in various applications including measurement instruments, industrial production equipment and communication devices. To make the contents of this chapter more practical, we will chiefly discuss optical detectors utilizing the photoelectric effects.

Optical detectors utilizing photoelectric effects can be further divided by their detection principle into two groups: one using external photoelectric effects and the other using internal photoelectric effects. Table B2.2 shows typical optical detectors utilizing these effects and their features. As can be seen from table B2.2, optical detectors also fall under two categories: point detectors that merely detect light intensity and two-dimensional detectors including position sensors and image sensors. Spectral response range (detectable wavelength band) also differs depending on the type of optical detector. In general, optical detectors utilizing the external photoelectric effect are represented by photomultiplier tubes (PMTs) and exhibit fast time response and high sensitivity. On the other hand, optical detectors using the internal photoelectric effect, such as photodiodes (PDs) and photoconductive cells, offer a wide spectral response range, compact size and easy operation. Along with recent trends towards image measurements, the product quality and quantity of two-dimensional detectors are improving and increasing.

B2.2 Photoelectric effects

As stated, photoelectric conversion is roughly divided into external photoelectric effects [1] by which bound electrons inside a semiconductor thin film are released into a vacuum when light strikes the semiconductor and internal photoelectric effects [2] where photoelectrons are generated inside a semiconductor by light and excited into the conduction band. The photocathode used as the photoemissive surface of a PMT has the former function. The photoconductive effect and photovoltaic effect take place by the latter principle.

Table B2.1. Classification of optical detectors.

Principle	Method	Detectable electromagnetic radiation
Physical or chemical changes	Dosimeters	Charged particles
	Photographic films	UV, visible, IR radiation, charged particles
	Cloud chambers, bubble chambers	X-rays, gamma-rays, charged particles
Solid or gas ionization	Proportional counters, etc	Charged particles, x-rays, gamma-rays
Scintillation	Solid state or liquid scintillators + optical detectors	Charged particles, x-rays, gamma-rays
Photoelectric effect	Optical detectors utilizing external photoelectric effect (photomultiplier tube, etc)	UV, visible, near IR radiation
	Optical detectors utilizing internal photoelectric effect (photodiodes, etc)	UV, visible, near IR radiation, x-rays, gamma-rays

Table B2.2. Types and classification of optical detectors.

Detecting principle		Detectors (point detectors)	Two-dimensional detectors	Spectral response range
External photoelectric effect		Phototubes Photomultiplier tubes	Image intensifiers Streak cameras	Vaccum UV to near IR
Internal photoelectric effect	Photoconductive effect	Photoconductive cells	Photoconductive type camera tubes (vidicons, etc)	Visible to IR
	Photovoltaic effect	Photodiodes Phototransistors Avalanche photodiodes	Semiconductor image sensors (CCD, etc) Semiconductor position sensors (PSD, etc)	UV to near IR
Thermal effect	Pyroelectric effect	Pyroelectric IR detectors	Pyroelectric image sensors	Near IR to far IR
	Photovoltaic type	Thermocouples		
	Conductivity type	Bolometers Thermistors		

B2.2.1 External photoelectric effect

Semiconductor thin films having a photoemissive surface are usually called a ‘photocathode’ [1, 3] and have a band model structure like that shown in figure B2.1. Inside a semiconductor, there exists a valence band occupied by electrons, a forbidden band that cannot be occupied by electrons and a conduction

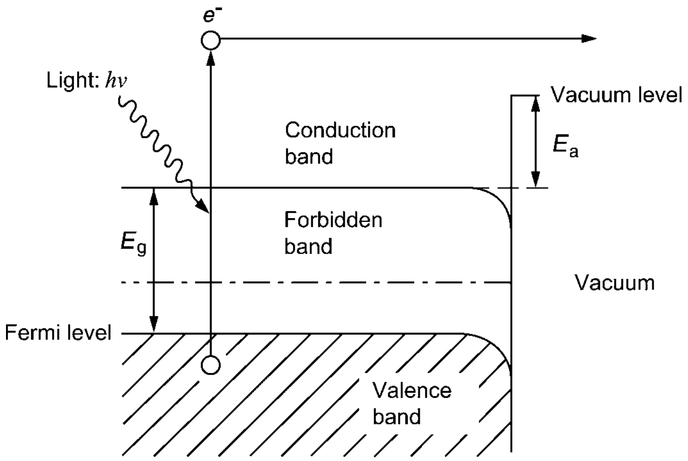

Figure B2.1. Photocathode band model.

band where electrons are free to move. When photons strike a photocathode, electrons in the valence band absorb photon energy *hv*, become excited into the conduction band and diffuse toward the photocathode surface. When the diffused electrons have enough energy to overcome the vacuum level barrier, they are emitted into the vacuum as photoelectrons. Photocathodes can be classified by photoelectron emission process into a reflection mode and a transmission mode. The reflection mode photocathode is usually formed on a metal plate and photoelectrons are emitted from the photocathode in the opposite direction to the incident light. The transmission mode photocathode is usually deposited as a thin film on an optically transparent flat plate and photoelectrons are emitted in the same direction as that of the incident light. Most photocathodes are made of a compound semiconductor chiefly consisting of alkali metals with a low work function such as Cs_3Sb, Na_2KSb, etc. Changing the photocathode materials makes it possible to achieve sensitivity in various bands of the spectrum from soft x-rays to near IR radiation (described later in detail).

PMTs [3] are the typical optical detectors utilizing the external photoelectric effect. They are vacuum tubes with a glass envelope and consist of a photoemissive cathode (photocathode), an electron multiplier and an electron collector (anode) in a vacuum tube. Figure B2.2 shows the schematic construction of a PMT. Light which enters a PMT is detected and produces an output signal through the following processes.

(1) Light passes through the input window and enters the photocathode in a vacuum.

(2) Excites the electrons in the photocathode so that photoelectrons are emitted into the vacuum (external photoelectric effect).

(3) Photoelectrons are accelerated and focused by the focusing electrode onto the first electrode called a ‘dynode’ in the electron multiplier section where they are multiplied by means of secondary electron emission. This secondary emission is repeated at each of the successive dynodes. (A dynode is an electrode capable of emitting secondary electrons. An electron multiplier used in a PMT usually has about 10 stages of dynodes.)

(4) A bunch of multiplied secondary electrons emitted from the last dynode are ultimately collected by the anode and output to an external circuit as an electrical signal. Since PMTs are a kind of

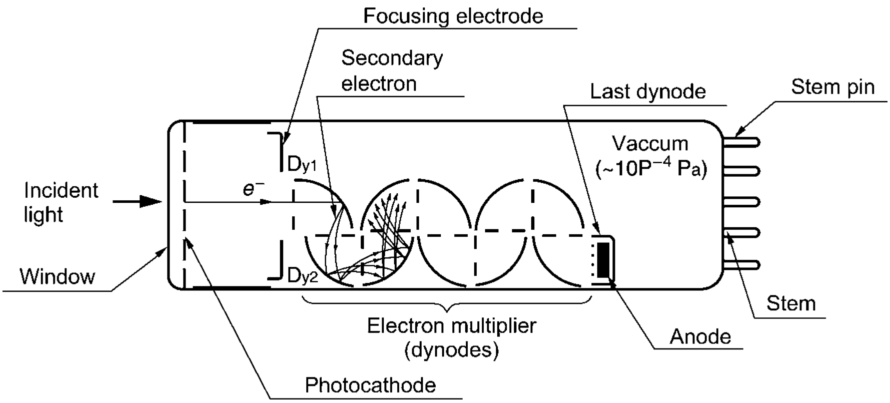

Figure B2.2. Construction of a photomultiplier tube.

electron tube, they are relatively large in size, but are superior in sensitivity and response speed, making them useful as optical detectors in a variety of applications such as analytical instruments, medical equipment and industrial measurement systems.

B2.2.2 Photovoltaic effect

Internal photoelectric effects will be explained by using a PD as an example.

A cross section of a typical PD is shown in figure B2.3(*a*). The p-layer at the light sensitive surface and the n-layer at the substrate form a p–n junction that serves as a photoelectric converter. The usual p-layer for a silicon PD is formed by selective diffusion of boron to a thickness of approximately 1 μm and the neutral region at the junction between the p-layer and n-layer is known as the depletion layer. By varying and controlling the thickness of the outer p-layer, substrate n-layer and bottom N+ layer as well as the doping concentration, the PD's spectral response and frequency response can be controlled.

A band model for photoelectric conversion that occurs at the p–n junction of a PD is shown in figure B2.3(*b*). When light strikes a PD and the light energy is greater than the band gap energy E_g, the electrons in the valence band are excited and pulled up into the conduction band, leaving holes in their place in the valence band. These electron–hole pairs are generated throughout the p-layer, depletion layer and n-layer. In the p-layer and depletion layer the electric field accelerates the electrons toward the n-layer and the holes toward the p-layer. Of the electron–hole pairs generated in the n-layer, the electrons are left in the n-layer conduction band along with electrons that have arrived from the p-layer, while the holes diffuse through the n-layer up to the p–n junction and collect in the p-layer valence band while being accelerated. In this manner, electron–hole pairs generated in proportion to the amount of incident light are accumulated in the n-layer and p-layer, resulting in a positive charge in the p-layer and a negative charge in the n-layer. When an external circuit is connected between the p-layer and n-layer, electrons will flow from the n-layer and holes from the p-layer toward the opposite electrode, respectively.

B2.2.3 Photoconductive effect

When light strikes some kinds of semiconductor, electron–hole pairs are generated and their internal electric conductivity increases. This phenomenon is called the 'photoconductive effect'. Photoconductive detectors are divided into intrinsic detectors and extrinsic detectors doped with impurities.

Figure B2.3. (*a*) Photodiode cross section, (*b*) photodiode p–n junction state.

Figure B2.4 shows the operation models of photoconductive detectors. Figure B2.4(*a*) is a phenomenon called 'intrinsic photoconduction'. When photons $h\nu$ with energy greater than the energy band gap E_g in the forbidden band enter an intrinsic detector, electron–hole pairs (carriers) are generated and the number of conductive charges in the conduction band changes. Figure B2.4(*b*) shows the operation of an extrinsic detector doped with impurity atoms. In this extrinsic detector, an impurity level is formed at a relatively deep energy level in an n-type semiconductor. When the input photons have energy higher than the ionization energy E_1, they mainly act on the impurities and create free electrons and bound holes, and the free electrons and free holes contribute to changes in the electric conductivity. This phenomenon is called 'extrinsic photoconduction'. Since $E_g \gg E_1$, extrinsic detectors are used for IR detection at longer wavelengths when compared to intrinsic detectors.

Figure B2.5 shows how a photoconductive sensor is used to detect light. When light enters the photoconductive sensor, its internal resistance changes to produce an increase of electric current, ΔI, which is added to the constant bias current I_b. This change in the electric current is detected as a signal.

Figure B2.5. Photoconductive sensor operation.

Various types of material are used to fabricate photoconductive sensors, such as CdS for visible light detection and PbS, PbSe and InSb for IR detection. Although photoconductive sensors have the disadvantages of slow response speeds they are still widely used because of the useful features such as small size, light weight and wide spectral response range (from visible to far infrared range).

B2.3 Spectral response characteristics of photodetectors

It is essential to select an appropriate type of photodetector that matches the wavelength region of light to be measured. This section explains photodetectors used to detect wavelengths in the x-ray to IR region.

B2.3.1 Definition of photodetector sensitivity

A wavelength spectrum of light from x-rays to IR rays is shown in figure B2.6 along with the name of each spectral region and unit systems as a reference to the following descriptions in this chapter.

Here, the definitions of sensitivity used to evaluate photodetectors will be mentioned. If light at a certain intensity level (W) enters a photodetector and a certain amount of photocurrent (A) flows after photoelectric conversion, then the following terms are usually used to define the photoelectric sensitivity of the photodetector.

Radiant sensitivity or photosensitivity S

Radiant sensitivity or photosensitivity S is the photocurrent A divided by the incident light level W as represented in equation (B2.1).

$$S = \frac{A}{W}\,(\mathrm{A\,W^{-1}}). \tag{B2.1}$$

Quantum efficiency

Quantum efficiency (QE) is the number of electrons or holes extracted as photocurrent divided by the number of incident photons, and generally expressed in percent (%). QE and radiant sensitivity $S\,(\mathrm{A\,W^{-1}})$ have the relationship of equation (B2.2) at a given wavelength λ (nm).

$$\mathrm{QE} = \frac{S \times 1240}{\lambda} \times 100\,(\%). \tag{B2.2}$$

Noise equivalent power

This is the amount of light equivalent to the noise level of the photodetector. In other words, it is the light level required to obtain a signal-to-noise ratio (S/N) of 1. Noise equivalent power (NEP) is usually

defined as shown in equation (B2.3) using the wavelength λ_p of maximum sensitivity and a bandwidth of 1 Hz.

$$\mathrm{NEP} = \frac{\text{Noise current } (\mathrm{A\,Hz^{-1/2}})}{\text{Photosensitivity at } \lambda_p\,(\mathrm{A\,W^{-1}})}\ (\mathrm{W\,Hz^{-1/2}}). \tag{B2.3}$$

*D**

This indicates how much the S/N ratio of a detector is when radiant energy of 1 W enters the detector. *D** is normalized by a sensitive area of 1 cm^2 and noise bandwidth of 1 Hz so as to compare detector materials regardless of the size and shape of the detector element. An optical chopper is usually used to measure *D** for passing and interrupting a beam of incident light. *D** is normally expressed in a format of *D**(*A*, *B*, *C*) where *A* is the colour temperature (K) of the light source, *B* is the chopping frequency (Hz) and *C* is the noise bandwidth (Hz). *D** is therefore represented in units of $\mathrm{cm\,Hz^{1/2}}$, and the higher the *D** value, the better the detector. *D** is given by

$$D^* = \frac{(\mathrm{S/N})\Delta f^{1/2}}{PA^{1/2}} \tag{B2.4}$$

where *S* is the signal, *N* is the noise, *P* is the incident light energy ($\mathrm{W\,cm^{-2}}$), *A* is the sensitive area (cm^2) and Δf is the noise bandwidth (Hz). The following relation is established by *D** and NEP.

$$D^* = \frac{A^{1/2}}{\mathrm{NEP}}. \tag{B2.5}$$

To define photodetector sensitivity, radiant sensitivity and quantum efficiency are usually used for UV to visible photodetectors, while NEP and *D** are frequently used for IR detectors.

B2.3.2 X-ray to vacuum UV photodetectors

Light tends to behave as particles more actively in the x-ray to vacuum UV (VUV) region and absorption of light by substance also changes a great deal in some wavelength bands of this region. Because of this, it is important in this region to consider the stopping power (efficiency) versus light and the performance characteristics of window materials as well as photoelectric conversion sensitivity. Typical transmittance characteristics of window materials [5] used in the VUV, soft x-ray and x-ray regions are shown in figure B2.7. As can be seen from this figure, organic films and light metals such as Be (beryllium) and Al (aluminium) can be used as a window in the x-ray region at several kiloelectron volts or less, although there are currently no window materials available for some bands of the x-ray region. Figure B2.8 shows typical spectral transmittance of optical windows used in the UV to VUV region. Quartz glass and UV-transmitting glass are preferably used as transparent window materials in the UV region. MgF_2 (magnesium fluoride) and LiF (lithium fluoride) crystals are chiefly used as windows for detectors in the VUV region where significant absorption of light by oxygen and nitrogen occurs. Table B2.3 shows a list of typical photodetectors [6] used in the x-ray to VUV region.

Photodetectors utilizing gas ionization

Proportional counter tubes and Geiger–Mueller (GM) tubes as photodetectors using gas ionization have been around for quite a long time. Since the operating principles of these tubes are slightly different from each other, proportional counter tubes are capable of detecting both radiation energy and dose rate, while GM tubes are used only to measure dose rate. Due to the transmission bands of the window material (Be window) and fill-gas absorption characteristics, proportional counter tube applications are

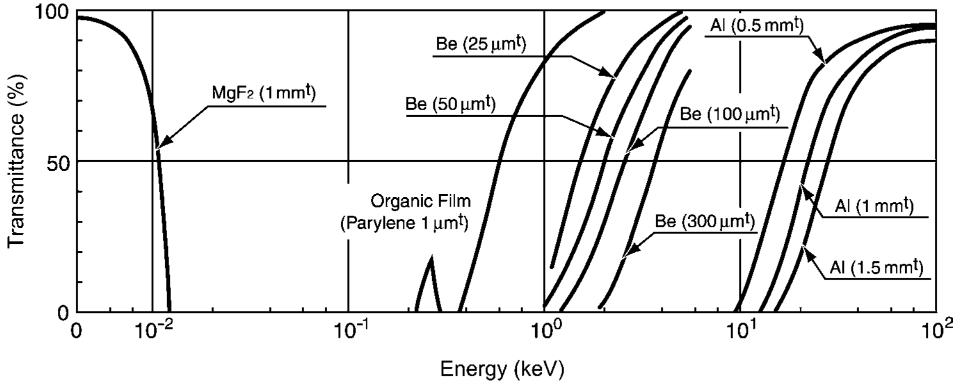

Figure B2.7. Transmittance of window materials used in VUV, soft x-ray and x-ray regions.

Table B2.3. Typical photodetectors used in x-ray to vacuum UV regions.

Detecting principle	Detectors	Detectable region	Energy (wavelength) region
Gas ionization	Proportional counter tube, GM tubes, MWPC	X-rays, γ-rays	A few keV to 1 MeV
Scintillation	Scintillator + PMT (or photodiode)	X-rays, γ-rays	A few keV to several dozen MeV
	X-ray image intensifiers	X-rays	20–150 MeV
Photoelectric effect	Semiconductor detectors	X-rays, γ-rays	A few keV to several dozen MeV
	PMT without window	Soft x-rays	A few to 100 nm
	PMT with window	VUV	100 nm or more

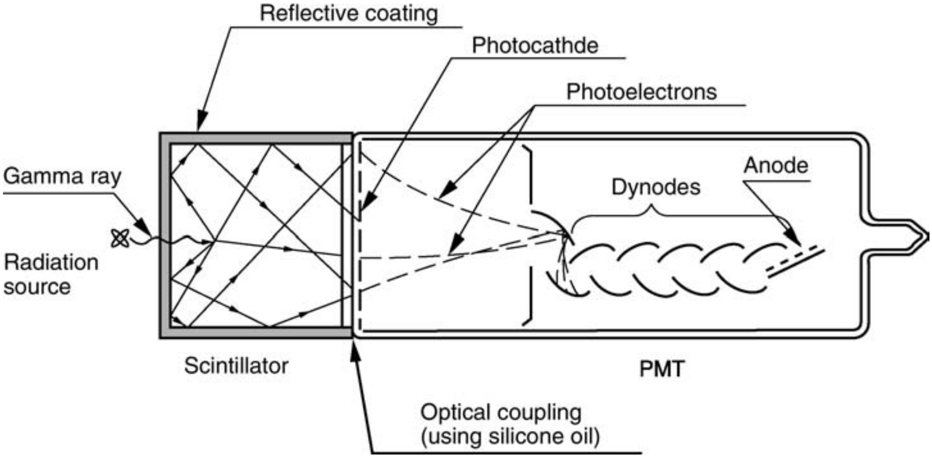

Figure B2.9. Scintillation photodetector for radiation measurement.

usually limited to a radiation energy region of 1–25 keV. Likewise, applications of GM tubes are determined by the transmission bands of the window material (Fe–Cr alloy) and by fill-gas absorption characteristics. GM tubes are therefore usable at a radiation energy of 50 keV–1 MeV. The multi-wire proportional counter (MWPC) is a position-sensitive proportional counter tube and is used as a two-dimensional detector in x-ray scattering, diffraction and synchrotron radiation experiments.

Scintillation photodetectors

In scintillation counting [7], a scintillator is used to convert radiation into visible light and this light is detected with a PMT or PD. Figure B2.9 shows a scintillation photodetector consisting of a scintillator coupled to a PMT. The amount of light emitted from a scintillator is proportional to the energy level of incident radiation, and this light emission is measured with a PMT or PD. Table B2.4 lists typical

Table B2.4. Typical characteristics and applications of scintillators.

	Density ($\mathrm{g\,cm^{-3}}$)	Relative emission intensity (NaI(Tl) = 100)	Emission time (ns)	Emission peak wavelength (nm)	Applications

characteristics and applications of major scintillators which are made of inorganic or organic materials. Scintillation counting is excellent in energy resolution when measuring radiation so it is used in nuclear medical equipment, nuclear physics experiments and oil well logging.

X-ray image intensifiers (IIs) [8] are a kind of scintillation photodetector. These are two-dimensional x-ray detectors having a phosphor-coated window for x-ray to visible light conversion and a photocathode sensitive to visible light. X-ray IIs can be fabricated with a large sensitive area, making them useful in x-ray medical equipment and industrial nondestructive inspection.

Photoconductive detectors

Among the photoconductive detectors, semiconductor radiation detectors [9] are classified by manufacturing method into the following groups:

(1) p–n junction type

(2) Surface barrier type

(3) Lithium (Si(Li)) drift type

(4) High-purity germanium type

Each type of these detectors makes use of the depletion layer that is formed when a reverse bias voltage is applied to the junction of p- and n-type semiconductors. Different photosensitive materials, size and window materials are used depending on the wavelength band (energy) to be detected.

Si(Li) drift type and high purity germanium type detectors are mainly used in the soft x-ray to x-ray region. Although the actual wavelengths that can be detected differ according to the detector material and structure, these can usually detect x-ray energy ranging from 1 keV to 10 MeV. These detectors are not easy to handle because liquid nitrogen cooling is required, but offer the advantage of high energy resolution. Recently, these detectors are available with a sensitive area from 2 or 3 up to 10 cm in diameter, and their detection sensitivity is constantly being improved. Multi-element detector arrays are also being developed.

Photocathodes (cathodes made of photoemissive materials) having external photoelectric effects are also used for detection in the UV to x-ray region. In a wavelength region where optically transparent windows are available, semi-transparent (transmission mode) photocathodes can be used, but at even shorter wavelength regions where proper window materials are unavailable, reflection mode photocathodes are exclusively used without windows. Typical photoemissive materials used to detect wavelengths shorter than the UV region are alkali halide metals, pure metals and metal oxide. Figure B2.10 shows typical spectral response characteristics of photoemissive materials that are usable in the soft x-ray region. These materials are applied to an x-ray to electron conversion surface such as the first stage of electron multipliers and also applied to a reflection mode photocathode by vacuum deposition onto the input edge surface of micro-channel plates (MCPs) (described later).

B2.3.3 UV detectors

Photodetectors used to measure radiant energy of UV rays can be divided into a photovoltaic type and photoemissive type.

As photovoltaic type semiconductor UV sensors, PDs using SiC, GaN, AlGaN and diamond thin films with a large band gap are now being developed [10]. In actual applications, UV sensors using a general-purpose PD combined with a UV filter are frequently used. Figure B2.11 shows a typical spectral response curve of a UV sensor, that can be obtained by the combination of a UV–visible sensitive

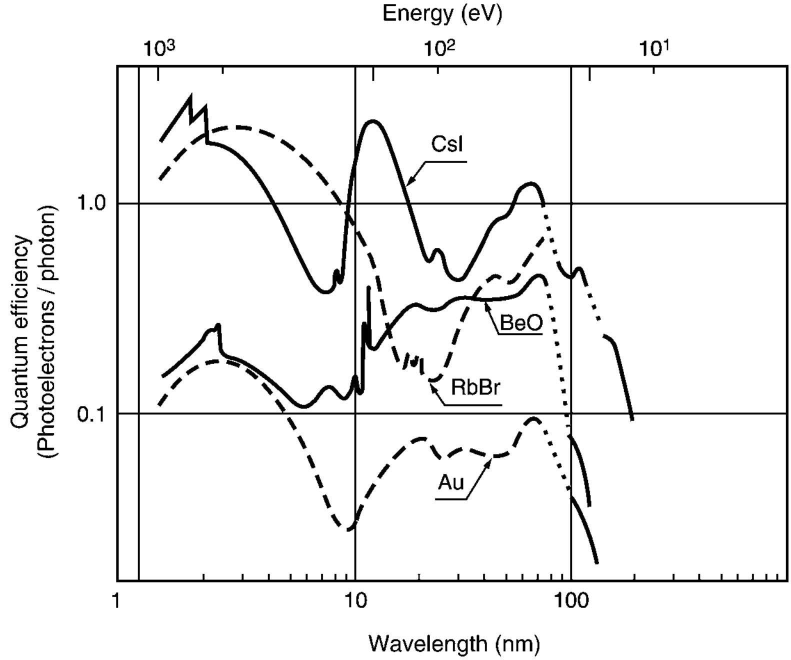

Figure B2.10. Typical spectral response characteristics of photoemissive materials in soft x-ray region.

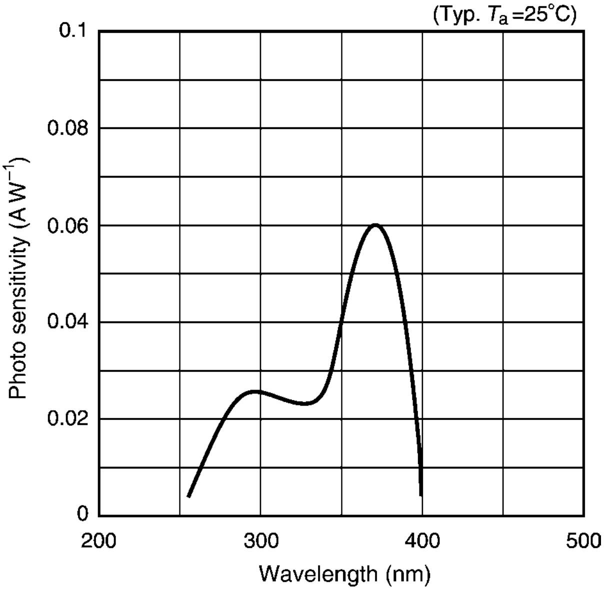

Figure B2.11. Typical spectral response curve of a semiconductor UV sensor.

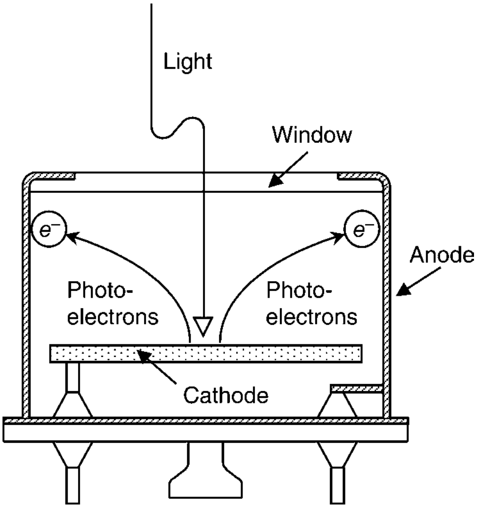

Figure B2.12. Construction of a phototube.

GaAsP PD and a UV-transmitting filter. Major applications of this type of UV sensor are UV measurement of sunlight, mercury lamp monitoring, etc.

Phototubes are also used in UV detection. They are made up of a photocathode using the external photoelectric effect and an anode for collecting photoelectrons emitted from the photocathode (see figure B2.12). Phototubes can be fabricated with various types of spectral response characteristic by changing the combination of photoemissive materials [11]. Figure B2.13 shows typical spectral response characteristics of photocathodes specifically selected and processed to have sensitivity only in the UV range. The spectral response characteristics on the short wavelength side are determined by absorption characteristics of window materials. Metals, alkali halide compounds and compound semiconductors having a large band gap are used as UV sensitive photocathode materials. Sensitivity in the longer wavelength region is determined by the band gap of each material. In addition to having various spectral response characteristics selectable by the combination of a window and photocathode materials, phototubes offer outstanding features such as high-speed response (nanosecond rise time) and low noise due to extremely high output impedance. Since UV phototubes are sensitive only in the UV region (insensitive to visible and longer wavelengths and often called 'solar blind'), they have found applications in colorimeters, pollution monitors, densitometers and UV laser detection.

B2.3.4 UV to visible photodetectors

Light is most actively utilized in this wavelength region. Compared to other regions of the electromagnetic spectrum, there are numerous types of photodetector available in the UV to visible region, in terms of both quantity and quality. Phototubes and PMTs utilizing the external photoelectric effect and PDs having the internal photovoltaic effect are most frequently used in this region.

Photodetectors utilizing external photoelectric effect (phototubes, PMTs)

Phototubes and PMTs are widely used in the UV to visible region. As stated earlier, these detectors use a semiconductor thin film that is a photoelectric converter surface called a 'photocathode'. Here, we will

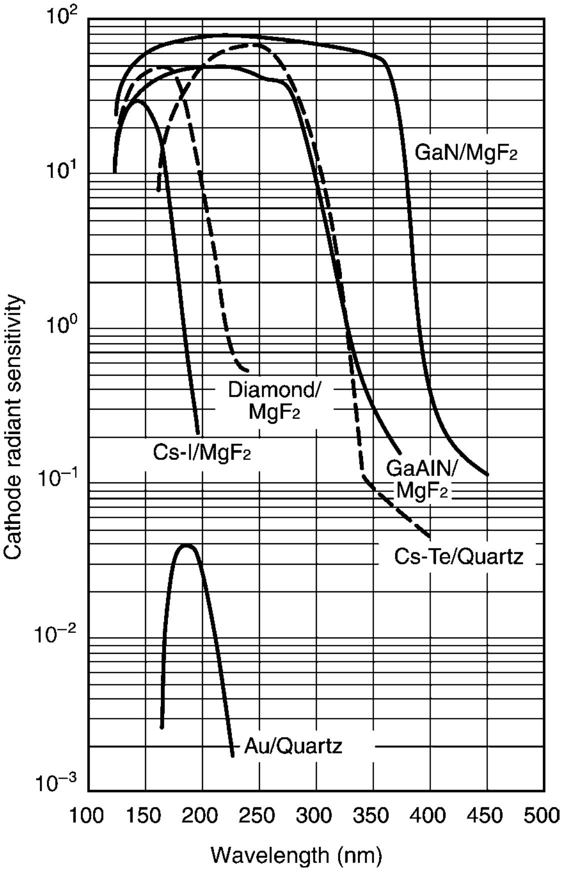

Figure B2.13. Typical spectral response characteristics of UV sensitive photocathodes.

briefly discuss the basic operating principle and operating method of a PMT. As shown in figure B2.11, a high voltage is applied between the photocathode and the anode. Photoelectrons emitted from the photocathode are accelerated and focused onto the first dynode (Dy1) to produce secondary electrons, which are then accelerated toward the subsequent dynodes (Dy2 to Dy*n*). When the accelerated electrons strike a dynode, secondary electrons are emitted with a secondary emission ratio (δ). Since this process is repeated to the last dynode (Dy*n*), the electrons are multiplied and increase. To make the operating circuit simpler, voltage dividing resistors are usually placed between the photocathode and the anode to distribute the supply voltage to each dynode, as shown in figure B2.14.

The secondary electron emission ratio δ is a function of the interstage voltage E between each dynode and is given by

$$\delta_1 = aE^k \qquad \text{(B2.6)}$$

where α is a constant, and k is a coefficient determined by the material and structure of an electrode (dynode) and has a value of 0.7–0.8.

The photoelectron current I_k (photocurrent that flows per unit light flux in lumens) emitted from the photocathode strikes the first dynode where a secondary electron current (I_{d1}) is emitted. At this point,

Figure B2.14. Photomultiplier tube operation circuit.

the secondary electron emission ratio δ of the first dynode is given by

$$\delta_1 = \frac{I_{\mathrm{d1}}}{I_{\mathrm{k}}}. \tag{B2.7}$$

These electrons are multiplied in a cascade process from the first dynode → second dynode → ··· → the nth dynode. The secondary emission ratio δ_n of the nth stage can be calculated by

$$\delta_n = \frac{I_{\mathrm{d}n}}{I_{\mathrm{d}(n-1)}}. \tag{B2.8}$$

The anode current I_{p} is given by

$$I_{\mathrm{p}} = I_{\mathrm{k}} \cdot \delta_1 \cdot \delta_2 \cdots \delta_n \tag{B2.9}$$

so that,

$$\frac{I_{\mathrm{p}}}{I_{\mathrm{k}}} = \delta_1 \cdot \delta_2 \cdots \delta_n. \tag{B2.10}$$

The product of $\delta_1, \delta_2, \ldots, \delta_n$ is called the gain (μ) and is given by

$$\mu = \delta_1 \cdot \delta_2 \cdots \delta_n. \tag{B2.11}$$

If the number of dynodes in a PMT is n, which is operated using an equal-division voltage divider, then changes in the gain μ versus the supply voltage V can be obtained by

$$\mu = \left(aE^k\right)^n = a^n \left(\frac{V}{n+1}\right)^{kn} = AV^{kn} \tag{B2.12}$$

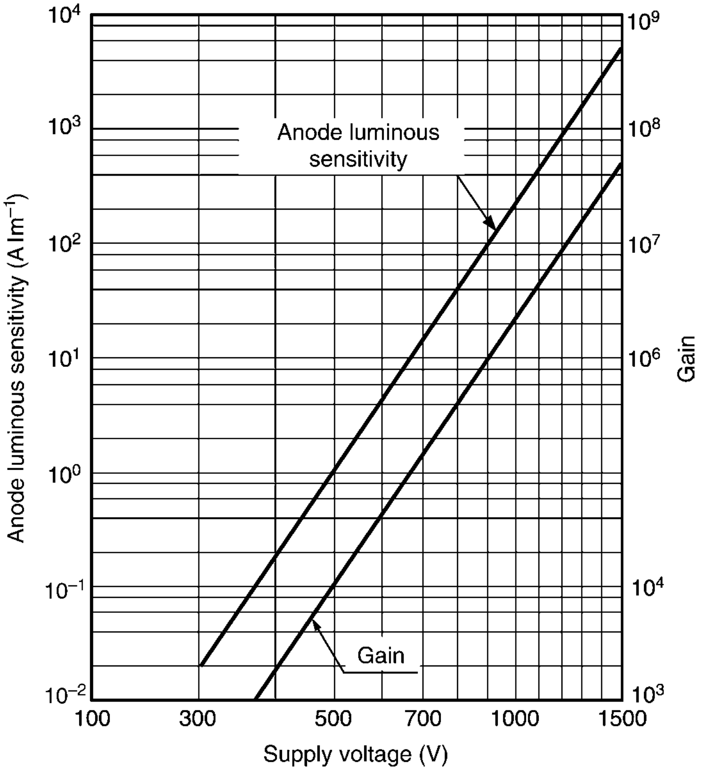

Figure B2.15. Luminous sensitivity and gain versus supply voltage.

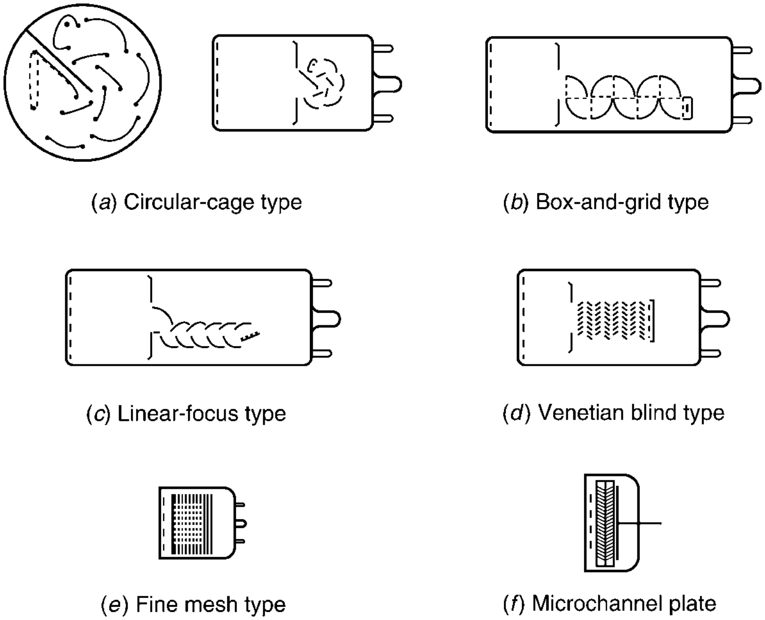
where A should be equal to $a^n/(n+1)^{kn}$. From this equation, it is clear that the gain μ is proportional to kn exponential power of the supply voltage. Typical gain versus supply voltage is shown in figure B2.15 along with luminous sensitivity. Since this figure is expressed in a logarithmic scale for both horizontal and vertical axes, the slope of the straight line becomes kn. The gain increases with an increase in the supply voltage, so a high gain of up to 10^7 or more can be obtained in most cases. Figure B2.16 shows various types of dynode structure. The circular-cage dynode is mainly used in side-on PMTs and has a high gain and fast time response. The box-and-grid dynode has a high gain, the linear-focused dynode offers fast time response, and the Venetian blind dynode features a high gain and compactness. Recently, the mesh type dynode and MCP have been put to practical use as an electron multiplier of PMTs. These dynode types each have merits and demerits in terms of time response, dynamic range and gain, so they should be carefully selected according to the application. A PMT is usually operated with a supply voltage of 1000–2000 V in order to obtain a high gain of 10^6–10^7, and can be used in photon counting mode (explained later). PMTs have excellent capability for low-light-level detection and also deliver extremely fast response with rise times of nanoseconds (PMTs using normal dynode types) to subnanoseconds (PMTs using MCP).

PMT spectral response is determined by the photocathode material on the long wavelength side and the transmittance of the window material on the short wavelength side. Typical photocathode spectral response characteristics are shown in figure B2.17. Up until now, photocathode sensitivity has been limited to the UV to near IR region. However, recent developments in semiconductor crystal materials [12]



(a) Circular-cage type
(b) Box-and-grid type

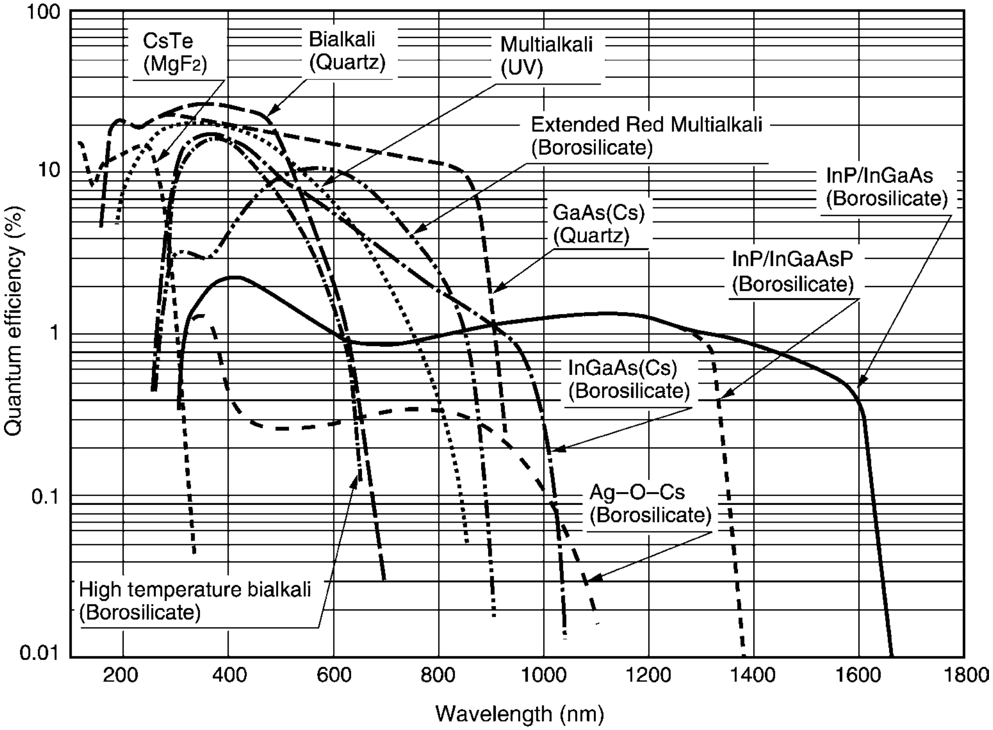

Figure B2.17. Typical photocathode spectral response characteristics.

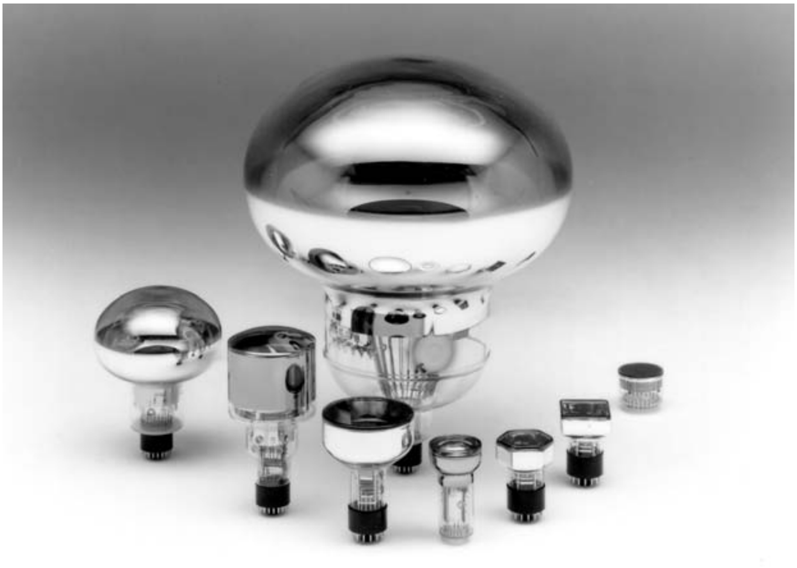

Figure B2.18. Typical photomultiplier tube products.

have extended photocathode sensitivity up to the IR region. Figure B2.18 shows a photograph of typical PMT products.

Photodetectors utilizing internal photovoltaic effect (PDs, etc)

Various types of semiconductor sensor have also been developed and used for light detection in the UV to visible region. Among these, PDs [4] are most extensively used. PDs can be classified according to their manufacturing method and structure as shown in figure B2.19. In the p–n type, light falling on a PD is absorbed in the depletion layer near the internal p–n junction after passing through the p^+-layer on the PD surface and is converted into an electrical signal of electron–hole pairs. The p–n type PDs have a planar structure that allows a relatively large active area with better sensitivity not only in the visible to IR region, but also in the UV region. However, these have a larger junction capacitance so response speed is limited. The pin type PDs have a high resistance i-layer formed between the p- and n-layers. This i-layer reduces the junction capacitance so response time is improved while maintaining high sensitivity. This type of PD exhibits an even faster response time when used with a reverse voltage applied and so is designed with low leak current.

Schottky type PDs have a structure in which a thin gold (Au) coating is sputtered onto the surface of an n-type semiconductor to form a Schottky effect p–n junction. Since the distance from the outer surface to the junction is small, UV sensitivity is high. Avalanche photodiodes (APDs) are used with a reverse voltage applied to the p–n junction so as to form a high electric field within the depletion layer. When light enters in this state, the generated electrons are accelerated by the electric field and collide with atoms to produce secondary electrons. This process occurs repeatedly so signals are amplified. This phenomenon is known as the avalanche effect and is ideal for detecting low level light.

Typical spectral response characteristics of PDs are shown in figure B2.20. Various types of PD are currently available with sensitivity in the UV, visible and also near IR regions. Recently, InGaAs PDs

Type	Structure
p–n type	pin type	Schottky type	Avalanche type (Reach-through type)

have become widely used as promising receivers in IR optical communications. Semiconductor photodetectors are small and compact yet have high sensitivity, so they are now used in large numbers in general electronics products and also other diverse applications. Figure B2.21 shows a photograph of typical PD products.

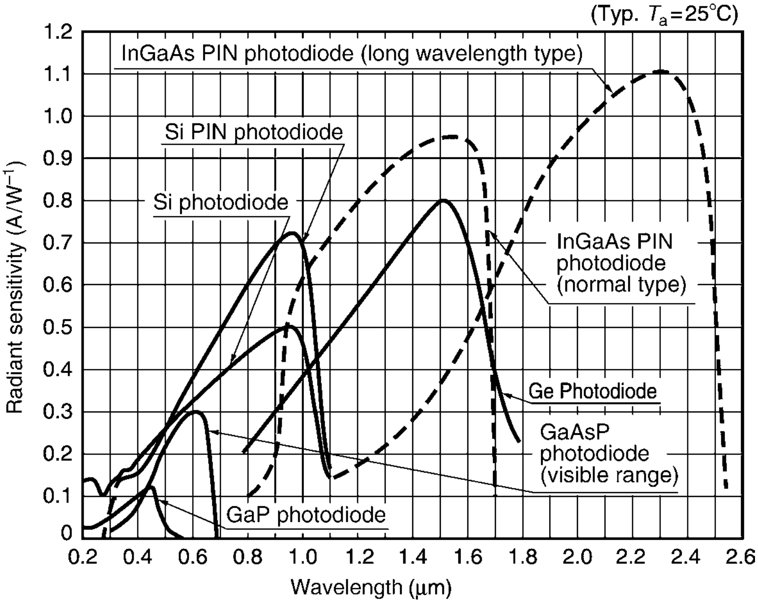

Figure B2.20. Typical spectral response characteristics of photodiodes.

B2.3.5 IR detectors [13]

IR radiation covers the electromagnetic spectrum at wavelengths from 0.8 μm to 1 mm. The wavelength region of 0.8–3 μm is called the near IR, the wavelength region of 3–15 μm the middle IR and the wavelength region of 15 μm–1 mm the far IR.

Table B2.5 shows types of IR detector and their characteristics [14]. In the IR region, thermal type and quantum type (photovoltaic and photoconductive) detectors are commonly used. Thermal type detectors make use of IR energy as heat, their responsivity is independent of wavelength and cooling is not required. However, their response speed is slow and detection sensitivity is not so high. Quantum type detectors, on the other hand, have higher responsivity and faster time response, while their responsivity depends on wavelength. Quantum type detectors often have to be cooled to ensure more stable operation.

Figure B2.22 shows typical spectral response characteristics of IR detectors. As can be seen from this figure, IR detectors using various kinds of photoelectric material have been developed to cover a broad spectral range from the near IR to far IR radiation. It should be noted that spectral responsivity of InGaAs, Ge and InSb detectors shifts to shorter wavelengths by cooling the detector element, while spectral responsivity of PbS, PbSe and MCT (HdCdTe) detectors shifts to longer wavelengths by cooling. Pyroelectric detectors are thermal type IR detectors made of pyroelectric materials such as $LiTaO_3$, TGS and PZT. Unlike quantum type detectors, pyroelectric detectors operate at room temperatures and their responsivity is not dependent on wavelength. One of their applications, recently the focus of much attention, is the 'human body sensor' that is finding wide applications in many fields such as home automation, security and energy saving.

IR detectors are used in diverse application fields including general electronics, security, disaster prevention, industrial measurement, communications, remote sensing, medical equipment and analytical instruments.

Table B2.5. Types of IR detector and their characteristics.

	Type of detector		Detectors	Spectral response range (μm)
Thermal type	Thermocouple, thermopile			
	Bolometer		Golay cell	Depends on window material
	Pneumatic cell		Capacitor microphone	
	Pyroelectric sensor		PZT, TGS, $LiTaO_3$	
Quantum type	Intrinsic type	Photoconductive type	PbS	1–3.6
			PbSe	1.5–5.8

B2.4 Photodetector signal processing methods and S/N ratio

To operate photodetectors in actual applications, optimum detectors must first be selected by considering the light wavelength to be detected, the required time response and S/N ratio. In addition, the signal processing circuit connected to photodetectors must also be optimized. In particular, when the incident light intensity is very low, it is important to take countermeasures against external noise and design measurement systems that will maintain a satisfactory S/N ratio.

B2.4.1 Incident light intensity and signal processing method

Figure B2.23 shows output signal waveforms of a photodetector (a PMT is used here) observed on an oscilloscope while changing the intensity of light emitted from a pulse-driven LED. When the light intensity is high, the photoelectron pulses generated after photoelectric conversion overlap each other and create an analogue waveform as shown in figure B2.23(*a*). When the light intensity is reduced slightly, the output waveform will contain more AC components than DC components like those shown in figures B2.23(*a*)–(*c*). If the light intensity is reduced further, the output signal will be discrete pulses as shown in figure B2.23(*d*). This is the so-called 'photon counting region' (digital count mode).

In this way, the output signal waveform differs depending on the incident light intensity so the subsequent signal processing [15, 16] may use various methods. Typical optical measurement methods are shown in figure B2.24. The DC measurement method in (*a*) amplifies DC components from the photodetector and detects them through a low-pass filter. This method is used in optical measurement at rather high intensity and has been extensively used for many years. In the AC or pulse measurement method in (*b*), only the AC components in the output are extracted via a capacitor, amplified by a pulse amplifier, and converted into digital signals by a high-speed AD converter. This method is frequently used for demodulating pulsed light signals of wide bandwidth such as in optical communications. The photon counting method shown in (*c*) is a pulse counting method in which photoelectron pulses from the photodetector are amplified one by one, and only the pulses with an amplitude higher than the preset discrimination pulse height are counted as signals. Though not shown in figure B2.24, there are other optical measurement methods suitable for low-light-level detection even in applications subject to excessive noise. These include the boxcar method and lock-in detection method used in conjunction with an optical chopper in spectrophotometry.

B2.4.2 Photon counting method

Here, we will discuss specific circuit configurations used to perform photon counting [17, 18] which is an effective technique for light detection at extremely low light levels.

Figure B2.25 shows a typical circuit configuration for photon counting and a pulse waveform obtained at each circuit. In a PMT input photons are converted into photoelectrons which are then

multiplied by the dynodes up to 10^6–10^7. The multiplied pulses output from the PMT are converted into voltage pulses by a wide-band amplifier and amplified. These voltage pulses are fed to the discriminator and counted by a counter via a pulse shaper. The discriminator usually employs a comparator IC that compares the input voltage pulses with the preset reference voltage (threshold level) and eliminates those pulses with amplitudes lower than this value. In general, the lower level discrimination (LLD) is set at the lower pulse height side and the upper level discrimination (ULD) is set at the higher pulse height side to eliminate noise pulses with higher amplitudes. The counter usually has a gate circuit to set the desired measurement timing and intervals. This photon counting method is most effective in detecting extremely low level light.

To enable photon counting, photodetectors must have the following performance characteristics.

(1) Photodetectors must have adequate gain. Usually a gain of 10^5 or more is required in consideration of the relation between the next circuit's amplifier noise level and noise index.

(2) High quantum efficiency at wavelengths to be measured, and few noise pulses in order to attain a high S/N ratio.

(3) Narrow pulse height distribution.

(4) Large photosensitive area (when measuring diffused light).

PMTs satisfy almost all of the above prerequisites, so they are widely used in low-light-level photometric equipment such as photon counters. In recent years, PMTs for photon counting have been improved significantly, leading to development of PMTs [19] that deliver an exceptionally low noise pulse count around 0.1 cps. This allows measurement at extremely low light levels equivalent to nearly 1 photon per second.

In fluorescence lifetime measurement, changes in the light emission persisting only a very short time must also be measured along with the photon counting, so sophisticated techniques called time-resolved photon counting and time-correlated photon counting are used.

B2.4.3 Signal-to-noise ratio

In optical measurements, S/N ratio [20, 21] is a critical factor in determining the lower detection limit of photodetectors.

Figure B2.26 shows a typical model of a photodetector connected to an external circuit. Light is converted into electrons in the photoelectric section of the photodetector and the electrons are amplified if the photodetector has an electron multiplier function. The output from the photodetector is then amplified by the externally connected electronic circuit and extracted as an output signal.

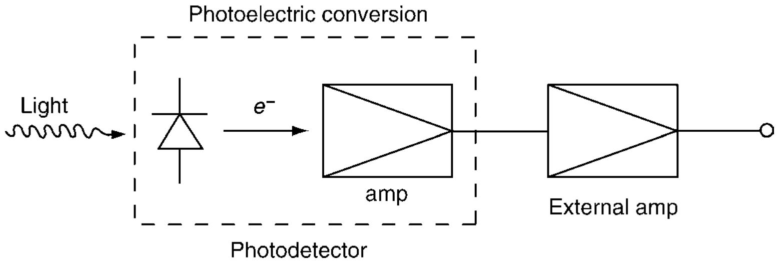

Figure B2.26. Typical model of photodetector connected to an external circuit.

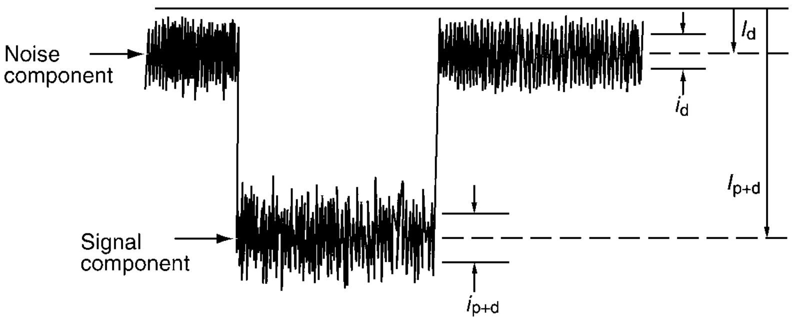

Figure B2.27. Analogue output waveform obtained from a photodetector.

Figure B2.27 shows an analogue output waveform generally obtained from a photodetector. This output contains both signal components produced by the incident light and noise components. These components can be defined as follows:

Mean value of noise component: I_d

AC component of noise: i_d (rms)

Mean value of signal (including noise component): I_{p+d}

AC component of signal (including noise component): i_{p+d} (rms)

Using these factors, the S/N ratio is given by

$$S/N = \frac{I_p}{i_{p+d}} \tag{B2.13}$$

where I_p is the mean value of the signal component obtained by subtracting I_p from I_{p+d}.

The extent of degradation in S/N ratio during the multiplication process is commonly expressed in terms of the noise figure (NF). The NF is defined by

$$NF = \frac{(S/N)^2_{in}}{(S/N)^2_{out}}. \tag{B2.14}$$

In general, the S/N ratio in analogue measurement regions can also be calculated by

$$S/N = \frac{I_k}{\sqrt{2eF_1(I_k + I_d) + \dfrac{4kTF_2}{R_L M^2}}} \frac{1}{\sqrt{B}} \tag{B2.15}$$

where I_k is the mean value of photocurrent generated by signal, e is the electron charge, F_1 is the noise figure of the photodetector, I_d is the mean value of dark current, k is Boltzmann's constant, T is the absolute temperature, F_2 is the noise figure of the externally connected amplifier, R_L is the equivalent resistance for connection to the externally connected amplifier, M is the gain of the photodetector, and B is the bandwidth of the entire system. The numerator in equation (B2.15) is the signal component and the denominator is the sum of the AC components (including the signal and noise) and the noise generated in the externally connected electronic circuit. The NF indicates the increase in noise ratio caused during the multiplication process in the photodetector. Since PMTs have high gain, the noise in the externally connected electron circuit can be ignored in most cases. The NF is about 1.3 for PMTs and 2–3 for APDs.

The second term of the noise of the numerator can be mostly ignored in PMTs since they have a high gain which can be regarded as infinite ($M = \infty$). On the other hand, this noise cannot be ignored in PDs because they have no gain ($M = 1$). If the bandwidth is widened, the S/N ratio will degrade.

In photon counting, the average value of the counts of individual photoelectron pulses is treated as a signal and fluctuations in the count values as noise. The S/N ratio in photon counting is given by

$$\mathrm{S/N} = \frac{N_\mathrm{s}\sqrt{T}}{\sqrt{N_\mathrm{s} + N_\mathrm{d}}} \tag{B2.16}$$

where N_S is the average value for the signal pulse count per second, N_d is the average value for the noise pulse count per second, and T is the counting time in seconds.

When comparing the S/N ratio of the photon counting and analogue methods (equations (B2.15) and (B2.16)), the extent of the NF makes it clear that the photon counting method is superior to the analogue method.

B2.5 High-speed photodetectors

There has been a shift in recent years away from conventional methods and towards using light in many ways. For example, light is extensively used to analyse substances and properties, make measurements and control various devices. A variety of different observation and measurement techniques have been developed for high-speed light measurement [22, 23] and put to practical use. To analyse even higher-speed phenomenon and achieve higher-speed information processing, light sources producing even shorter pulses and demodulators (photodetector and electrical circuit) with high-speed time response [24] are demanded. Here, high-speed photodetectors will be described after touching briefly on general methods for high-speed light measurement.

B2.5.1 High-speed light measurement techniques

Typical methods for measuring short light pulse signals from high-speed phenomena are shown in table B2.6. The analogue measurement sampling technique is a method for finding the waveform of a high-speed PD or PMT on an oscilloscope or other device. The response boundaries of this method are determined by the response of the high-speed photodetector, and the frequency bandwidth of the oscilloscope. Current technology has achieved a time resolution of around 10 ps. Among the real time measurement methods, the streak method [25] has the best time resolution (picosecond to subnanosecond range).

The auto-correlation method attains a time resolution of 10 fs and excellent high-speed characteristics yet cannot find the optical waveform itself due to its measurement principle.

The time-correlated photon counting (TCPC) method [26], along with having a comparatively fast time resolution, also has high sensitivity to low-level light, and a wide dynamic range (10^5–10^6) but also has the drawback of a long measurement time.

B2.5.2 High-speed photodetectors

High-speed photodetector types and time response characteristics are shown in table B2.7. Besides showing whether or not the detector has an amplification mechanism, this table also reveals large differences in photodetector response speeds. The biplanar phototube has a rise time of 60 ps but no amplification mechanism so detection is limited to strong pulsed light. Conventional PMTs have

Table B2.6. Typical methods for measuring short light pulses.

Measurement method	Detectors	Time resolution	Features	
Analogue measurement sampling method	Photodiodes Biplanar phototubes	Nanoseconds	Merits:	Easy to use, relatively fast response
	Photomultiplier tubes MCP-PMT	Subnanoseconds	Demerit:	Narrow dynamic range
Streak method	Streak camera	Femtoseconds	Merit:	Ultra-fast response
Auto-correlation method	SHG correlator	Femtoseconds	Merit:	Measurement of ultra-fast phenomenon
			Demerit:	Optical waveform cannot be measured directly
Time-resolved photon counting method	Photomultiplier tubes	Subnanoseconds	Merits:	Fast response, wide dynamic range
			Demerit:	Longer measurement time than analogue method

Table B2.7. High-speed photodetector types and time response characteristics.

Detectors	Amplification	Response speed
Biplanar phototubes	No	60 ps
Photomultiplier tubes	Yes	A few to several dozen nanoseconds
MCP-PMT	Yes	25 ps
Photodiodes	No	Subnanoseconds to microseconds
APDs	Yes	Subnanoseconds to microseconds
Streak tubes	Yes	0.2–20 ps

response in the nanosecond range but the PMT using MCPs (MCP-PMT) has a time resolution of 25 ps and a gain of 10^6.

Semiconductor photodetectors are widely used in measurement, control and analysis equipment as well as optical communications. Time response characteristics of semiconductor photodetectors are determined by carrier transit time in the depletion layer, the delay time set by the CR time constant, and in the case of APDs the time response is additionally determined by the avalanche rise time. Figure B2.28 shows the effective area versus frequency characteristics of pin PDs. As shown in the figure, the photosensitive area of the pin PDs is nearly proportional to the frequency response. A response up to 300 MHz is shown for an area size of 1.5 mm in diameter but even smaller photosensitive areas have a better response of several gigahertz.

High-speed photodetectors are particularly indispensable in the optical communications field due to their large data communication capacity and high speed. Current technology has achieved frequency characteristics up to 10 GHz using a long-wavelength band InGaAs PD, yet photodetectors with response characteristics of 50–90 GHz on up to the terahertz range will be in actual use in future.

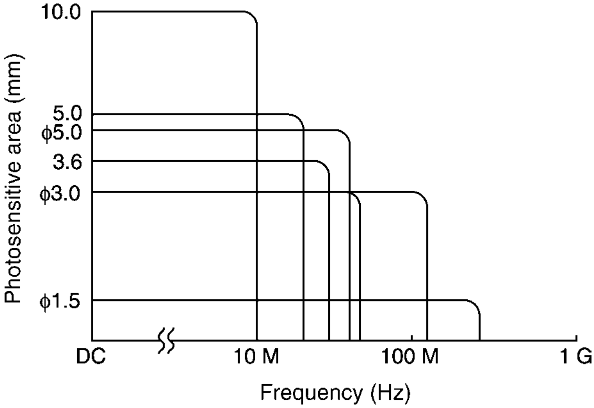

Figure B2.28. Effective area versus frequency characteristics of pin photodiodes.

High-speed devices called metal–semiconductor–metal photodetectors (or MSM-PD) using GaAs as the substrate are well known among semiconductor photodetectors. The MSM has a response of 20 ps (rise time) in actual operation and it was reported that a high-speed response in the subpicosecond [27] level could be attained.

Streak tubes have the highest speed among currently used photosensors, delivering a time resolution of 2 ps, but in recent years some have also attained the subpicosecond range. Development work on femtosecond streak tubes has attained a time resolution of 360 fs and just recently a time resolution of 180 fs has reportedly been reached [28]. Streak tubes are used for researching chemical reaction dynamics, measuring the semiconductor device relaxation process, and observation of super-high-speed phenomena such as implosions in laser nuclear fusion.

B2.5.3 Photodetectors for optical communication

Here we will discuss photodetectors used in optical communication. Digital communication [29] using light has become a useful tool in a wide range of applications mainly due to technical advances such as long-wavelength optical fibres (1.3 and 1.5 μm bands) having low transmission loss as well as rapid progress in wavelength multiplexing technology. High-speed digital communication using optical fibres requires photodetectors [30] with fast response speeds and high sensitivity that can be easily coupled to fibre optic cables.

Optical fibre communication

A typical block diagram for information transmission using an optical fibre is shown in figure B2.29. An information source is converted from electrical signals to optical signals (E/O conversion) after being

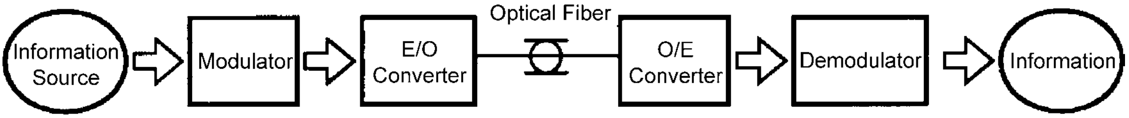

Figure B2.29. Typical block diagram for information transmission using an optical fibre.

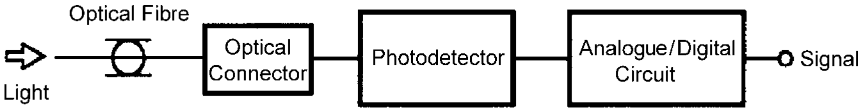

Figure B2.30. Typical configuration for fibre optic receiver.

modulated by various means and is then transmitted to the receiver side through the optical fibre. At the receiver, the optical signals are converted to electrical signals (O/E conversion) and then demodulated back into the original information. Optical fibre communication has the following advantages compared to conventional information transmission by electrical signals.

(1) High resistance to noise since there is no electromagnetic induction.
(2) Good insulation.
(3) Lower transmission loss means long-distance communication.
(4) Optical fibres are lightweight and take up less space.
(5) Huge bandwidth.

Performance required of photodetectors in optical fibre communication

Figure B2.30 shows a typical configuration for a fibre optic receiver. Light transmitted through an optical fibre is detected by a photodetector via an optical connector and converted to electrical signals. These signals are electrically processed by an analogue/digital circuit and then output. The following characteristics are required of photodetectors for use in optical fibre communication.

(1) High sensitivity at signal light wavelength.
(2) Time response fast enough for system transmission speed.
(3) Low noise level.
(4) High stability and long service life under continuous operation.

Besides optical connectors such as shown above for coupling between the optical fibre and photodetector, fibre-to-fibre direct coupling using pigtail type photodetector modules (see figure B2.31) is often used.

Receiver modules for optical fibre communication

In optical fibre communication, rather than as a discrete component, photodetectors generally come attached to optical fibres (pigtail type) or as the so-called optical receiver modules with preamplifiers built in for signal amplification. Various types of packaged receiver module are shown in the photograph [31] in figure B2.31. This photograph shows typical products including coaxial types with internal preamplifier, coaxial types without internal preamplifier, and a fibre jointed device (pigtail type). Long-distance communication uses laser diodes on the 1.3 and 1.5 μm bands, so InGaAs compound semiconductor photodetectors are used rather than silicon photodetectors. Due to the need for optical coupling with the fibres and high-speed response, APDs or PDs having a small sensitive area of 20–80 μm in diameter are generally used.

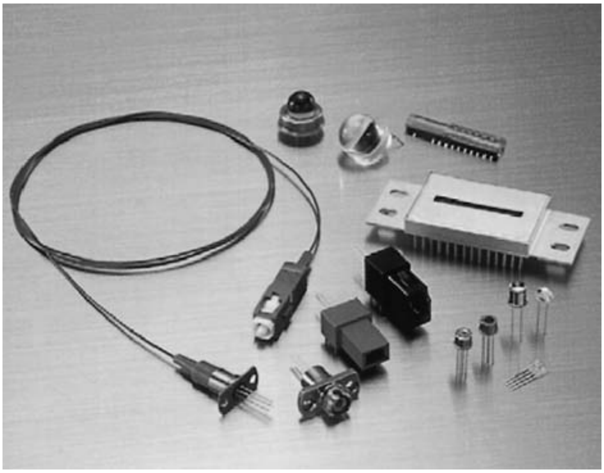

Figure B2.31. Various types of packaged receiver module.

Device characteristics of the most recent receiver modules of InGaAs PIN-PDs and InGaAs APDs are shown in table B2.8. The highest-speed modules are used in 10 Gbps long-distance communication.

Even further advances in optical communication technology are predicted. Technical innovations will expand communication now attainable at 10–40 Gbps and further future advances will take optical communication to speeds in the terabit per second range.

B2.6 Image sensors

Up to here in this chapter, we have defined photodetectors as sensors that only detect the intensity of light. We now however define image sensors as photodetectors that not only detect the intensity of light but also detect one-dimensional or two-dimensional information.

Table B2.8. Typical characteristics of receiver modules for optical communications.

	Active area (μm)	Sensitivity ($A W^{-1}$) Typical	Wavelength (nm)	Bandwidth fc (GHz) Minimum	Preamplifier	Package	Data rate
InGaAs PIN-PD	40	1.00	1550	8.0	Built in	17-pin mini butterfly	10 Gbps
	50	0.89 0.94	1310 1550	2.5	No	Coaxial	2.5 Gbps
	80	0.89 0.94	1310 1550	2.5	No	Coaxial	≤622 Mbps
InGaAs APD	20	0.7	1550	7.0	Built in	17-pin mini butterfly	10 Gbps
	50	0.94 0.96	1310 1550	2.5	Built in	Coaxial	2.5 Gbps
	50	0.94 0.96	1310 1550	1.0	No	Coaxial	≤622 Mbps
	50	0.94 0.96	1310 1550	2.5	No	Coaxial	2.5 Gbps

Table B2.9. Categories of image sensors.

Detecting principle	Readout method	Typical product	Sensitivity	Wavelength range
Image sensors				
External photoelectric (electron tube sensor)	Photoemissive	Image intensifier	Super-high sensitivity	VUV to near IR
	Photoconductive	Vidicon	Sensitive to invisible light	Visible to IR
Internal photoelectric (solid-state sensor)	Address type	MOS CID	High sensitivity	UV to near IR
	Charge transfer	CCD	High sensitivity	UV to near IR
Hybrid sensor		ICCD EBCCD	Super-high sensitivity	VUV to near IR

Table B2.9 shows categories of image sensors. Image sensors can be roughly classified into electron tube image sensors, solid state image sensors and hybrid image sensors combining both types. Electron tube image sensors are further divided into those using the external photoelectric effect or the internal photoelectric effect. IIs are typical electron tube image sensors using the external photoelectric effect. IIs are extremely high-sensitivity image sensors since they have an internal electron multiplier called MCP that delivers a multiplication factor (gain) of 10^3–10^6 times. IIs were primarily developed for low-light imaging such as at night time so they are still referred to as night vision tubes. In addition to low-light imaging applications, IIs are applied to high-speed shutter cameras because an electronic shutter that works in subnanoseconds can be implemented. Image pickup tubes or camera tubes are the best known among electron tube image sensors using the internal photoelectric effect. Among these, camera tubes called 'vidicon' have been used for many years in various applications from the UV, visible and IR regions by changing their photoconductive target materials (Sb_2S_3, PbO, CdSe).

Typical solid state image sensors are charge transfer type CCD image sensors and CID image sensors, and addressed type MOS image sensors. More recently, hybrid image sensors using an electron tube image sensor and a semiconductor image sensor have been developed and put to practical use.

Image sensors can also be classified by application into quantitative measurement such as for spectrophotometry and pattern recognition; and general imaging such as home video cameras. Since only limited space is available, this section will explain about image sensors designed for measurement applications.

B2.6.1 Electron tube image sensors

Camera tubes, the best known electron tube image sensors, have been used in many imaging applications. In recent years, however, camera tubes have been almost completely replaced by semiconductor image sensors and are now seldom used in the visible light region.

IIs [32, 33] are electron tube image sensors with ultra-high sensitivity and a high-speed electronic shutter mechanism.

Figure B2.32 illustrates the structure of a proximity-focused II. In operation of this type of II, an optical image from a low-light-level object is converted into photoelectrons by the photocathode, multiplied by the MCP and reconverted into an amplified optical image on the phosphor screen.

(Electron to light conversion)

Figure B2.32. Structure of a proximity-focused image intensifier.

An MCP consists of a multitude of glass capillaries (channels) of 10–20 μm in inner diameter, fused together and formed into the shape of a thin disc of 0.1–1.0 mm thick. The inner wall of each channel is coated with a secondary emissive material with a proper resistance value, so each channel serves as an independent, nondiscrete secondary electron multiplier. For example, in an MCP of 18 mm in outside diameter, about 10^6 channels are arrayed in two dimensions so each channel corresponds to a pixel when used as a two-dimensional sensor. This MCP multiplication function allows IIs to have a high gain of 10^3–10^6 (depending on the number of MCP stages), so that they are used in night vision devices and low-level-light image sensors. Figure B2.33 is a circuit for driving a high-speed electronic shutter (gate) built into an II. By applying a negative pulse between the photocathode and the MCP, the photoelectrons emitted from the photocathode can be controlled so as to have an electronic shutter function [34] that turns the II operation on or off. In figure B2.33, the shutter turns on when a negative voltage pulse is applied to the photocathode. This electronic shutter is used at speeds of nanoseconds to microseconds in most applications, although special shutters are designed to operate at ultra-high speeds of 50 ps [35]. When viewing highly repetitive phenomena, phosphor materials [36] having a short decay time τ

designated P47 ($\tau = 0.1\ \mu s$), P46 ($\tau = 0.2\ \mu s$) or P24 ($\tau = 8\ \mu s$) are used. But, in general applications, P43 ($\tau = 1$ ms) is used because of high emission efficiency.

By selecting the window and photocathode materials, IIs can be used for imaging in various wavelength regions of the spectrum from soft x-rays to IR radiation. II products are shown in the photograph in figure B2.34.

B2.6.2 Semiconductor image sensors

Charge coupled device (CCD) image sensors and MOS image sensors are typical semiconductor image sensors [37, 38]. They are broadly divided by structure into one-dimensional arrays (linear image sensors) and two-dimensional array sensors (area image sensors). Semiconductor image sensors are generally mass-produced for image capturing applications but here we will discuss their use in making measurements.

Semiconductor image sensors are also grouped into address types and charge transfer types according to their scan method.

The address type shown in figure B2.35(*a*) is a two-dimensional array of pixels consisting of photoelectric elements such as PDs. Each pixel is respectively connected to a vertical and horizontal shift register. To read out signal charges from pixels, an external pulse is sent in sequence to the pixels, and the signal charge accumulated at the intersecting pixel is read out. In the charge transfer type shown in figure B2.35(*b*), signal charges of pixels comprised of PDs are sequentially transferred in parallel vertically, and also transferred one line at a time horizontally, and the signal charge then read out. MOS (metal-oxide semiconductor) image sensors are typical address type sensors, while CCD image sensors are typical charge transfer type sensors.

The CCD has high sensitivity, low noise and is capable of handling large numbers of pixels. The CCD is the most dependable yet least expensive device among currently available image sensors and is used in large numbers. MOS image sensors offer a large photosensitive area capable of handling a large

storage charge and have low power consumption. One disadvantage of MOS image sensors is large capacitive noise compared to CCD, and the S/N ratio gets worse under low level light.

In this section, we cover image sensors intended mainly for optical measurement, so refer to other texts if seeking information on general-purpose image sensors such as for video cameras [39].

Linear image sensors [40]

Linear image sensors are image sensors segmented in only one dimension. A typical application of CCD linear image sensors is for facsimile readout and image sensors are also used in multichannel wavelength detectors in polychromators for spectrophotometry.

Figure B2.36 shows the structure of an n-MOS linear image sensor. The photosensitive area is a p–n junction PD consisting of a p-type silicon substrate on which an n-type diffusion layer is formed. The sensor has a photoelectric function to convert the optical signal into an electrical signal and a function to temporarily store the acquired signal charge.

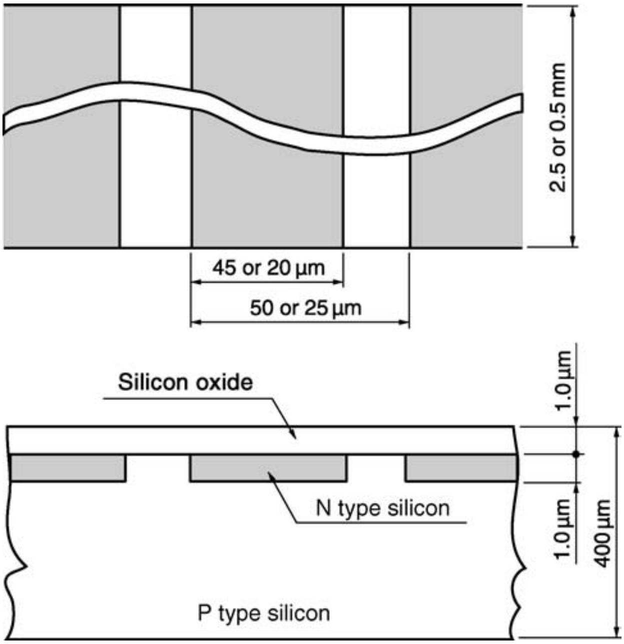

Figure B2.36. Structure of an n-MOS linear image sensor.

Table B2.10 shows typical structure and device characteristics of linear image sensors having a photoelectric surface made of InGaAs or silicon material. The photosensitive layers of InGaAs or silicon, respectively, match the visible-to-near-IR and the IR regions. Pixel size is several millimetres in height and up to 100 µm in width, with some hundreds to thousands of pixels fabricated as channels. Figure B2.37 shows an equivalent circuit of an n-MOS linear image sensor. The photosensitive area of the PD, as shown in the figure, is comprised of a switching section to read out the PD signal, and a shift register to address that switch. The linear image sensor using silicon may be fabricated to have a maximum of 2048 channels. These image sensors are usually used singly but may often be used in combination with an II described later on.

The image sensor using InGaAs is utilized for spectrophotometry in the IR on a wavelength of approximately 1–2.6 µm. As a photodetector for near-IR multichannel spectrophotometry this has

Table B2.10. Typical structure and device characteristics of linear image sensors.

Detector material	Window material	Spectral response range	Cooling	Pixel size	Number of pixels
Si	Quartz	200–1000 nm	Yes	50 µm × 2.5 mm 25 µm × 2.5 mm 50 µm × 0.5 mm 25 µm × 0.5 mm	256–2048
InGaAs	Sapphire	0.9–1.7 µm	No	50 µm × 250 µm	128–512
		0.9–1.7 µm	Yes	25 µm × 250 µm	
		1.2–2.6 µm	Yes	50 µm × 0.5 mm 25 µm × 0.5 mm

applications in inspection of farm products by the IR absorption technique, radiation thermometers and nondestructive inspections, etc.

Area image sensors

Two-dimensional image sensors (area image sensors) for measurement applications often use CCD image sensors [41]. The transfer method, structure and characteristics of CCD image sensors are described below.

CCD image sensor transfer method. CCD image sensors can typically be grouped into one of the following three types of transfer method:

1. Frame transfer type: The frame transfer (FT) type CCD shown in figure B2.38 is comprised of two vertical shift registers made up of a photosensitive area and charge storage area, one horizontal shift register and an output section. A transparent electrode such as polycrystalline silicon is generally used as the metal electrode for the photosensitive area. The areas other than the photosensitive area are covered with a nontransparent electrode such as aluminium so that light will not enter those areas.

2. Full frame transfer type: The full frame transfer (FFT) type CCD in figure B2.39 is basically the FT type CCD without the charge storage area. Since there is no charge storage section, it must normally be used with some kind of external shutter mechanism. This limitation makes it difficult to use as a video camera so its use is mainly limited to measurement applications.

3. Interline transfer type: In the interline transfer (IT) type CCD shown in figure B2.40, the photosensitive area is formed separately from the transfer section. Here the vertical shift register is formed on the sides so as to enclose the PD that constitutes the photosensitive area. Because of this structure, the numerical aperture is low, so this type is not suited for measurement applications.

To sum up the above described methods, the IT type is used in video cameras while the FT and FFT types are mainly used in measurement applications.

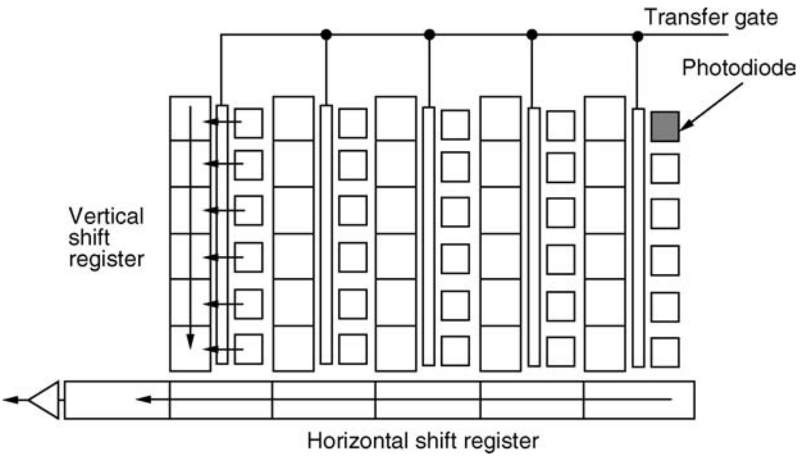

Figure B2.40. Structure of an interline transfer type CCD.

Structure of area image sensor for measurement work. To function effectively in measurement applications, the area image sensor must have high sensitivity, a wide dynamic range and be multichannel. Table B2.11 shows pixel formats of typical area image sensors used in measurement applications. The structure of an FFT (or FT) type CCD image sensor is generally used. A rectangular format is generally used for spectrophotometry as a precondition for binning (described later), and a square format is used for imaging. Actual CCD image sensor products are shown in the photograph in figure B2.41.

To improve measurement performance of the CCD image sensor, low noise is achieved by cooling (to −20°C), sensitivity is improved by back-illumination, and scanning is used in the binning operation.

Figure B2.42 shows the structure of a back-illumination CCD [42] (also called 'back-thinned CCD' since the backside of the CCD chip is thinned).

As shown in the figure, light enters from the front surface on a normal CCD. However, light loss occurs when light is input from the front due to absorption of light by the oxide film and the electrodes. In contrast, in the back-illumination CCD there is no such light loss, high sensitivity is obtained and a quantum efficiency as high as 90% is achieved. Even in the UV region, a high quantum efficiency of 40% or more is achieved. Spectral response characteristics of the back-illumination CCD are shown in figure B2.43, along with characteristics of the front-illumination CCD for comparison. A great increase in sensitivity can be seen in the UV region as well as in the visible region.

Table B2.11. Pixel formats of typical area image sensors used in measurement applications.

Applications	Number of pixels (H × V)	Pixel size
Spectrophotometry	532 × 64	24 μm × 24 μm
	1044 × 64	24 μm × 24 μm
Imaging	512 × 512	24 μm × 24 μm

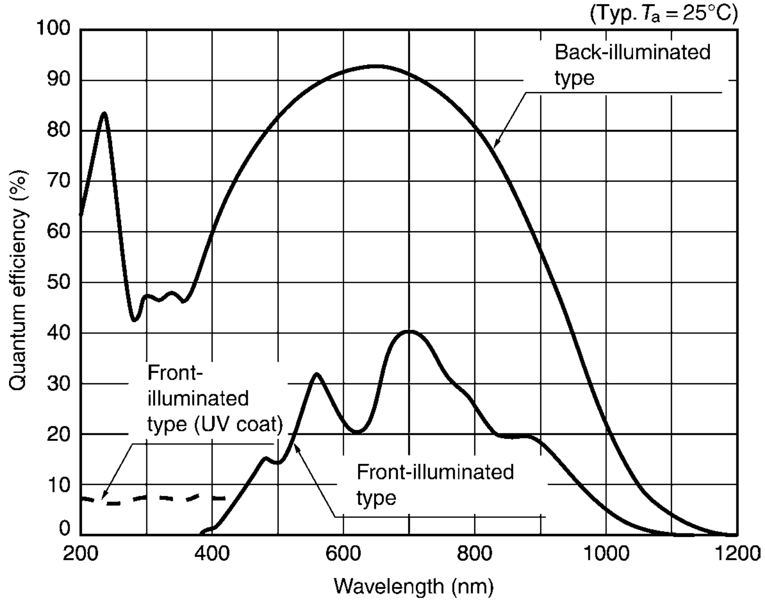
The binning operation unique to CCD image sensors is described next. Figure B2.44 shows the principle of the binning operation in the CCD image sensor. In the FFT-CCD, the signal charges are stored in the potential well during the integration time, and when integration time ends the signal charges are stored two-dimensionally. Here, signals can be summed in the line direction (line binning) as shown in the figure, by transferring charges separately to the vertical shift register and horizontal shift register. Besides vertical binning that adds signals perpendicularly in this way, binning can also be performed horizontally.



Hamamatsu Photonics; Image Sensors, Cat. No. KMPD0002E01(2001)

Figure B2.43. Spectral response characteristics of a back-illumination CCD (without window).

Binning allows using a two-dimensional image sensor as a one-dimensional image sensor (line binning) and changing the number of effective channels (horizontal binning).

Spectrophotometric applications of semiconductor image sensors are expanding to fluorescence spectrometry, ICP, Raman spectrometry, and multichannel spectrometry. Imaging applications include fields such as bio-imaging, semiconductor device analysis, and astronomical observation.

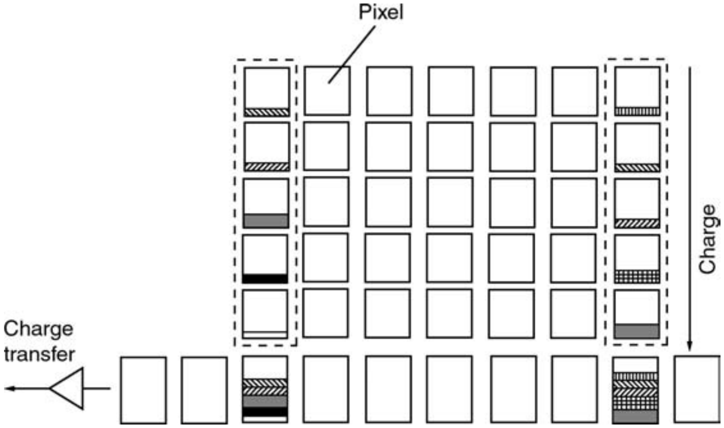


Figure B2.44. Principle of binning operation in the CCD image sensor.

B2.6.3 Hybrid image sensors

Combining electron tube image sensors with semiconductor image sensors allows boosting performance much more than would be possible with a single type of image sensor. Hybrid image sensors with additional functions are now seeing wide practical use.

One type of hybrid image sensor is a high-sensitivity multichannel detector [40] combining an II with a semiconductor linear image sensor. Figure B2.45 shows a high-sensitivity multichannel detector combining an II with a semiconductor linear PD array (512-channel MOS PD array) as well as its signal processing diagram. Light input to the II is converted to photoelectrons by the photocathode, amplified 10^3-10^4 times by the MCP, and converted to an optical image on the phosphor screen. The optical image on the phosphor screen is then photoelectrically converted by the linear image sensor, and the signal from the PD array is output as a video signal through a signal processing circuit. A gain of 10^6 or more can be obtained when a two- or three-stage MCP is used, allowing photon counting [43]. High-speed shutter operation on the subnanosecond level can also be obtained by applying a gate pulse to the II as needed.

The high-sensitivity multichannel detector described here has applications in observation of internal combustion engines, plasma, fluorescence, biochemical emissions, calcium ion density distribution, Raman spectrometry, semiconductor device evaluation, etc. Its use has also become common on production lines, laboratories, and field test measurements.

Figure B2.46 shows the structure of an intensified CCD (ICCD) [44] developed for imaging of low-level light. The ICCD amplifies low-level input light in an II and the output image produced on the phosphor screen is read out by an externally coupled CCD area image sensor. Amplification in an ICCD depends on the number of MCPs incorporated in the II and the applied voltage. Under high-sensitivity conditions the ICCD is even capable of photon counting (photon counting imaging) [45].

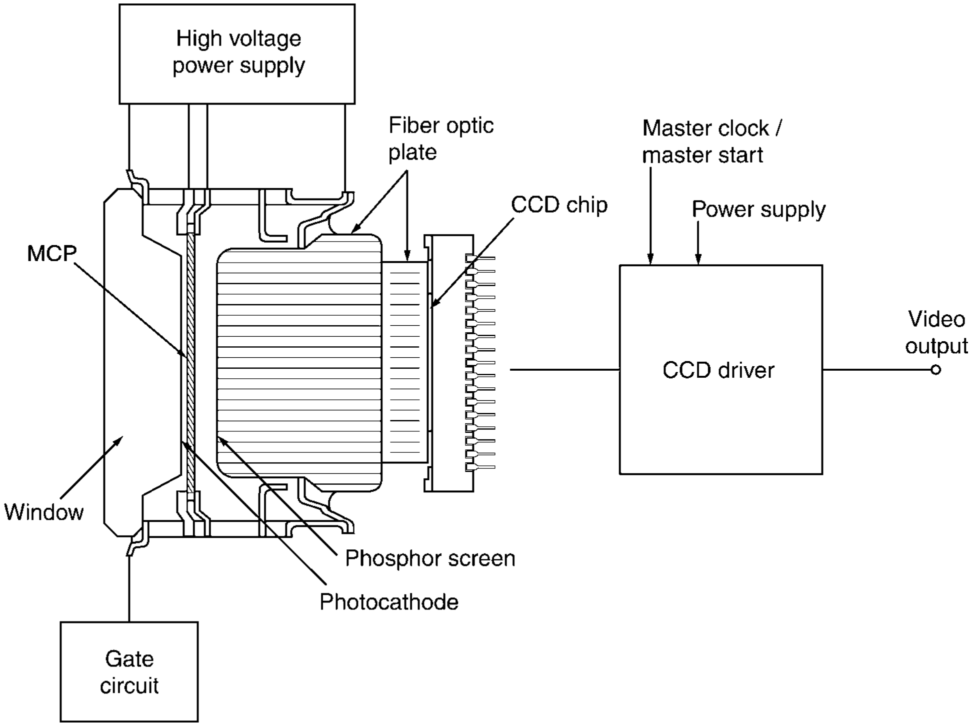

Figure B2.46. Structure of an ICCD.

The ICCD is utilized in imaging applications in the state-of-the-art fields such as combustion analysis in internal combustion engines, imaging of high-speed moving objects, and bioluminescence imaging.

In recent years, a unique imaging device called electron bombardment CCD (EBCCD) [46, 47] has been developed for low-light-level imaging. The EBCCD uses a back-illumination CCD sealed in a photoelectric vacuum tube. Electrons emitted from the photoelectric surface (photocathode) are directly detected by the internal CCD. As shown in figure B2.47, the EBCCD utilizes the gain resulting from electron bombardment multiplication occurring when accelerated electrons lose energy and generate many electron–hole pairs within the CCD. This device has the advantage of a high numerical aperture and low gain fluctuation. The EBCCD yields a gain of 50–1300 times that is nearly equal to the gain obtainable with an ICCD using a single MCP. The EBCCD is mainly utilized in low-level fluorescence imaging under a microscope.

Figure B2.48 is a table comparing image sensor detection sensitivity such as in CCD and ICCD image sensors. The CCD has no amplifying function and is therefore restricted to use in areas of strong light intensity and also has a limited dynamic range due to the charge saturation and noise level. The ICCD takes advantage of the MCP amplification effect to achieve a wide dynamic range and ultra-high sensitivity by changing the number of MCP stages and applied voltage. As mentioned earlier, the II not only delivers ultra-high sensitivity but can also function as a high-speed shutter camera by joint use with an ultra-high-speed gate on the nanosecond to subnanosecond level.

B2.7 Future prospects

This chapter has discussed categories, basic principles and various characteristics of photodetectors or optical detectors. Future years will show accelerated progress in applying light to the measurement, machining, control technology, communications, general electronics, and basic science fields. Along with these advances, extensive effort will be poured into developing practical photodetectors with higher sensitivity and time response, greater miniaturization or integration and multichannel detection capabilities.

B3
Optical fibre devices

Suzanne Lacroix and Xavier Daxhelet

B3.1 Introduction

Maximizing the capacity of the fibre as a transmitting medium is the major challenge met by network operators. Solitonic propagation as well as wavelength division multiplexing (WDM) are among the solutions presently proposed to increase the flow of information propagating in these networks. This progress is made possible thanks to the development of such essential components as the erbium doped fibre amplifier (EDFA) and frequency stabilized laser sources. However, other components to perform all the functions (routing, filtering, dispersion compensation, etc) are not less essential. Different approaches to design and realize the corresponding components are commonly used. The advantage of the all-fibre approach over its competitors (micro- and integrated optics) lies undoubtedly in the fact that all-fibre components are readily integrated to the network without significant splicing loss. In addition, their polarization sensitivity (which would induce loss and dispersion) is intrinsically much smaller than that of their integrated optic counterparts.

The present chapter content is restricted to all-fibre components, their micro-optics and integrated-optics equivalents being treated in chapters A16 and B8, respectively. Unless expressly mentioned, these all-fibre components are made of single-mode fibre. The emphasis is put on the way they function and their intrinsic limitations, leaving out details about fabrication and packaging problems, which are treated elsewhere (see chapter B12). Besides, only passive components are considered. Optical amplifiers and lasers can be found in chapters A18 and B6. Some other more advanced components, such as wavelength converters, are based on non-linear effects (see chapter A2.4). They usually take advantage of the inherent third-order non-linear effects, but second-order effects can also be induced as explained in chapter B14. These components are not treated in the present chapter.

In the following section, we present the basic technologies that are involved. The subsequent section gives concepts that determine the behaviour of these all-fibre components. Example components are presented in the third section.

B3.2 Technologies

Two main technologies are presently used to manufacture all-fibre components:

1. the fusion and tapering technology;
2. the inscription of gratings including both short-period gratings (usually referred to as Bragg gratings) and long-period gratings (LPGs).

B3.2.1 Fusion and tapering

The tapering technique consists of locally heating and stretching a fibre using a micro-torch or a CO_2 laser, thus creating a biconical structure such as that of figure B3.1.

Before tapering, one may laterally fuse two (or more) fibres together so as to create a more complex transverse structure in order to transfer power from one guide to another. Such structures are referred to as couplers.

Irrespective of the transverse structure, the behaviour of the component is largely determined by the slopes of the longitudinal structure. In the case of a tapered single fibre, however, the angle is made small enough everywhere so that only a negligible leakage of power from the fundamental mode as it propagates along the structure is ensured. In such cases, the propagation and, by extension, the taper itself is said to be *adiabatic*, where the fibre transmission is not affected by the tapering process [1]. In contrast, when the slopes are abrupt, such as those of the structure shown in figure B3.1, one may observe large oscillations in the transmitted power, as the fibre is elongated. In addition, for a given elongation, similar oscillations are seen in the transmission as a function of wavelength (figure B3.20) or of the refractive index surrounding the tapered part of the fibre [2].

While adiabaticity is usually required for couplers, non-adiabaticity of tapered single fibres can be used to design a variety of all-fibre spectral filter.

B3.2.2 Gratings

All-fibre short- and long-period gratings are periodically perturbed fibres. The number of periods ranges from ten to several thousands depending on the intensity of the index perturbation (up to 10^{-2}). Both short- and long-period gratings operate according to a resonant coupling effect resulting in a condition relating to the modal wave vectors $\vec{\beta}_1$ and $\vec{\beta}_2$ with the grating one $\vec{\beta}_B$

$$\vec{\beta}_1 = \vec{\beta}_2 + \vec{\beta}_B. \tag{B3.1}$$

Wave vector resonance conditions are shown in figure B3.2 for contra- and codirectional coupling. Short periods $\Lambda = 2\pi/\beta_B$ are of the order of 0.5 μm and long ones 500 μm. As their periods are of the order of half the wavelength in silica, short-period gratings reflect the fundamental mode into itself (through contradirectional coupling) at a given wavelength ($\vec{\beta}_2 = -\vec{\beta}_1$). They also reflect higher-order cladding modes at shorter wavelengths with lesser efficiency, unless especially designed for this purpose. On the other hand, long-period gratings couple, at a given wavelength, the fundamental mode into

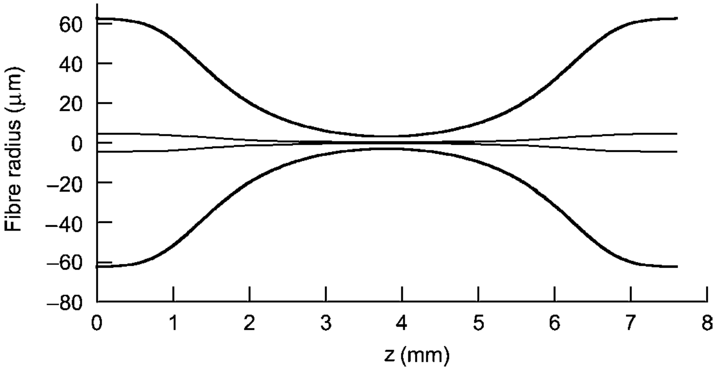

Figure B3.1. Profile of an abruptly tapered fibre.

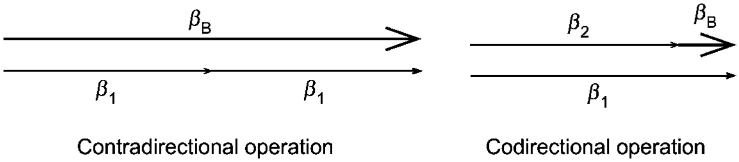

Figure B3.2. Wave vector conservation in fibre gratings. Contradirectional coupling corresponds to large grating wave vectors β_B and thus small grating periods Λ (typically half a μm), while codirectional coupling corresponds to small grating wave vectors β_B and thus large grating periods Λ (several hundred μm).

copropagating higher-order modes (through codirectional coupling), which are eventually absorbed by the fibre jacket. Both types of grating are thus rejection filters in transmission.

Short-period gratings

There are essentially two methods to manufacture this type of grating. Both are, however, based on photosensitivity—a stable refractive index change of the order of a few 10^{-4} up to 10^{-2} that the Ge-doped core of the fibre experiences, when exposed to near UV-radiation.

1. The first method consists of exposing the fibre to an interference field created by two locally planar waves of a UV-laser such as doubled Ar^+, dye lasers or copper vapour lasers. The period Λ is then given by

$$\Lambda = \frac{\lambda_{\mathrm{UV}}}{2\sin(\theta/2)} \tag{B3.2}$$

where λ_{UV} is the writing wavelength and θ the angle between the interfering waves. This method referred to as the holographic method is very flexible because any periodicity may be realized. A number of practical implementations have been designed [3, 4]. However, as for any holographic setup, stability is an issue. It is thus easier to implement it in a pulsed regime.

2. The alternative method uses a phase mask as schematized in figure B3.3. It is a phase grating having a periodicity Λ_m, twice that of the grating to be written in the fibre ($\Lambda_m = 2\Lambda$). Its depth e and refractive index n (at λ_{UV}) are related by $2(n-1)e = \lambda_{\mathrm{UV}}$ ensuring that the zero order is not transmitted. Waves from orders $+1$ and -1 thus interfere in a similar manner to that described above for the holographic method.

The main advantage of the phase mask method over the holographic one is that the UV-source may have a limited spatial and temporal coherence. This is the case of excimer lasers (KrF lasing at $\lambda_{\mathrm{UV}} = 248$ nm and ArF at $\lambda_{\mathrm{UV}} = 193$ nm), which are frequently used for fibre grating inscriptions. The fibre and the mask are then separated by only a few micrometres. The disadvantage of this method is that the Bragg period is determined by that of the phase mask, which is an expensive component.

This drawback may, however, be overcome by a combination of both methods in set-ups such as the Talbot interferometer in which the phase mask is used as a splitting plate and the fringe periodicity is varied through a mirror angle [3, 4].

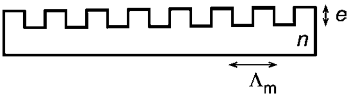

Figure B3.3. Phase mask.

Long-period gratings

As their period is long ($\Lambda = 300-800\,\mu\text{m}$), this type of grating usually does not require sophisticated set-ups such as those of their short-period counterparts. Most of the time they use step-by-step methods.

1. The fibre may be irradiated by a UV-source just as in the short-period case. One may use the step-by-step method or an amplitude mask.
2. CO_2-laser irradiation ($\lambda = 10, 6\,\mu\text{m}$) also induces index changes of the same order of magnitude, but the mechanism responsible for this change, although not completely identified, is certainly different as the perturbation persists at higher temperatures than photosensitivity [5].
3. Larger index changes (up to a few 10^{-3}) may also be induced by an electrical discharge. The grating is also stable at high temperatures and its inscription is clearly related to the fibre inner stresses [5].
4. Femtosecond intense Ti:sapphire lasers are also known to induce large refractive index changes that may be used to manufacture long-period gratings.
5. Finally, one may manufacture LPGs by periodical tapering of the fibre.

All these fabrication techniques (fusion-tapering and grating inscription) may be viewed from a theoretical viewpoint as perturbations to the longitudinal invariance of the fibre structure. These perturbations in turn induce coupling between the modes and thus power the transfer from the fundamental mode to others. These effects are described by the coupled mode formalism, which is now presented.

B3.3 Coupled mode theory

Except for the propagation factor $e^{i\beta_j z}$ along the guide, modes of an unperturbed guide, identified by their indices j, are z-invariant solutions of Maxwell equations. Any solution, i.e. any electromagnetic field propagating along the guide, is a superposition of these modes with amplitudes a_j.

When the guide is perturbed, these modes are no longer solutions and the optical power may transfer from one mode to another. This is described by permitting the modal amplitudes a_j to vary with z.

Whatever the perturbation, periodical or not, resonant or not, between co- or contradirectional modes, it always consists of a variation of the refractive index, i.e. of the polarization vector. Coupled mode equations may be demonstrated from Maxwell equations by expanding the electromagnetic field on a modal basis [6]. These equations may be written as

$$\frac{da_j}{dz} - i\beta_j a_j = i\sum_{\ell} C_{j\ell}(z)a_{\ell} \tag{B3.3}$$

where a_j and β_j are, respectively, the amplitude and the propagation constant of mode j and $C_{j\ell}(z)$ the coupling coefficient between mode j and mode ℓ. This coupling coefficient may be real or complex depending on the waveguide perturbation. As the set of all the modes (guided as well as radiation modes) of an unperturbed guide constitutes a basis for the expansion of any electromagnetic field, it is natural to choose a_j to be amplitudes of the normal modes of a guide. The choice of the guide used for the basis depends on the problem as will be shown in the following section.

B3.3.1 Ideal mode coupling

As shown in figure B3.4, whenever the perturbation is a slight departure from a z-invariant guide, referred to as the *ideal guide*, the natural basis is the set of modes of this ideal guide. One also refers to this expansion as the *ideal mode* expansion. The coupling coefficient in the scalar approximation [6] is shown to be

$$C_{j\ell} = \frac{k^2}{2\sqrt{|\beta_j\beta_\ell|}} \int_{A_\infty} (n^2 - \bar{n}^2)\hat{\psi}_j^* \hat{\psi}_\ell \, \mathrm{d}A \tag{B3.4}$$

where $n(x, y)$ is the perturbed guide index profile, $\bar{n}(x, y)$ the unperturbed one, A_∞ the guide cross-section area $\hat{\psi}_j$ and $\hat{\psi}_\ell$ the normalized *scalar* normal fields obeying

$$\int_{A_\infty} \hat{\psi}_j^* \hat{\psi}_\ell \, \mathrm{d}A = \delta_{j\ell} \tag{B3.5}$$

with $\delta_{j\ell}$ the Krönecker symbol.

B3.3.2 Local mode coupling

Whenever, as shown in figure B3.5, the guide varies slowly along z, one can define, in each z cross-section plane, a guide which locally coincides with the perturbed guide. Then, the so-called *local mode* expansion is performed. In this case, as opposed to the former one, the basis modes depend on z in particular through their propagation constants $\beta_j(z)$. The coupling coefficient, in the scalar approximation, is shown when one neglects longitudinal variations of the modal field

$$C_{j\ell} = -\mathrm{i}\frac{k^2}{2\sqrt{|\beta_j\beta_\ell|}} \frac{1}{\beta_j - \beta_\ell} \int_{A_\infty} \frac{\partial n^2}{\partial z} \hat{\psi}_j^* \hat{\psi}_\ell \, \mathrm{d}A. \tag{B3.6}$$

B3.3.3 Individual guide coupling

In the case of couplers made of single-mode waveguides, as shown in figure B3.6, the amplitudes a_j and a_ℓ of equation B3.3 are the fundamental mode amplitudes of the unperturbed guides (i.e. without the other guides). Although obviously not constituting a basis, these modes serve as an expansion set, which permits us to describe the power exchange between the guides quite accurately. The coupling coefficient takes the same form as in equation (B3.4) although, here, $\hat{\psi}_j$ and $\hat{\psi}_\ell$ are the normalized modal fields of individual guides j and ℓ; the unperturbed index profile $\bar{n}(x, y)$ is that of the individual guide supposed alone and $n(x, y)$ the index profile of the whole coupler.

Note, however, that in the case of a fused coupler, single-mode guides are not defined for any cross-section so that one must abandon this concept and use supermodes instead, as described in more detail in section B3.3.1.

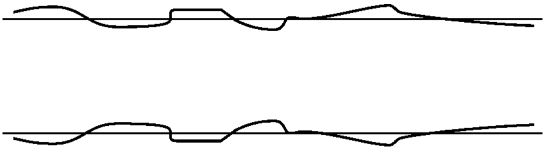

Figure B3.4. Perturbation of an ideal guide.

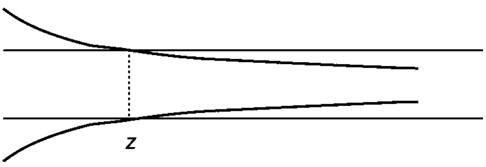

Figure B3.5. Perturbation of local guide.

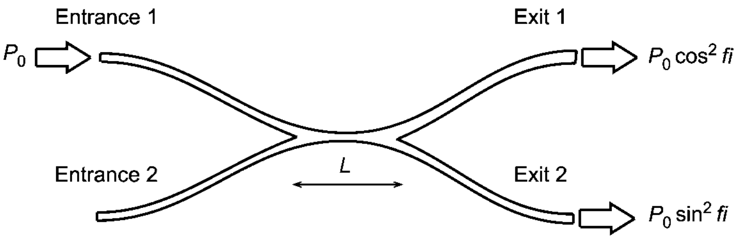

Figure B3.6. Diagram of a 2 × 2 coupler.

B3.3.4 Beating and coupling lengths

The beating and coupling lengths are the key parameters to predict the behaviour of components.

Let $C_{j\ell}$ be the coupling coefficient between modes j and ℓ. Whenever the coupling coefficients do not depend on z, solutions of the coupled mode equation (B3.3) are sinusoidal functions. The coupling length L_{C} is defined as the length for which a complete *power* transfer cycle takes place (transfer from mode j to mode ℓ and back to mode j). One thus defines

$$L_{\mathrm{C}} = \frac{2\pi}{|C_{j\ell}|}. \tag{B3.7}$$

The beating length z_{b} between these two modes is defined as the length along which the modes accumulate a 2π phase difference. One thus has

$$z_{\mathrm{b}} = \frac{2\pi}{|\beta_j - \beta_\ell|}. \tag{B3.8}$$

These length scales permit us to define a criterion to discriminate between slowly varying adiabatic structures and abruptly varying ones for which modes are coupled. A rule of the thumb is given by the condition

$$L_{\mathrm{C}} = z_{\mathrm{b}}. \tag{B3.9}$$

1. If the coupling length of two given modes is larger than their beating length $L_{\mathrm{C}} > z_{\mathrm{b}}$, the modes accumulate a phase difference through the beating phenomenon without an exchange of power. The process may be considered as an adiabatic one.
2. If the coupling length of two given modes is smaller than their beating length $L_{\mathrm{C}} < z_{\mathrm{b}}$, the modes exchange power through the coupling process over such distances that their propagation phase difference is negligible. The process is then non-adiabatic.

B3.4 All-fibre passive components

Passive components are defined as components that do not necessitate an external source of energy, as opposed to lasers, amplifiers and other active components. Most of the time, all-fibre passive components are based on the technologies such as fusion-tapering and grating inscription described earlier. The fabrication parameters of an individual structure, tapered fibre coupler or grating, may be varied to obtain a prescribed behaviour. In addition, several individual components may be concatenated, cascaded or mixed to accomplish more complex functionalities. The following sections give the essential basic concepts to understand the principles underlying the operation of all these components and describe some of the example components based on these principles.

These components are characterized by several parameters. Essential parameters are IL, CD, PDL and DGD.

1. The *insertion loss* (IL) is the transmittance in dB, defined by $\mathrm{IL} = 10 \log T$.
2. The *chromatic dispersion* (CD) is the pulse broadening per unit wavelength and length of propagation, resulting from both material and waveguide contributions. For fibres, it is expressed in $\mathrm{ps\,nm^{-1}\,km^{-1}}$ and, for step index profiles, the main contribution comes from the material CD, i.e. the dependence of the index of silica on wavelength. In components, it is expressed in $\mathrm{ps\,nm^{-1}}$ and is usually small except for gratings, which may be designed to compensate the dispersion accumulated over several kilometres of fibre.
3. The *polarization dependent loss* (PDL) is due to the component birefringence. This birefringence results an IL depending on polarization. The PDL parameter is defined by the difference of the ILs for the best and worst polarization states and is thus expressed in dB.
4. The *differential group delay* (DGD) characterizes the variation of the group delay with polarization. It is defined by the difference between group delays for the fastest and slowest polarization states, and is usually expressed in ps. Note that the length of fibre is characterized by its *polarization mode dispersion* (PMD) expressed in $\mathrm{ps\,km^{-1/2}}$, as the DGD accumulates statistically as the square root of distance of propagation.

B3.4.1 Splitters and combiners

All-fibre splitters and combiners are based on couplers which are, most of the time, made by the fusion and tapering technique. Although a coupler may consist of an arbitrary number of fused possibly different fibres, most of them are 2×2 couplers made of identical fibres. Two geometric parameters determine their behaviour:

- Their degree of fusion f that may theoretically vary from zero (tangent fibres) to one (completely fused fibres resulting in a circular cross-section) [7].
- Their longitudinal profile that is described by the variation of the inverse taper ratio (ITR-) parameter along z. In a first approximation, the tapering process is assumed to preserve the structure respective dimensions, so that one can characterize the transverse reduction by the ratio of a given length (e.g. the core radius or the coupler width) measured after and before the tapering process. This is the definition of the ITR-parameter.

Principle of operation

Concept of supermodes

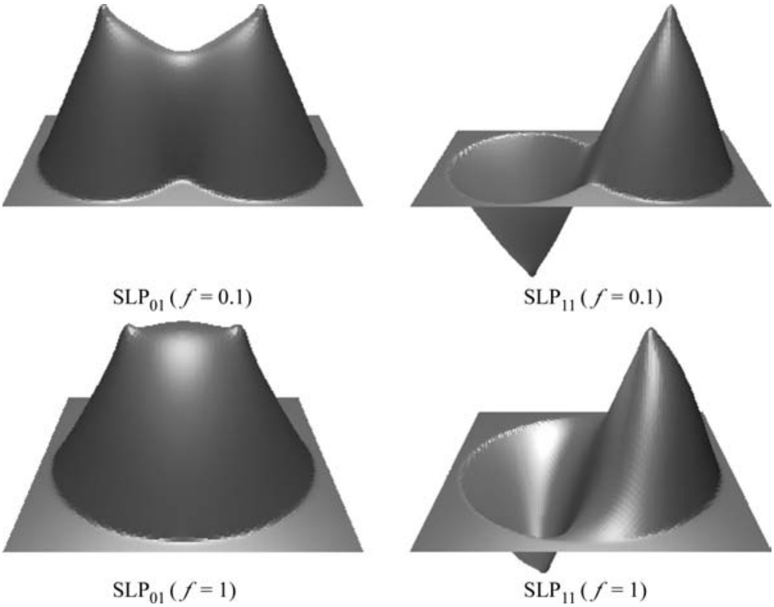
As a fused and tapered coupler is not longitudinally invariant, one must work with the *local modes* (or in other words, *local supermodes*) of the fused structure. As explained later, in identical fibre couplers, the power exchange from the main to the secondary branch, and vice versa, takes place via the *beating* phenomenon between supermodes. Supermode *coupling*, which would arise from very abrupt slopes, is undesirable as it would create loss. Symmetric fused couplers are thus, most of the time, adiabatic structures.

1. At the coupler entrance, the fibres are not tapered: modes of individual guides are confined in the cores, and one can consider that the supermodes are combinations of individual guide modes. The two supermodes of a symmetrical 2 × 2 coupler, i.e. made of two identical fibres, are

$$|\Psi_+\rangle = \frac{|\psi_1\rangle + |\psi_2\rangle}{\sqrt{2}} \quad \text{and} \quad |\Psi_-\rangle = \frac{|\psi_1\rangle - |\psi_2\rangle}{\sqrt{2}} \tag{B3.10}$$

where the Dirac notation $|\psi_1\rangle$ and $|\psi_2\rangle$ is used to describe the fields of the fundamental (scalar) LP_{01} modes of guides 1 and 2. The supermodes corresponding to $|\Psi_+\rangle$ and $|\Psi_-\rangle$ are, respectively, called SLP_{01} and SLP_{11} after their circular two-layer fibre counterparts as can be seen in figure B3.7 for degree of fusion $f = 1$. Whenever one excites $|\psi_1\rangle$, the fundamental mode of fibre 1 at the entrance of the coupler, one actually excites a superposition of both supermodes, which can be written as

$$|\psi_1\rangle = \frac{|\Psi_+\rangle + |\Psi_-\rangle}{\sqrt{2}} \quad \text{and} \quad |\psi_2\rangle = \frac{|\Psi_+\rangle - |\Psi_-\rangle}{\sqrt{2}}. \tag{B3.11}$$



SLP_{01} ($f = 0.1$)

SLP_{11} ($f = 0.1$)

SLP_{01} ($f = 1$)

SLP_{11} ($f = 1$)

Figure B3.7. Fields of the first two supermodes of a 2 × 2 coupler for two different values of the degree of fusion and for an ITR = 0.1.

All these modes are degenerate, i.e. the supermode propagation constants, β_+ and β_-, are identical to that of the each individual guide fundamental mode, β ($\beta = \beta_1 = \beta_2 = \beta_+ = \beta_-$).

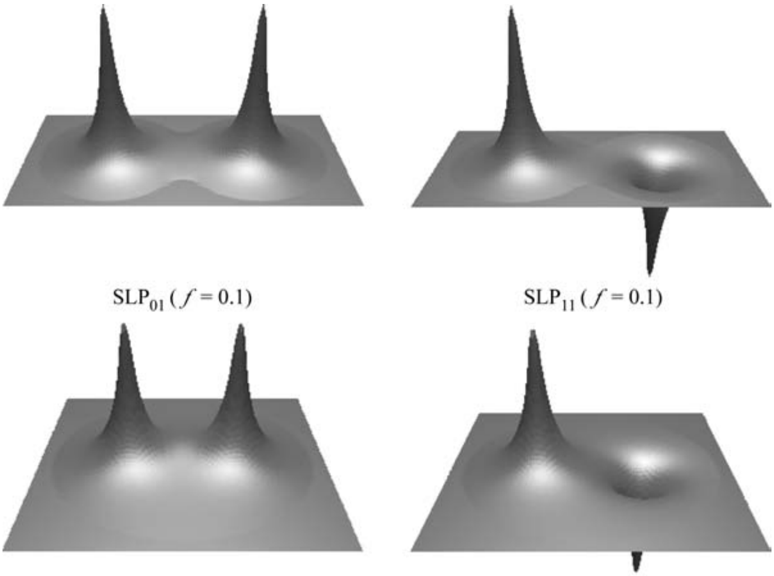
Figure B3.8 shows, as an example, supermode fields for two different degrees of fusion ($f = 0.1$ and 1) in the case of a core guiding structure. For a coupler made of standard telecommunication fibres, supermodes may be approximated by superpositions of individual fibre modes as long as ITR > 0.4.

2. In the central region of the coupler, the individual guides lose their identity and the cores in their guiding roles. Only supermodes keep a physical meaning. Figure B3.7 shows the supermodes for the same degrees of fusion as in figure B3.8, but for ITR $= 0.1$.

As shown in figures B3.9 and B3.10 for two different degrees of fusion, the effective indices $n_{\mathrm{eff}} = n_\pm$ (and thus propagation constants $\beta_\pm = 2\pi n_\pm/\lambda$) of the first two supermodes (SLP_{01} and SLP_{11}) split apart in the central region of the coupler (for which ITR < 0.4). Supermodes accumulate a phase difference as they propagate along the coupler structure. In other words, it is the supermode *beating* phenomenon which governs the power exchange process.

3. At the coupler exit, the situation resembles that of the entrance, i.e. the guides are sufficiently separated so that the supermodes are again superpositions of individual guide modes and are consequently degenerated. It is thus the phase difference accumulated in the central region that determines the power splitting ratio at the exit of the coupler.

Expressions of the individual modes (equation (B3.11)) show that whenever the supermodes are in phase, the power is recovered in branch 1 and, whenever they are out of phase, it is recovered in branch 2. A 50/50 splitting ratio—which corresponds to the so-called 3 dB coupler—occurs whenever the supermodes exit the coupler with a $\pi/2$ phase difference.



SLP_{01} ($f = 0.1$) SLP_{11} ($f = 0.1$)

SLP_{01} ($f = 1$) SLP_{11} ($f = 1$)

Figure B3.8. Fields of the first two supermodes of a 2 × 2 coupler for two different values of the degree of fusion and for an ITR $= 0.5$.

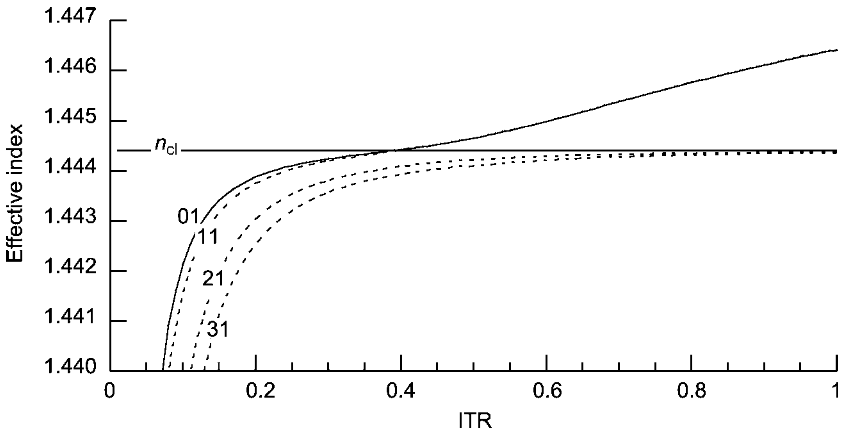


Figure B3.9. Effective indices of the first two symmetric SLP_{01} and SLP_{21} supermodes and of the first two antisymmetric SLP_{11} and SLP_{31} supermodes as functions of ITR at wavelength $\lambda = 1550\,\text{nm}$ for a slightly fused coupler ($f = 0.1$).

Birefringence

As detailed in the following section, a coupler is characterized by its transfer matrix, which relates individual guide amplitudes at the exit of the coupler to the entrance ones. This matrix depends on the accumulated supermode phase difference and thus on their local propagation constants $\beta_+(z)$ and $\beta_-(z)$.

As the transverse cross-section of a coupler does not show the circular symmetry (even though $f = 1$, the cores break off the symmetry), two propagation constants must be attributed to each supermode $SLP_{\ell m}$ corresponding to both polarizations along the symmetry axes. As a result, two transfer matrices must be defined, one for each polarization. Thus, from a general viewpoint, couplers are birefringent and their transmissions are polarization dependent. The less fused the coupler, the more obvious the departure from circular symmetry. One then understands that the birefringence is larger

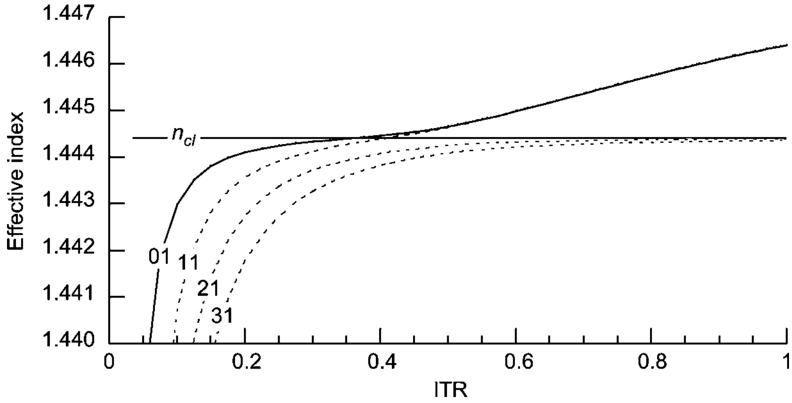

Figure B3.10. Effective indices of the first two symmetric SLP_{01} and SLP_{21} supermodes and of the first two antisymmetric SLP_{11} and SLP_{31} supermodes as functions of ITR at wavelength $\lambda = 1550\,\text{nm}$ for a strongly fused coupler ($f = 1$).

for slightly fused couplers than for those approaching $f = 1$. If the birefringence is negligible, the scalar approximation is sufficient for the calculations. Otherwise, polarization corrections (see chapter 13 of [6]) or exact (i.e. vectorial) calculations must be made.

Transfer matrices

The coupler transmissions as functions of elongation and wavelength greatly depend on the fabrication parameters, degree of fusion and longitudinal profile. These fabrication parameters determine the transfer matrix, which relates individual guide amplitudes at the exit of the coupler to the entrance ones. For a coupler of length L, one has [7]

$$\mathbf{M}_{2\times 2}(\alpha) = \mathrm{e}^{\mathrm{i}\bar{\alpha}} \begin{bmatrix} \cos\alpha & \mathrm{i}\sin\alpha \\ \mathrm{i}\sin\alpha & \cos\alpha \end{bmatrix} \tag{B3.12}$$

with the average propagation phase

$$\bar{\alpha} = \int_0^L \bar{\beta}(z)\,\mathrm{d}z, \qquad \bar{\beta}(z) = \frac{\beta_+(z) + \beta_-(z)}{2} \tag{B3.13}$$

and the supermode accumulated phase difference

$$\alpha = \int_0^L \frac{\beta_+(z) - \beta_-(z)}{2}\,\mathrm{d}z. \tag{B3.14}$$

Here $\beta_+(z)$ and $\beta_-(z)$ are the propagation constants of the local fundamental supermode SLP_{01} and of the first antisymmetric supermode SLP_{11}, respectively. The parameter 2α is the phase difference accumulated by these two supermodes along the coupler.

From the transfer matrix, one may, for a given entrance condition, calculate the transmitted power in both branches. For example, excitation in branch 1 corresponds to a column vector

$$\begin{bmatrix} 1 \\ 0 \end{bmatrix}$$

and, as a result, in a power transmission in the same branch

$$T_1 = \cos^2\alpha = \frac{1}{2}[1 + \cos 2\alpha] \tag{B3.15}$$

and, in the secondary branch

$$T_2 = \sin^2\alpha = \frac{1}{2}[1 - \cos 2\alpha]. \tag{B3.16}$$

Whenever the modes are in phase ($2\alpha = 0 + 2p\pi$ with p an integer) at $z = L$, the transmission is maximum in the main branch ($T_1 = 1$). Whenever they are out of phase ($2\alpha = \pi + 2p\pi$) at $z = L$, the transmission is minimum ($T_1 = 0$), corresponding to a complete power transfer in the secondary branch ($T_2 = 1$). This power exchange for a strongly fused 2 × 2 coupler is shown in figure B3.11, which displays an experimental response as well as the theoretical one predicted from the fabrication parameters. The polarization effects are clearly visible in this example recording. From a more general viewpoint, the overall transmission is a superposition of both the polarization transmissions. For a polarization entering at 45° from the cross-section symmetry axes x and y, the transmission in the main branch may be written as

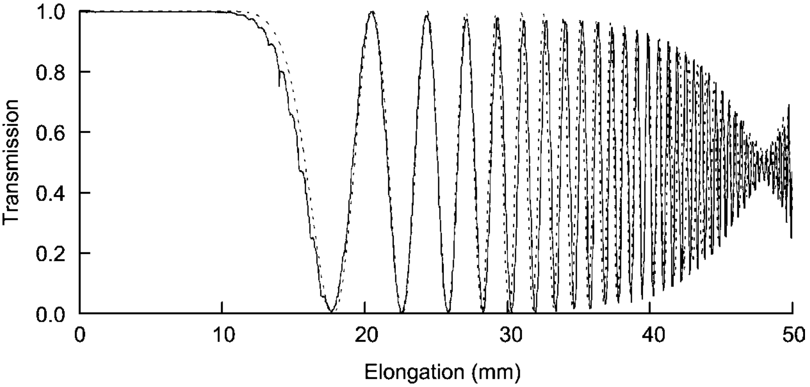

Figure B3.11. Recording (plain line) of the main branch transmission of a strongly fused 2 × 2 coupler as a function of elongation at a given wavelength ($\lambda = 1550\,\text{nm}$). The transmission in the secondary branch, if the losses are negligible, is the complement. The dashed line is the corresponding numerical calculation. Loss of contrast is due to the coupler birefringence.

$$T_1 = \frac{\mathrm{T}_{1x} + \mathrm{T}_{1y}}{2} = \frac{\cos^2\alpha_x + \cos^2\alpha_y}{2} = \frac{1}{2}\left\{\{1 + \cos(\alpha_x - \alpha_y)\cos[2(\alpha_x + \alpha_y)]\right\} \tag{B3.17}$$

with α_x and α_y the supermode accumulated phase difference for polarization x and y, respectively. In figure B3.11, the birefringence appears as an overmodulation of the power exchange with nodes, whenever both polarization transmissions are out of phase ($2\alpha_x - 2\alpha_y = \pi \pm 2m\pi$). In the first power exchange cycles, the birefringence effect is negligible, which permits us to manufacture 3 dB polarization-independent couplers. In contrast, slightly fused couplers present strong birefringence [7].

Oscillations visible in figure B3.11 as a function of elongation also occur as a function of wavelength, which confer to couplers spectral filtering or multiplexing applications as shown in the following sections.

Components

Power splitters

The simplest component to be conceived is the power splitter. According to the figure B3.11 recording, any polarization-independent splitting ratio may be obtained for a relatively short elongation. They are, however, wavelength dependent, which may be undesirable for a number of applications.

Wavelength-independent splitters may be realized using 2 × 2 dissymmetric couplers. As opposed to the symmetric coupler, modes of individual guides of a dissymmetric coupler are not degenerated. When the individual guides are sufficiently separated, at the coupler entrance and exit, the supermodes are the individual guide modes. Quite paradoxically, an adiabatic dissymmetrical coupler would not experience any power exchange. It is thus a supermode *coupling* process (as opposed to a *beating* process) which governs the power transfer in a dissymmetric coupler. This power transfer may be complete or do not depend, for a given asymmetry, on the slopes of the longitudinal structure. The calculation of the adiabaticity criterion as a function of the ITR-parameter is then critical to design a coupler with a prescribed response [8].

An alternative technique is by concatenating two 3 dB couplers in a Mach–Zehnder (MZ) arrangement with a π phase difference between the two branches [9].

Both solutions are used in practice. Any coupling ratio is attainable with these techniques as exemplified in figure B3.12.

Polarization splitters/combiners and depolarizers

Although considered a nuisance for power splitters, one may take advantage of the intrinsic polarization dependence of couplers, to realize polarization splitters—the all-fibre equivalent of polarizing cubes. These all-fibre polarizers consist of couplers elongated until the polarization node (obtained for an elongation of about 47 mm in figure B3.11) is attained. Used in the reverse configuration, they serve as polarization combiners. These polarization splitters/combiners, however, suffer from being narrowband. A wideband alternative consists in an all-fibre MZ structure with a short length (half the beatlength) of a polarization maintaining fibre in one branch. An example response of a wideband polarization splitter/combiner is shown in figure B3.13. These components are particularly useful as polarization pump combiners in Raman amplifiers. For a given power of the pump sources, they allow us to double the pump power at a given wavelength and reduce the impact of the inherent polarization dependence of the Raman gain.

An alternative solution to obtain a polarization-independent Raman amplifier is to depolarize the pump source. This can be done with the help of a depolarizer that consists of an unbalanced interferometer. The arm length difference is longer than the polarization coherence length (which coincides with the usual light source coherence length) so as to uncorrelate the two polarizations. Different designs of depolarizers may be found in [10]. The highest-performance device takes advantage of the MZ polarization combiner (described in the previous section) combined with a fibre ring delay line working in a non-interferometric operation, i.e. with a loop length much longer than the coherence length of the light source. This type of device is characterized by its degree of polarization (DOP) defined as follows

$$\mathrm{DOP} = \sqrt{1 - 4\left[\frac{I_x I_y}{(I_x + I_y)^2}\right](1 - |g_{xy}|^2)} \tag{B3.18}$$

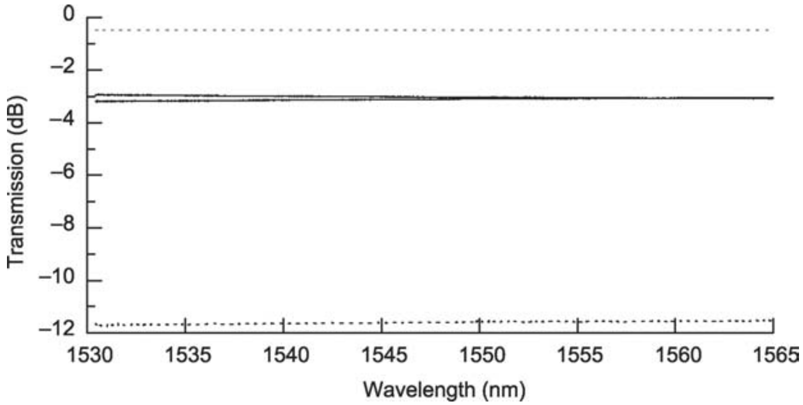

Figure B3.12. Experimental transmissions in dB (also referred to as IL) in both branches of wavelength-independent fused fibre 2 × 2 couplers as a function of wavelength. The plain lines are the transmission of a 3 dB wavelength-independent coupler while the dotted lines are those of a coupler with a large coupling ratio (around 12 dB) (by courtesy of ITF Optical Technologies).

where I_x and I_y are the autocorrelation functions for perpendicular polarizations and g_{xy} the cross-correlation normalized coefficient.

An example response of such a depolarizer is shown in figure B3.14. It features a DOP of the order of 10% over a 120 nm spectral band for any temperature between 0 and 70°C. This type of device is also of use for test and measurement applications.

Wavelength splitters/combiners

Fused couplers present an almost inherent sinusoidal wavelength dependence, with a period that decreases when the elongation increases. This wavelength dependence is the basis of several WDM applications. However, their intrinsic properties limit their application.

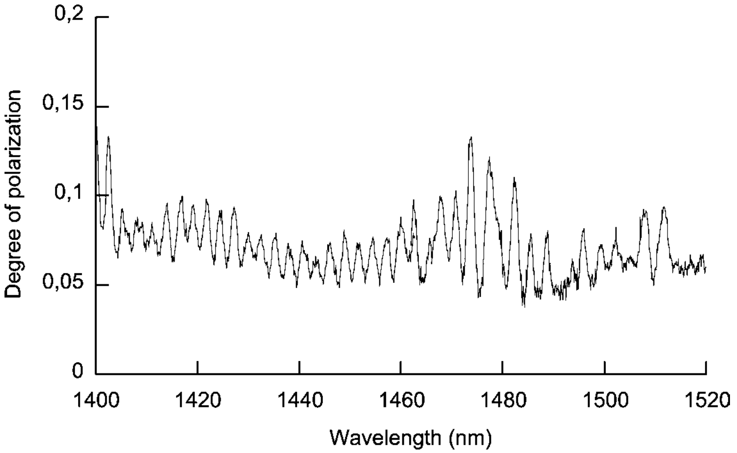

Figure B3.14. DOP as a function of wavelength of a wideband depolarizer. The ripples are due to imperfect alignment of the components in the MZ polarization combiner (by courtesy of ITF Optical Technologies).

1. Even for a relatively large wavelength separation, the inherent sinusoidal spectral response might be a limitation. This is the case for a 1480 nm pump–1550 nm signal multiplexer, useful for Er-doped amplifiers/lasers.
2. The shortest wavelength period attainable is limited by the polarization dependence of the couplers as mentioned earlier. They are consequently not suitable to realize dense wavelength division multiplexing (DWDM) interleavers able to de/multiplex channels as close as 1 nm or less.

In both the cases, alternative solutions may be found by concatenating couplers in MZ arrangements.

1. Figure B3.15 shows, as an example, the spectral response of an MZ 1480–1550 nm WDM allowing a large band around 1550 nm.
2. Dense interleavers are also usually made of an unbalanced MZ structure. Simple MZ consists of two concatenated 3 dB couplers, but more sophisticated non-sinusoidal responses may be obtained by concatenating several MZ structures. Figure B3.16 shows an example of spectral response of such a device. These interleavers are then cascaded in a tree arrangement to effectively separate (or combine) the channels as shown in figure B3.17. Challenges are to make them temperature insensitive with a high isolation, and to respect, over a large spectral range, the ITU grid which is characterized by constant frequency intervals.

Single couplers are nevertheless useful, among other things, to realize de/multiplexers for well-separated signal channels (coarse WDM such as that shown in figure B3.18), pump–signal multiplexers and pump combiners for Er-doped and Raman amplifiers.

Mode splitters/combiners

When made of two-mode fibres, fused couplers may be designed to separate the modes, LP_{01} staying in the main branch while LP_{11} is transferred to the secondary branch [11]. This modal splitter in

combination with a reflecting modal converter Bragg grating opens up the possibility to get rid of inherently lossy micro-optic circulators.

B3.4.2 Spectral filters and dispersion compensators

Principles of operation

Most of these components, as opposed to couplers, have only one entrance and one exit branch. Some are based on the tapering technology, others on the grating inscription technology. Combination of both the technologies, as in the optical add and drop multiplexers (OADM) described later, may also be used. The tapering technology takes advantage of the sinusoidal wavelength responses of tapered fibres while

gratings are resonant devices: they couple, at a given wavelength λ, two modes of propagation constants β_1 and β_2 through the matching condition of equation (B3.1)

$$(\beta_1 - \beta_2)\Lambda = 2\pi \tag{B3.19}$$

where Λ is the grating period. Mode 1 is usually the fundamental core mode, while mode 2 is, in the case of a short-period grating, the counterpropagating fundamental mode ($\beta_2 = -\beta_1$) and, in the case of a long-period grating, a copropagating cladding mode.

Tapered fibres

Oscillatory transmissions

When the slopes of a tapered single-mode fibre are abrupt, such as those of figure B3.1, one observes oscillations in the transmitted power as a function of elongation (see figure B3.19). For a given elongation, similar oscillations occur in the transmission as a function of wavelength (see figure B3.20). This behaviour may be explained in terms of coupling and beating of the local modes of the tapered structure [12].

When the downtaper is so abrupt that the adiabaticity criterion is not fulfilled, the fundamental mode LP_{01} is unable to adapt its field and propagation constant to the guide change and it is transformed through the coupling process into a superposition of modes of the same symmetry (LP_{01}, LP_{02}, LP_{03},...), which propagate along the adiabatic central region, thus accumulating phase differences. When they enter the uptapered region, they again experience a coupling process. Power is then recovered in the core. The core transmission depends on the relative phase of the different modes. If they exit the component in phase, transmission is 1. Otherwise, power is dispatched between the fundamental core mode and cladding modes. Cladding mode power is eventually lost in the jacket.

This coupling–beatings–coupling process thus confers to a tapered fibre an oscillatory transmission. Large-amplitude oscillations seen in figure B3.20 come from LP_{01} and LP_{02} modes, while small-amplitude and larger-frequency oscillations only occur if LP_{03} and possibly higher-order modes participate in the process [13]. Besides, the LP_{01}–LP_{02} period Λ of the tapered fibre spectral

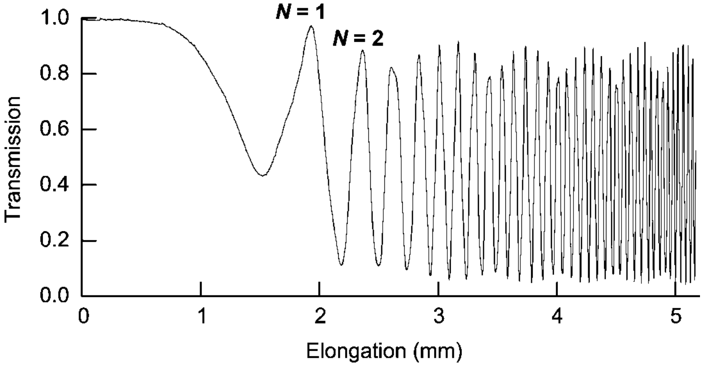

Figure B3.19. Fundamental mode transmission of a tapered single-mode fibre as a function of elongation.

response may be predicted from N, the number of oscillations observed during elongation performed at wavelength λ. For sufficiently large N, one has

$$\Lambda = \frac{\lambda}{N}. \tag{B3.20}$$

This oscillatory predictable spectral response is the basis for spectral filtering devices made of tapered fibres.

Long-period gratings (LPGs)

Gratings are also useful in terms of their filtering applications, but as opposed to tapered fibres their behaviour is based on a resonant coupling resulting in a wavelength peak in their spectral response.

- *Transfer matrix*: A sinusoidal perturbation of period $\Lambda = 2\pi/\beta_B$ induces a coupling coefficient

$$C_{12} = 2c\cos(\beta_B z + \phi) \tag{B3.21}$$

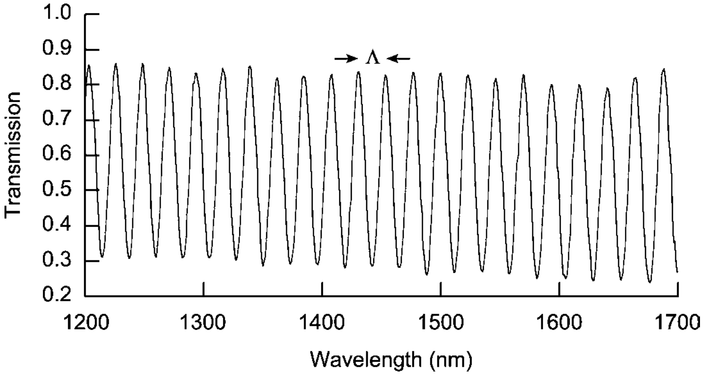

Figure B3.20. Spectral response of the tapered fibre of figure B3.19.

which, around resonance condition (B3.19), couples two codirectional modes of propagation constants β_1 and β_2. One can show, by solving coupled mode equations, that the transfer matrix is

$$\mathbf{M}_{\mathrm{LPG}} = \begin{bmatrix} \left[\cos(\gamma\ell) + \mathrm{i}\frac{\Delta}{\gamma}\sin(\gamma\ell)\right]\mathrm{e}^{\mathrm{i}(\beta_1-\Delta)\ell} & \mathrm{i}\frac{c}{\gamma}\sin(\gamma\ell)\mathrm{e}^{\mathrm{i}[(\beta_1-\Delta)\ell+\beta_{\mathrm{B}}z_0+\phi]} \\ \mathrm{i}\frac{c}{\gamma}\sin(\gamma\ell)\mathrm{e}^{\mathrm{i}[(\beta_2+\Delta)\ell-\beta_{\mathrm{B}}z_0-\phi]} & \left[\cos(\gamma\ell) - \mathrm{i}\frac{\Delta}{\gamma}\sin(\gamma\ell)\right]\mathrm{e}^{\mathrm{i}(\beta_2+\Delta)\ell} \end{bmatrix}. \tag{B3.22}$$

Here ℓ is the length of the grating extending from z_0 to $z_0+\ell$ and the other parameters are defined as follows

$$\Delta = \frac{\beta_1-\beta_2-\beta_{\mathrm{B}}}{2} = \frac{\beta_1-\beta_2}{2} - \frac{\pi}{\Lambda} \quad \text{and} \quad \gamma^2 = \Delta^2 + c^2. \tag{B3.23}$$

As for the coupler, if one assumes injection in mode 1 ($a_2(z_0)=0$), the power transfer to mode 2 is readily calculated to be

$$T_2(z_0+\ell) = |M_{21}|^2 = \frac{c^2}{\gamma^2}\sin^2(\gamma\ell). \tag{B3.24}$$

Remaining power in mode 1 can be calculated by $T_1 = |M_{11}|^2$ or using the energy conservation condition $T_1 + T_2 = 1$.

The power transfer to mode 2 is sinusoidal as a function of ℓ, but a sinc function of $\gamma = \pm\sqrt{\Delta^2+c^2}$. The peak-to-peak amplitude of the transmission is

$$T_{2\mathrm{MAX}} = \frac{c^2}{\gamma^2} = \frac{c^2}{\Delta^2+c^2}. \tag{B3.25}$$

It is always smaller than 1, being maximum for $\Delta = 0$, i.e. at resonance. Figure B3.21 shows the oscillatory fundamental mode transmission along z.

- *Bandwidth*: Let the LPG length ℓ equal half the coupling length defined by equation (B3.7): $\ell = L_{\mathrm{C}}/2 = \pi/(2c)$ so that, at resonance, the power transfer is complete. (This would occur for any odd number of $L_{\mathrm{C}}/2$.) Figure B3.22 shows, for a component of length $L_{\mathrm{C}}/2$, the power transfer from mode 1 to mode 2 as a function of the detuning $|\Delta|$.

The LPG used as a filter may be characterized by its bandwidth, i.e. by the FWHM of its transmission, or approximately of $T_{2\mathrm{MAX}}$, which in terms of Δ is equal to $2c$. It is readily converted in terms of wavelength to give

$$\delta\lambda = \frac{2\lambda^2}{L_{\mathrm{C}}|n_{\mathrm{g}1}-n_{\mathrm{g}2}|} \tag{B3.26}$$

where $n_{\mathrm{g}1}$ and $n_{\mathrm{g}2}$ are the group indices defined by

$$n_{\mathrm{g}i} = n_i - \lambda\frac{\mathrm{d}n_i}{\mathrm{d}\lambda}. \tag{B3.27}$$

The following approximation

$$\delta\lambda \approx \frac{2\lambda\Lambda}{L_{\mathrm{C}}} = \frac{\lambda}{N} \tag{B3.28}$$

is valid inasmuch as $n_{\mathrm{g}1} - n_{\mathrm{g}2} \approx n_1 - n_2$. Here, n_i are the modal effective indices ($n_i = 2\pi\beta_i/\lambda$), λ is the peak wavelength and N the total number of steps. As a result, the greater the number of steps, the more

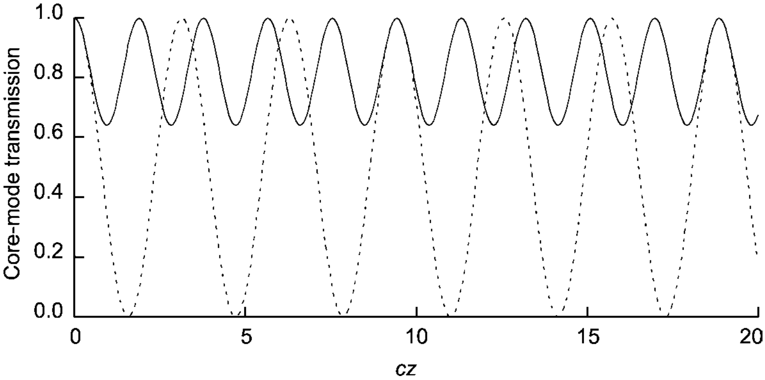

Figure B3.21. Fundamental mode transmission along the grating for different values of the detuning parameter Δ. The oscillation amplitude is maximum (equal to 1) for $\Delta = 0$ and the frequency minimum (dotted line). As Δ increases, γ increases as well, making the amplitude decrease and the frequency increase: the transmission is shown for $\Delta/c = 4/3$ (plain line).

selective the grating will be. For a given grating step (determined by the pair of chosen modes at λ), the longer the grating (and as a consequence the smaller the coupling coefficient c, since $L = L_C/2$), the narrower its bandwidth.

- *Fundamental mode transmission*: The cladding modes being absorbed by the jacket, most of the time, one only has access to T_1. LPGs are thus rejection band filters. Actually, for a given grating step Λ, several pairs of modes (i,j) may be resonant in a wavelength range inasmuch as the following condition is fulfilled.

$$\beta_i - \beta_j = \frac{2\pi}{z_{ij}} = \frac{2\pi}{\lambda}(n_i - n_j) = \frac{2\pi}{\Lambda}. \tag{B3.29}$$

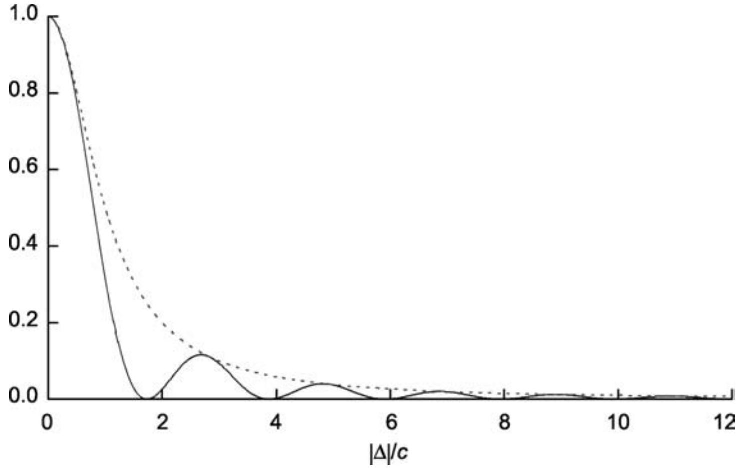

Figure B3.22. Power transfer T_2 as a function of the detuning $|\Delta|$ in a component of length $L_C/2$ (plain line). Its amplitude $T_{2\mathrm{MAX}}$ is the dotted line.

Here, z_{ij} is the beating length of modes i and j and n_i and n_j their effective indices, which depend on the wavelength λ. This equation generalizes the matching condition written in equation (B3.19). If, as in tapered fibres, the perturbation preserves the circular symmetry, only modes of the same symmetry are involved. Figure B3.23 shows the beating lengths z_{1j} for $LP_{01}-LP_{0j}$ modal pairs as functions of λ. This graph permits us to find the resonance wavelengths for a given step Λ. Alternatively, it gives the periods that may be chosen to realize a filter at a given wavelength.

Figure B3.24 gives, as a function of wavelength, the dB transmission in the fundamental mode of a grating of step $\Lambda = 525\ \mu m$ in a standard telecommunication fibre.

Note finally that, with slanted gratings, it is also possible to transfer power from the fundamental core mode LP_{01} to cladding modes with different symmetry such as LP_{11} and LP_{21}.

The main limitation of the LPGs used as filtering components is their temperature dependence of the order of $100-150\ \text{pm}\ {}^\circ\text{C}^{-1}$ (10–15 nm/100°C). This high figure, which largely depends on the fibre, comes from the fact that the principle of operation of an LPG is based on the coupling of a core mode with a cladding mode. Being made up of different materials, these two layers are subjected during hot drawing and subsequent cooling of fibre to different stresses, which result in a different thermal sensitivity. LPGs made of standard SMF28 *Corning* fibres exhibit a thermal dependence of $50\ \text{pm}\ {}^\circ\text{C}^{-1}$.

Short-period gratings

Let the period $\Lambda = 2\pi/\beta_B$ of the sinusoidal perturbation couple two contradirectional modes of the same propagation constant $\beta_1 = -\beta_2 = \beta$. The corresponding coupling coefficient may be written as

$$C_{12} = 2ic\cos(\beta_B z + \phi). \tag{B3.30}$$

With a notation similar to that used in the codirectional case, one has

$$\Delta = \frac{\beta_1 - \beta_2}{2} - \frac{\beta_B}{2} = \beta - \frac{\beta_B}{2} = \beta - \frac{\pi}{\Lambda}.$$

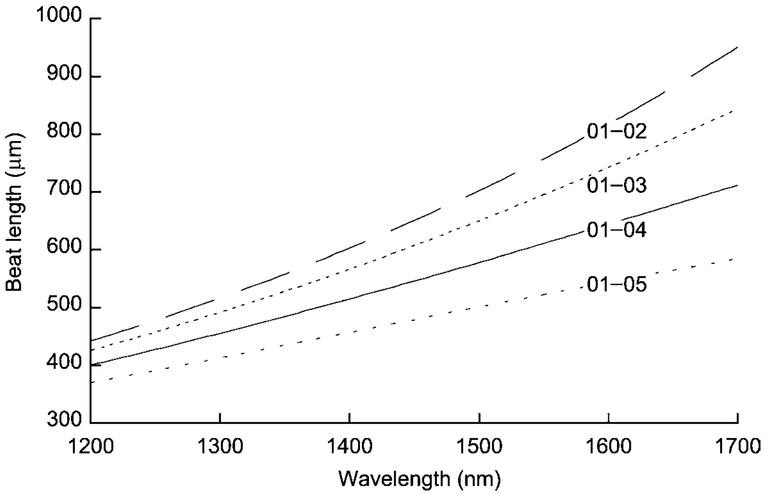

Figure B3.23. Beating lengths of $LP_{01}-LP_{0j}$ modal pairs for a typical telecommunication fibre.

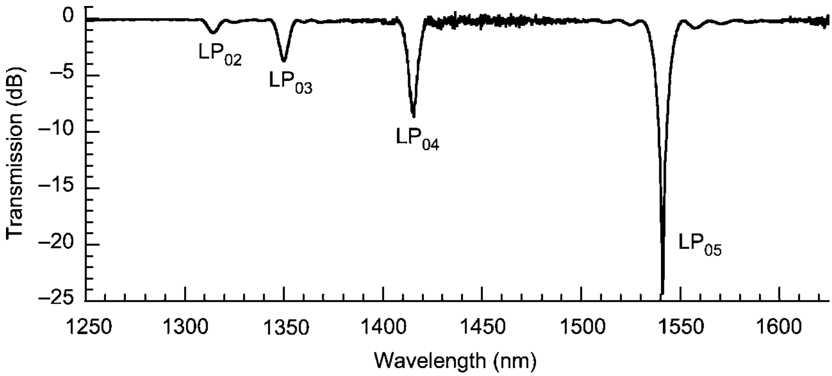

Figure B3.24. Fundamental mode transmission of a long-period grating. Experimental response (plain line) is compared to the calculated one (dotted line). The grating was made by irradiating a standard telecommunication fibre with a CO_2 laser. It consists of 118 steps of 525 μm. The peaks are identified by the $0m$ indices of the LP cladding mode, which is coupled with the fundamental core mode.

- *Transfer matrix*: By solving the coupled mode equations, one then finds the transfer matrix of a grating extending from z_0 to $z_0 + \ell$

$$\mathbf{M}_{\mathrm{SPG}} = \begin{bmatrix} \left[\cosh(\gamma\ell) + \mathrm{i}\frac{\Delta}{\gamma}\sinh(\gamma\ell)\right]\mathrm{e}^{\mathrm{i}(\beta-\Delta)\ell} & \mathrm{i}\frac{c}{\gamma}\sinh(\gamma\ell)\mathrm{e}^{\mathrm{i}[(\beta-\Delta)\ell+\beta_{\mathrm{B}}z_0+\phi]} \\ -\mathrm{i}\frac{c}{\gamma}\sinh(\gamma\ell)\mathrm{e}^{-\mathrm{i}[(\beta-\Delta)\ell+\beta_{\mathrm{B}}z_0-\phi]} & \left[\cosh(\gamma\ell) - \mathrm{i}\frac{\Delta}{\gamma}\sinh(\gamma\ell)\right]\mathrm{e}^{-\mathrm{i}(\beta-\Delta)\ell} \end{bmatrix} \tag{B3.31}$$

where

$$\gamma^2 = c^2 - \Delta^2. \tag{B3.32}$$

1. If $\Delta \leq c$,

$$\gamma = \sqrt{c^2 - \Delta^2} \tag{B3.33}$$

and solutions are those written in equation (B3.31) with γ real.

2. If $\Delta \geq c$,

$$\gamma = \mathrm{i}\sqrt{\Delta^2 - c^2} \tag{B3.34}$$

so that solutions can be written as in equation (B3.31), but with $\gamma = \mathrm{i}|\gamma|$ an imaginary number. Using then $\cosh(\mathrm{i}|\gamma|z_0) = \cos(|\gamma|z_0)$ and $\sinh(\mathrm{i}|\gamma|z_0) = \mathrm{i}\sin(|\gamma|z_0)$, one can rewrite them as sinusoidal functions.

- *Fundamental mode reflection and transmission*: The reflection and transmission coefficients may then be calculated for given limit conditions. Inversion of the matrix $\mathbf{M}_{\mathrm{SPG}}$ gives

$$\begin{bmatrix} a_1(z_0) \\ a_2(z_0) \end{bmatrix} = \begin{bmatrix} M_{22} & -M_{12} \\ -M_{21} & M_{11} \end{bmatrix} \begin{bmatrix} a_1(z_0+\ell) \\ a_2(z_0+\ell) \end{bmatrix}. \tag{B3.35}$$

Let $z_0 = 0$. Usually one has $a_2(\ell) = 0$, so that one finds the amplitude reflection and transmission coefficients

$$r = \frac{a_2(0)}{a_1(0)} = -\frac{M_{21}}{M_{22}} \quad \text{and} \quad t = \frac{a_1(\ell)}{a_1(0)} = \frac{1}{M_{22}} \tag{B3.36}$$

and the power coefficients

$$R = R(0) = \frac{|M_{21}|^2}{|M_{22}|^2} = \frac{|M_{21}|^2}{|M_{11}|^2} \quad \text{and} \quad T = T(\ell) = \frac{1}{|M_{22}|^2} = \frac{1}{|M_{11}|^2} \tag{B3.37}$$

Explicitly, one has to distinguish the cases depending on the detuning with respect to the coupling coefficient.

1. If $\Delta \leq c$

$$R(z) = \frac{|a_2(z)|^2}{|a_1(0)|^2} = \frac{c^2}{\gamma^2} \frac{\sinh^2[\gamma(\ell - z)]}{\cosh^2(\gamma\ell) + \frac{\Delta^2}{\gamma^2}\sinh^2(\gamma\ell)} \tag{B3.38}$$

$$T(z) = \frac{|a_1(z)|^2}{|a_1(0)|^2} = \frac{\cosh^2[\gamma(\ell - z)] + \frac{\Delta^2}{\gamma^2}\sinh^2[\gamma(\ell - z)]}{\cosh^2(\gamma\ell) + \frac{\Delta^2}{\gamma^2}\sinh^2(\gamma\ell)} \tag{B3.39}$$

with $\gamma = \sqrt{c^2 - \Delta^2}$.

2. If $\Delta \geq c$

$$R(z) = \frac{|a_2(z)|^2}{|a_1(0)|^2} = \frac{c^2}{\gamma^2} \frac{\sin^2[\gamma(\ell - z)]}{\cos^2(\gamma\ell) + \frac{\Delta^2}{\gamma^2}\sin^2(\gamma\ell)} \tag{B3.40}$$

$$T(z) = \frac{|a_1(z)|^2}{|a_1(0)|^2} = \frac{\cos^2[\gamma(\ell - z)] + \frac{\Delta^2}{\gamma^2}\sin^2[\gamma(\ell - z)]}{\cos^2(\gamma\ell) + \frac{\Delta^2}{\gamma^2}\sin^2(\gamma\ell)} \tag{B3.41}$$

with $\gamma = \sqrt{\Delta^2 - c^2}$.

The minimum transmission (corresponding to a maximum reflection) takes place at resonance: $\Delta = 0$ or $\gamma = c$ (figure B3.25). For a grating of length ℓ one calculates

$$R_{\text{Max}} = \tanh^2(c\ell) \quad \text{and} \quad T_{\min} = \frac{1}{\cosh^2(c\ell)} \tag{B3.42}$$

Figures B3.26 and B3.27 show the reflection and transmission behaviour as a function of z depending on the value of the detuning parameter Δ. The transmission coefficient $T(z)$ may be locally >1. This local energy accumulation, similar to that observed in a Fabry–Perot interferometer, is due to the resonance or stationary waves between the grating ends. This effect, which gives rise to side lobes in the spectral response, is undesirable for spectral filtering applications. It may be suppressed by apodizing techniques as explained in a subsequent section.

- *Spectral response*: As for LPGs, the wavelength response is determined by the transmission and reflection coefficients as functions of the Δ parameter. The magnitude of Δ compared to that of the coupling coefficient c determines γ as per equation (B3.32), which is real close to the resonance condition, but purely imaginary as soon as $\Delta > c$. Transmission then becomes oscillatory, resulting in the typical spectral side lobes. The $\Delta = c$ condition, as in the LPG case, may thus be used to define the peak width. An example spectral response in reflection is shown in figure B3.28.

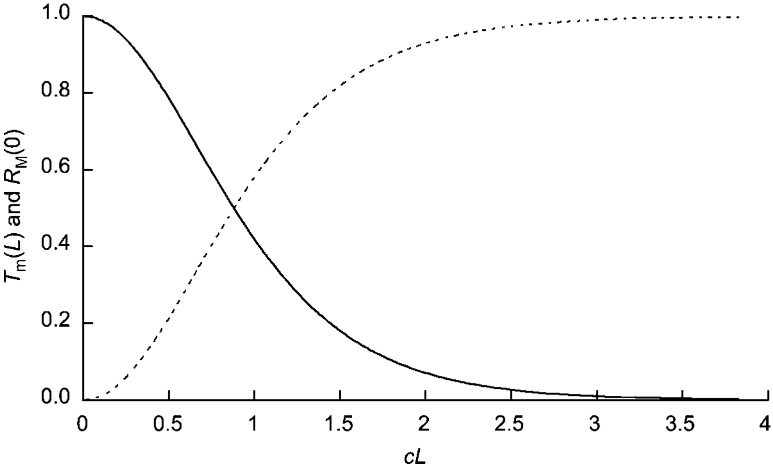

Figure B3.25. Reflection and transmission in the fundamental core mode at resonance ($\Delta = 0$) as a function of the grating length.

- *Apodization*: For most applications, side lobes seen in the spectral response are undesirable. They originate from the multiple reflections that take place between the grating ends as in a Fabry–Perot resonator. One can also understand this effect by remembering that, in a first approximation (i.e. when the perturbation is weak), the spectral response of a grating is the Fourier transform of the amplitude c of the refractive index modulation. The Fourier transform of a rectangular function is a sinc function. The larger the rectangular function, the narrower the sinc function. Similar observations are valid for the grating: the longer the grating, the narrower the spectral width and its side lobes.

One can reduce these side lobes by smoothing the coupling coefficient, giving it a gaussian envelope. This results in smoothing the wavelength response (in other words, apodizing). To be efficient both on the short- and long-wavelength sides, the average refraction index all over the grating length should be uniform. Figure B3.29 shows the effect of apodization on the grating of figure B3.28.

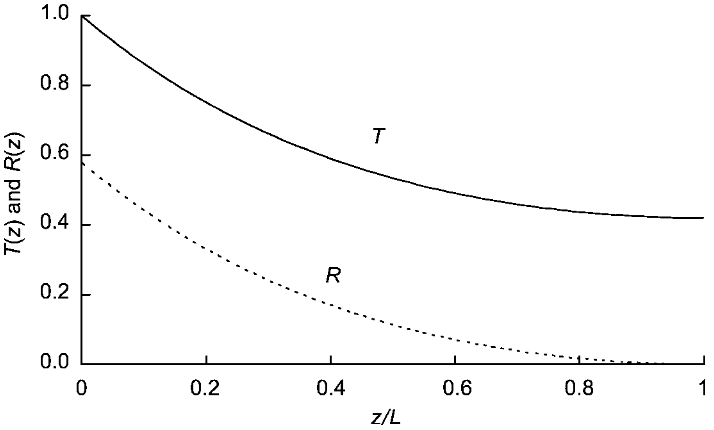

Figure B3.26. Reflection $R(z)$ and transmission $T(z)$ in the fundamental mode along the grating of length $\ell = 1/c$ at resonance, i.e. for $\Delta = 0$. Since $\Delta < c$, the amplitude varies exponentially.

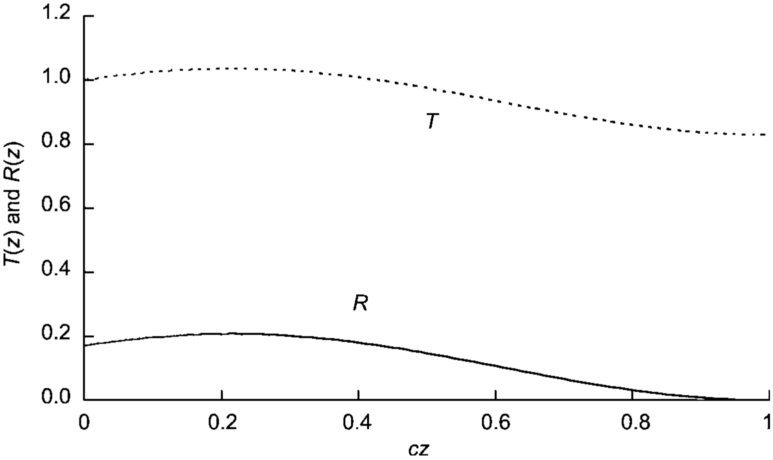

Figure B3.27. Reflection $R(z)$ and transmission $T(z)$ in the fundamental mode along the grating for a far from resonance case $\Delta > c$. In this case, the amplitude shows a sinusoidal variation. The calculation is made for $\Delta/c = \sqrt{17}$.

The thermal dependence of SPGs is much weaker than that of LPGs. It is typically 10 pm °C^{-1} (1 nm/100°C), i.e. approximately ten times less than that of LPGs, and does not depend on the fibre. Nevertheless, the thermal sensitivity of these gratings, irrespective of their application, must be compensated by an appropriate packaging.

Spectral filters

Spectral filtering is a key function of WDM networks. Some applications are described below.

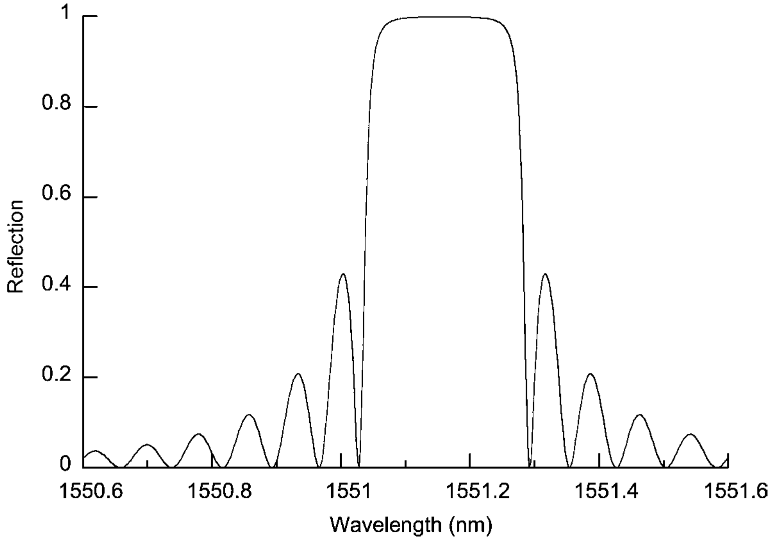

Figure B3.28. Power reflection coefficient of a short-period grating as a function of wavelength (simulation).

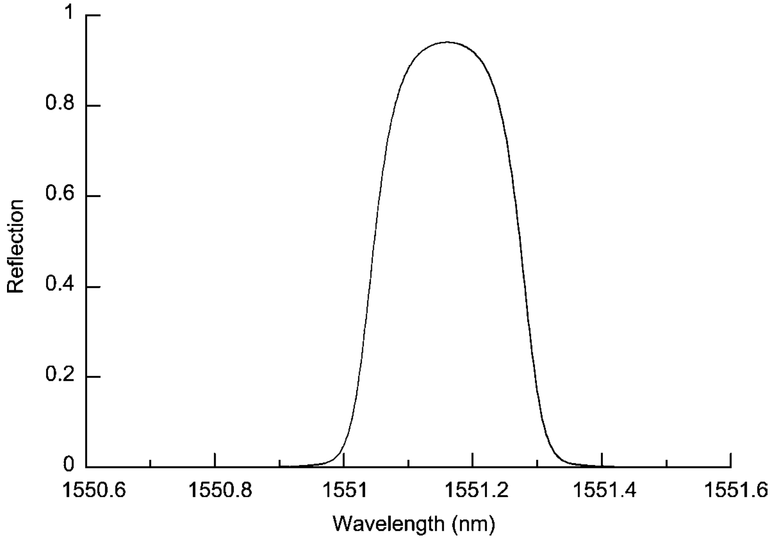

Figure B3.29. Power reflection coefficient of an apodized short-period grating as a function of wavelength (simulation).

Narrow-width spectral filters

The most immediate application of the Bragg SPGs is to use them as selective mirrors in all-fibre lasers in linear (as opposed to loop) configuration. They are currently found in doped fibre lasers as well as cascaded Raman lasers used to pump Raman gain amplifiers.

Bragg SPGs are also used to stabilize both the wavelength and power of semiconductor pump laser diodes. In this case, the grating, with a reflection coefficient of only a few per cent, is integrated in the pigtail at a distance exceeding the coherence length of the laser.

Finally, filters are needed to enhance isolation between the pump and the signal or between two adjacent signal channels. They are also used in combination with a circulator (which is a micro-optic device) to drop the signal of a particular wavelength channel. The ideal spectral amplitude shape to accomplish this type of function is then a rectangular response with a prescribed bandwidth. The Bragg reflection grating remains well suited for this type of filtering, especially if narrowness is an issue: although not perfectly rectangular, well-known standard apodization techniques are used to eliminate undesirable side lobes and give rise to excellent spectral characteristics. However, as can be seen in figure B3.30 (top), such a standard grating filter has a parabolic group delay profile that adversely affects signals at the transmission rates of 10 and 40 Gb s^{-1}. More complex apodization profiles with phase shifts allow for correction and equalization of this parabolic group delay characteristic and result in an ultra-low dispersion over the filter passband. As shown in figure B3.30 (bottom), group delay can be minimized to a ripple function of less than ± 5 ps in amplitude [14].

Large-width spectral filters

Other filters with larger bandwidths are also needed. Among them, the most often used is the gain flattening filter (GFF) designed to equalize the channels amplified by Er-doped fibre gain. The following all-fibre technologies have been explored and implemented sometimes in conjunction.

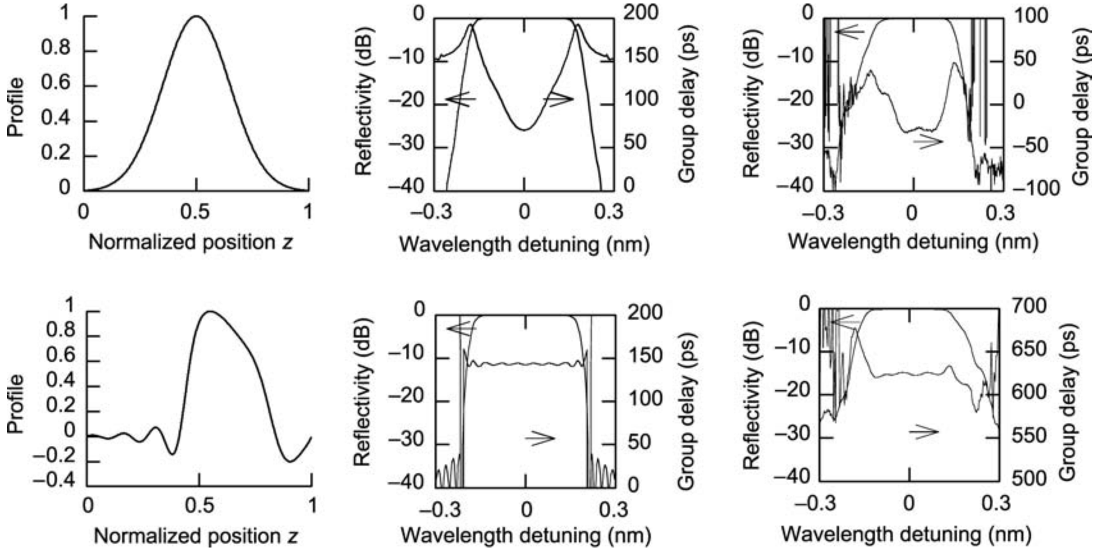

Figure B3.30. Comparison of standard (top) and low-dispersion (bottom) designs of Bragg SPG 50 GHz filters. The apodization profile (left column), theoretical reflectivity and group delay spectra (centre column) and experimental measurements (right) are compared (by courtesy of TeraXion).

1. fusion-tapering technology;
2. short-period gratings (SPGs), straight or slanted;
3. long-period gratings (LPGs), straight or slanted;
4. thin-film technology.

However, the best fits to the inverse gain curve are obtained by using concatenated tapered structures or chirped short-period unslanted Bragg gratings in the transmission mode. Both types of GFF offer similar performance in terms of error function ($<\pm 0.1$ dB), PMD (<0.05 ps). Thermal stability is better for gratings ($<0.5\,\mathrm{pm\,°C^{-1}}$) than for tapered fibre filters ($<2\,\mathrm{pm\,°C^{-1}}$). While the grating solution is more compact, it suffers back reflection, which needs an additional isolator. Group delay ripples, which result from undesired weak reflections occurring along the grating, are negligible with a typical amplitude of ± 0.3 ps. They both are commercially available. Example responses are shown in figures B3.31 and B3.32.

Mode converters

At the resonance wavelength, an LPG is a mode converter operating in the codirectional scheme. Similarly, an SPG can also be used as a mode converter, but operates in the contradirectional scheme, since not only the fundamental mode, but other contradirectional modes may also be reflected through a short-period Bragg grating [15]. By choosing the step, the length and the grating tilt with respect to the fibre axis, one can choose the wavelength and the mode(s) in which there is conversion. Figure B3.33 shows the spectral response of an LP_{01}–LP_{11} converter. To avoid undesirable conversion to cladding modes,

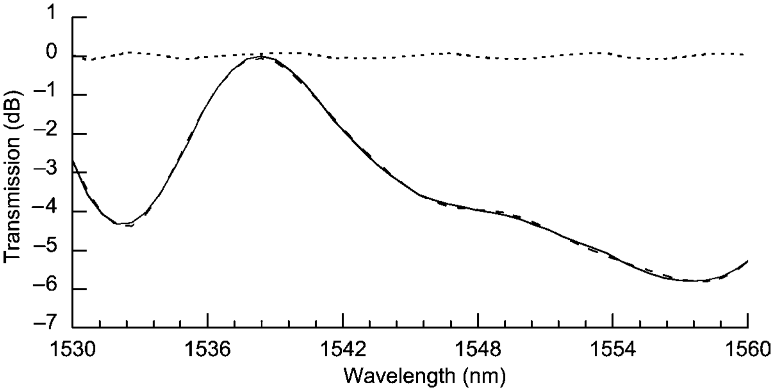

Figure B3.31. Transmission of a GFF made with the fusion-tapering technique. The plain line shows the target filter transmission, while the dashed one is that of the manufactured filter. The dotted line around 0 dB shows the error function. Its amplitude is less than ±0.1 dB (by courtesy of ITF Optical Technologies).

a special fibre should be used. Used in conjunction with mode splitters, the mode converters open up the design of new all-fibre components, which would get rid of micro-optic devices such as circulators.

OADMs

A signal at the Bragg wavelength rather than reflected from a short-period grating back to the source can be extracted. It is then a selective wavelength demultiplexer, which has a significant role to play in future communication networks. Indeed, the strategy that is implemented to currently increase the data flow in a fibre link is the DWDM. Channel frequency spacing is typically 100 GHz (corresponding to 0.8 nm around $\lambda = 1550$ nm), which makes it possible to put 40 channels in the EDFA gain bandwidth

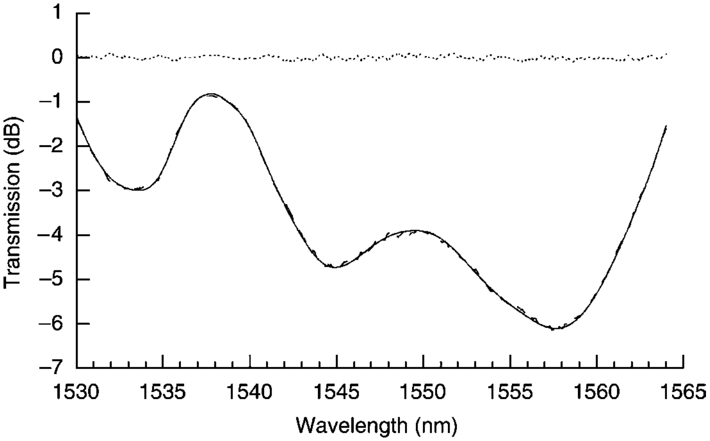

Figure B3.32. Transmission of a GFF made of a chirped Bragg grating. The plain line shows the target filter transmission, while the dashed one is that of the manufactured filter. The dotted line around 0 dB shows the error function. Its amplitude is less than ±0.1 dB (by courtesy of TeraXion).

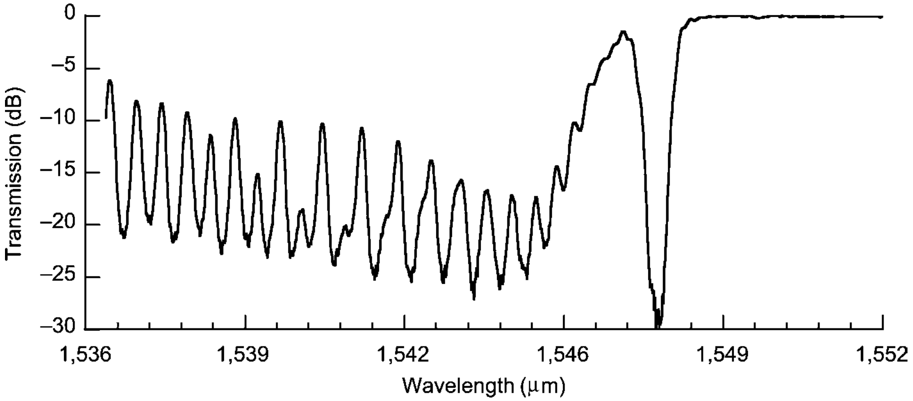

Figure B3.33. Experimental transmission of a mode converter as a function of wavelength. The component consists in a slanted short-period grating written in a bimodal fibre. The fundamental LP_{01} core mode is converted into the LP_{11} core mode at $\lambda = 1547.5$ nm. At shorter wavelengths conversion to higher-order LP_{1m}, LP_{2m}, LP_{3m} cladding modes can be seen.

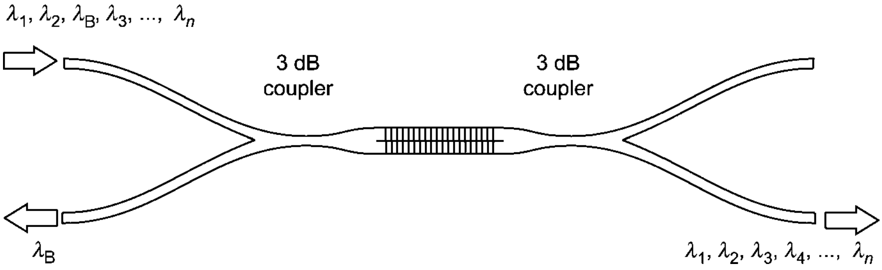
(the C-band) and thus to multiply the current flow by 40, which is of 2.5 Gbit s^{-1}. Narrower spacings such as 50 and 25 GHz (0.4 and 0.2 nm) are also used (see figure B3.16 for an example 50 GHz spacing component).

To extract the reflected signal, one can use a circulator, which is made up of micro-optic components. An alternative all-fibre solution is shown in figure B3.34, which makes use of identical gratings in an MZ arrangement. Cross-talk between channels must be avoided by apodizing the spectral response and by a proper design of the fibre to get rid of the cladding mode reflections. From the fabrication viewpoint, the symmetry of the component is critical for its correct operation. Alternative solutions making use of a single grating written in the central region of a single coupler were also studied [16].

Dispersion compensators

Dispersion in standard fibres mainly comes from material CD, which happens to be zero around $\lambda = 1.3\ \mu m$. In the C-band (around $\lambda = 1.55\ \mu m$), dispersion causes a pulse to spread in time, the highest frequencies (shortest wavelengths) arriving before the lowest ones. CD is inherently troublesome and solutions to eliminate it completely by using dispersion-shifted fibre were rapidly abandoned because



$\lambda_1, \lambda_2, \lambda_B, \lambda_3, \ldots, \lambda_n$
3 dB coupler

Figure B3.34. Principle of operation of an all-fibre OADM.

four-wave mixing (a non-linear effect, which induces cross-talk between channels) is automatically phase matched around the zero-dispersion wavelength. It is thus better to compensate for dispersion by using additional devices.

The simplest way is to use a dispersion compensation module (DCM), which consists of a length of a different fibre with a carefully designed index profile to tailor the modal propagation constant. A relatively long fibre length of compensating fibre must be used (typically 20 km of compensating fibre for 100 km of standard fibre), and it only partially compensates for higher-order dispersion effects (typically 60% of the slope), which is the channel-to-channel variation of the dispersion.

Because of their compactness, Bragg SPGs are alternative promising devices that may be used for dispersion compensation. Chirped SPGs (CSPGs) shown in figure B3.35 reflect different frequency components of a pulse at different locations. Its first step being longer than the last, with a careful design, it can compensate for the delay of the low frequencies on the high ones. To recover the reflected signal, a circulator (a micro-optic component) is necessary. An SPG can have a dispersion of several orders of magnitude higher than a similar length of fibre, so that a few cm long dispersion compensator compensates for the dispersion of many kilometres of optical fibre. While relatively narrowband in nature, CSPGs can be made wideband by making them multi-channel. A multi-channel CFBG-based dispersion compensator can be made by writing many CSPG components in separate sections of a fibre or by superimposing many CSPG components on the same section of fibre, the latter solution resulting in a very compact component. Another advantage of the SPGs over standard broadband compensation techniques such as DCF is that they are inherently independent of each other, which allows the design of complex structures including channel skipping and channel-to-channel variation of the dispersion.

Using the superimposed approach, compensation over up to 32 channels has been achieved with 100 GHz spacing and allowing for compensation of both the second- and third-order CD accumulated

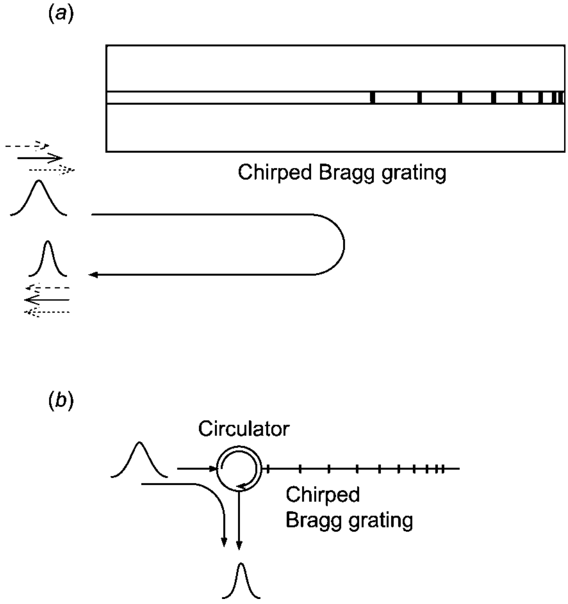

Figure B3.35. (*a*) Principle of operation of a chirped SPG to compensate pulse dispersion; (*b*) dispersion compensator made of a chirped SPG associated with a circulator.

over 50 km of SMF-28 fibre [14]. Due to the possible adjustment of the dispersion on a per-channel basis, the wideband compensation based on a superimposed grating is a good candidate for compensating such a residual CD. As an example, figure B3.36 shows the reflectivity and group delay spectra of a 32-channel dispersion compensation grating with a 100 GHz spacing in which the dispersion varies from channel to channel: from -860 to $-800\,\mathrm{ps\,nm^{-1}}$.

CSPGs can also be used in conjunction with DCM to fully manage the dispersion over a large number of WDM channels.

B3.5 Conclusion

This chapter has highlighted the importance of all-fibre components, which are an integral part of the current telecommunication networks. They already perform extremely diversified functions and their performance, thanks to the maturity of manufacturing technologies, is excellent. Depending on applications, they must sometimes compete with their integrated or micro-optics equivalents. The future communication networks will undoubtedly take advantage of all the available technologies, but the all-fibre will keep a privileged position thanks to the inherent low excess loss.

B4
Optical modulators

Nadir Dagli

B4.1 Introduction

Optical modulators accept as input the CW or pulsed output of the laser diode and generate as output a modulated optical waveform. The modulating signal is an electrical input voltage either in digital or analogue format. Using an external modulator allows the laser to operate independently. Hence its output power and frequency is controlled very accurately. There are many different applications that require modulators. One very important application is the digital fibre optic communication systems. The advent and widespread use of the Internet increased the data transmission rates drastically. The demand for more bandwidth continues on an ongoing basis. Fibre optic communication networks have the capability to deliver such demand. At present, 40 Gbit s^{-1} fibre optic transmission systems are being developed and installed all around the globe. This requires the modulation of the optical signal at such rates. Since most data generated are in electrical form, some form of electrical to optical modulation is required. This can be achieved by directly modulating the output of a laser diode through its drive current. There are laser diodes with small signal modulation bandwidths approaching 40 GHz [1]. Although this approach is simple, typically it is not used over 2.5 Gbit s^{-1} mainly because of the chirp of the directly modulated laser output [5]. The undesired frequency modulation associated with amplitude modulation severely limits the transmission distance over the fibre at high bit rates. This difficulty necessitated the development of external optical modulators. Transmission of analogue signals also requires external modulators. Analogue transmission is typically used to carry and distribute analogue cable TV signals. Such distribution eliminates frequent microwave amplification needed on a coaxial distribution system, improving the reach and reliability [2]. Subcarrier multiplexing is another scheme that allows transmission independent of data format. It can be combined with digital transmission to improve functionality, such as optical labelling and header recognition [3]. Modulators are also used in military applications, especially in phased array radar [4]. Control signals to different radiating elements can be carried over the optical fibre, allowing for large separation between the antenna and the control site in radar. Furthermore, much other functionality in the microwave domain, such as tunable filtering, tunable delaying and high-speed analogue to digital conversion, can be performed using photonics techniques. All these microwave photonics applications rely on optical modulators for electrical to optical conversion. However, the required properties of the modulator for each one of these applications are different. Digital applications typically require low drive voltages, wide bandwidth and adjustable chirp. On the other hand, analogue applications require a high degree of linearity and very low insertion loss. These requirements are most often conflicting and impose significant challenges on the modulator design and fabrication.

This chapter starts with the description of the criteria used to characterize an optical modulator. Next fundamentals of phase and amplitude modulators are given. After that the travelling wave modulation technique, which is universally used in all high-speed modulators, is described. This is followed by the description of physical effects used in optical modulation. Both electroabsorptive and electro-optic effects are described. Then specific examples of modulators in different material systems are given. These are electroabsorption, $LiNbO_3$, III–V compound semiconductor, and polymer modulators. Finally, a brief summary is presented.

B4.2 Modulator specifications

A modulator, which is described as a block diagram shown in figure B4.1, is characterized using certain specifications. These are defined and described briefly in the following subsections. Their ranges and specifics for different technologies are described in detail later on.

B4.2.1 Insertion loss

This is the optical power loss in the on state. It is typically given in units of decibels and is defined as

$$10\log\left(\frac{(P_{\mathrm{Out}})_{\mathrm{On}}}{P_{\mathrm{In}}}\right) \tag{B4.1}$$

where $(P_{\mathrm{Out}})_{\mathrm{On}}$ and P_{In} are the output power in the on state and input power, respectively.

B4.2.2 Extinction ratio

This is the ratio of the off state output power, $(P_{\mathrm{Out}})_{\mathrm{Off}}$, to the on state output power and typically is defined in decibel units as

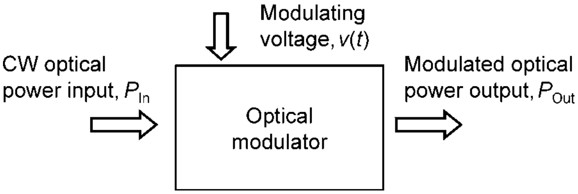
$$10\log\left(\frac{(P_{\mathrm{Out}})_{\mathrm{Off}}}{(P_{\mathrm{Out}})_{\mathrm{On}}}\right). \tag{B4.2}$$

B4.2.3 Drive voltage

This is the voltage required to switch the modulator from on to off state. This voltage is most often referred to as V_π. V_π is desired to be as low as possible, especially for high-speed operation, where the generation of voltages larger than a few volts may be very difficult. Most commercial modulators require a modulator driver, which amplifies the voltage available to a level sufficient to drive the modulator at the required impedance level.

B4.2.4 Chirp

In a modulator, amplitude and phase changes are coupled. That means that every time amplitude changes so does the phase and vice versa. This coupling could be due to material properties and/or



Modulating voltage, v(t)

Optical modulator
Modulated optical power output, P_Out

Figure B4.1. Block diagram of an optical modulator.

modulator geometry. Since frequency is time rate of change of phase, phase modulation accompanying amplitude modulation changes the instantaneous frequency of the optical wave. This is known as chirping. Chirping combined with dispersion could severely limit the transmission distance of high-speed pulses in a communication system [5]. The chirp of a modulator is quantified using a chirp parameter, σ, which is the ratio of phase modulation to amplitude modulation, as

$$\sigma = \frac{\dfrac{\mathrm{d}\phi}{\mathrm{d}t}}{\dfrac{1}{|\mathscr{E}|}\dfrac{\mathrm{d}|\mathscr{E}|}{\mathrm{d}t}} \tag{B4.3}$$

where ϕ and $|\mathscr{E}|$ are the phase and the amplitude of the optical electric field at the output of the modulator. The chirp parameter is expected to be zero for a pure amplitude modulator and infinity for a pure phase modulator.

B4.2.5 Polarization dependence

This quantifies the performance of the modulator for different polarizations. Since any incoming polarization can be considered as the superposition of two mutually orthogonal polarizations, usually the performance of the modulator is specified with respect to two mutually orthogonal polarizations. These polarizations are chosen as transverse electric (TE) and transverse magnetic (TM) in a guided wave modulator. The physical effect used in most modulators is observed only for certain polarizations of the optical mode. In other words, the operation of the modulator is polarization dependent. This is not a major concern since the modulator is used right after the laser diode. However, this could become an important issue if the modulator is used after some fibre transmission, which can generate random polarization at the input of the modulator. Such difficulty can be dealt with using polarization diversity schemes, which separates the random output polarization into two mutually orthogonal polarizations and deal with each polarization component separately.

B4.2.6 Bandwidth

Bandwidth specifies the range of modulation frequencies over which the device can be operated. The bandwidth is usually taken as the difference between the upper and lower frequencies at which the modulation depth falls to 50% of its maximum value.

B4.2.7 Bias stability and drift

For some modulators the bias voltage required to keep the modulator properly operating may change over time. Therefore, constant monitoring of the bias point and its continuous adjustment using a feedback circuitry may be required.

B4.3 Phase modulators

As described in section B4.6, the index of refraction of a material can be changed using external perturbations. Changes in the index of refraction create changes in the phase velocity and the phase of the optical wave. Therefore, an optical wave propagating in a material whose index of refraction is modulated is phase modulated. Phase modulation can be achieved either in bulk material or in an optical waveguide.

In either case, any component of the electric field of the propagating optical wave can be expressed as

$$\mathscr{E}(z,t) = \mathscr{E}_0 \cos(\omega t - \beta z) = \mathscr{E}_0 \cos(\omega t - \frac{2\pi}{\lambda_0} nz). \tag{B4.4}$$

If the index of refraction n is perturbed using a time varying external voltage $v(t)$

$$n(t) = n_0 + \Delta n = n_0 + Kv(t) \tag{B4.5}$$

where K is a proportionality constant depending on the physical effect, geometry and the material used. Specific K values depend on the technology and are described in detail in section B4.7. With this perturbation the electric field at the end of the propagation through the material of length L becomes

$$\mathscr{E}(L,t) = \mathscr{E}_0 \cos\left(\omega t - \frac{2\pi}{\lambda_0} n_0 L - \frac{2\pi}{\lambda_0} KLv(t)\right) = \mathscr{E}_0 \cos(\omega t - mv(t)). \tag{B4.6}$$

Clearly, the output wave is phase modulated with a modulation index $m = (2\pi/\lambda_0)KL$. The term $(2\pi/\lambda_0)n_0L$ was dropped, because it is a fixed phase delay. In other words, by choosing the time origin appropriately, it can always be eliminated. The optical spectrum of such a phase-modulated wave can be quite complicated. For example, for a simple sinusoidal modulating voltage

$$\begin{aligned}\mathscr{E}(L,t) &= \mathscr{E}_0 \cos(\omega t + m \sin \omega_m t)\\ &= \mathscr{E}_0[J_0(m)\cos \omega_0 t + J_1(m)\cos[(\omega_0 + \omega_m)t] - J_1(m)\cos[(\omega_0 - \omega_m)t] + J_2(m)\cos[(\omega_0\\ &\quad + 2\omega_m)t] + J_2(m)\cos[(\omega_0 - 2\omega_m)t] + J_3(m)\cos[(\omega_0 + 3\omega_m)t] - J_3(m)\cos[(\omega_0 - 3\omega_m)t]\\ &\quad + J_4(m)\cos[(\omega_0 + 4\omega_m)t] - J_4(m)\cos[(\omega_0 - 4\omega_m)t] + \cdots]\end{aligned} \tag{B4.7}$$

where J_ms are the Bessel functions of the first kind of order m. As this expression shows, as soon as a single-frequency optical wave enters an index-modulated medium, its spectrum broadens and is no longer a single-frequency waveform due to phase modulation.

B4.4 Amplitude modulators

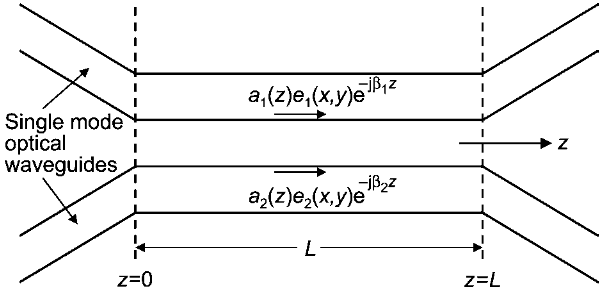
Amplitude modulation can be achieved based on absorption or index changes. Amplitude modulation based on index changes requires converting phase modulation into amplitude modulation. This is most commonly done using either Mach–Zehnder interferometers or directional couplers, which are described next.

B4.4.1 Directional coupler amplitude modulators

An optical directional coupler consists of two single-mode optical waveguides brought in close proximity over a length L as illustrated schematically in figure B4.2. If the separation between the waveguides is sufficiently small, the evanescent tail of the optical waveguide mode of one waveguide does not completely decay to zero before reaching the other waveguide. As a result, coupling between the waveguides occurs. Hence part of the wave in one waveguide can cross over or couple to the other waveguide. This situation is typically analysed using coupled mode theory [6, 12]. The field over the coupled section can be approximated as

$$\mathscr{E}(x,y,z) = a_1(z)e_1(x,y)e^{-j\beta_1 z} + a_2(z)e_2(x,y)e^{-j\beta_2 z}. \tag{B4.8}$$

This is the superposition of individual normalized waveguide modes, $e_1(x,y)$ and $e_2(x,y)$, with propagation constants β_1 and β_2. The amplitudes of the individual waveguide modes $a_1(z)$ and $a_2(z)$ are



$a_1(z)e_1(x,y)e^{-j\beta_1 z}$
$a_2(z)e_2(x,y)e^{-j\beta_2 z}$
Single mode optical waveguides
z
L
z=0
z=L

Figure B4.2. Schematic of an optical directional coupler.

z dependent due to coupling between the waveguides. If only one of the waveguides is excited at the input, such that $a_1(0) = 1$ and $a_2(0) = 0$,

$$\mathscr{E}_1(x,y,L) = e_1(x,y)\left(\cos\left(\sqrt{\delta^2+\kappa^2}L\right) + \mathrm{j}\frac{\delta}{\sqrt{\delta^2+\kappa^2}}\sin\left(\sqrt{\delta^2+\kappa^2}L\right)\right)\mathrm{e}^{-\mathrm{j}\left(\frac{\beta_1+\beta_2}{2}\right)L} \tag{B4.9}$$

$$\mathscr{E}_2(x,y,L) = e_2(x,y)\left(\frac{\mathrm{j}\kappa}{\sqrt{\delta^2+\kappa^2}}\sin\left(\sqrt{\delta^2+\kappa^2}L\right)\right)\mathrm{e}^{-\mathrm{j}\left(\frac{\beta_1+\beta_2}{2}\right)L} \tag{B4.10}$$

where $\delta = (\beta_1 - \beta_2)/2$ is the detuning between the waveguides and κ is the coupling coefficient. κ depends on the degree of spatial overlap between the individual waveguide modes [6]. Hence over a given length a certain fraction of the input power will cross over to the other waveguide. In particular, if $\beta_1 = \beta_2 = \beta_0$

$$|a_1(z)|^2 = \cos^2(\kappa z) \text{ and } |a_2(z)| = \sin^2(\kappa z).$$

Hence for

$$\kappa L = \frac{\pi}{2} \text{ or } L = \frac{\pi}{2\kappa} \tag{B4.11}$$

complete cross over takes place. It is possible to eliminate complete cross over by modulating the index of refraction hence the propagation constant of one or both waveguides. For example if $\sqrt{\delta^2+\kappa^2}L = \pi$, all the optical power will switch back to the input waveguide. The required detuning is found after eliminating L using equation (B4.11) as

$$\delta = \frac{\beta_1 - \beta_2}{2} = \sqrt{3}\kappa. \tag{B4.12}$$

If we express β_1 and β_2 as

$$\beta_1 = \beta_0 + \Delta\beta_1 = \frac{2\pi}{\lambda_0}(n_0 + \Delta n_{1\mathrm{eff}}) = \frac{2\pi}{\lambda_0}(n_0 + K_1 v(t)) \tag{B4.13}$$

$$\beta_2 = \beta_0 + \Delta\beta_2 = \frac{2\pi}{\lambda_0}(n_0 + \Delta n_{2\mathrm{eff}}) = \frac{2\pi}{\lambda_0}(n_0 + K_2 v(t)) \tag{B4.14}$$

then

$$\delta = \frac{\pi}{\lambda_0}(K_1 - K_2)v(t) \tag{B4.15}$$

and the required external voltage is found as

$$V_\pi = \frac{\sqrt{3}\lambda_0 \kappa}{\pi(K_1 - K_2)} = \frac{\sqrt{3}\lambda_0}{2L(K_1 - K_2)}. \tag{B4.16}$$

The required voltage magnitude is minimized if $K_1 = -K_2 = K$. This requires index changes of equal magnitude and opposite sign in the coupled waveguides. This is known as the push–pull drive. Depending on the applied voltage, different degrees of coupling will occur. The variation of the coupled power as a function of the applied voltage is known as the transfer function of the modulator. Mathematically, this would be expressed in the cross over waveguide as

$$\frac{|a_2(L)|^2}{|a_1(0)|^2} = \frac{1}{1 + \left(\sqrt{3}\frac{v(t)}{V_\pi}\right)^2}\sin^2\left(\frac{\pi}{2}\sqrt{1 + \left(\sqrt{3}\frac{v(t)}{V_\pi}\right)^2}\right) \tag{B4.17}$$

where V_π is the required voltage swing to turn the modulator off and is given as

$$V_\pi = \frac{\sqrt{3}\lambda_0}{4LK}. \tag{B4.18}$$

The transfer function of a directional coupler modulator is shown in figure B4.3.

One can also use the result of this analysis to determine the chirp of a directional coupler modulator. Examining equation (B4.10) it is seen that the phase of $E_2(x, y, L)$ can be kept constant if the drive is push–pull, i.e. if β_1 increases a certain amount and β_2 decreases the same amount, which leaves $(\beta_1 + \beta_2)/2$ unchanged. This results in chirp free operation. This is not possible for $E_1(x, y, L)$ since its phase depends on the drive conditions. Therefore, if a chirp free operation is desired using a directional coupler modulator modulated power should be taken out of the cross over waveguide and push–pull drive should be used [7].

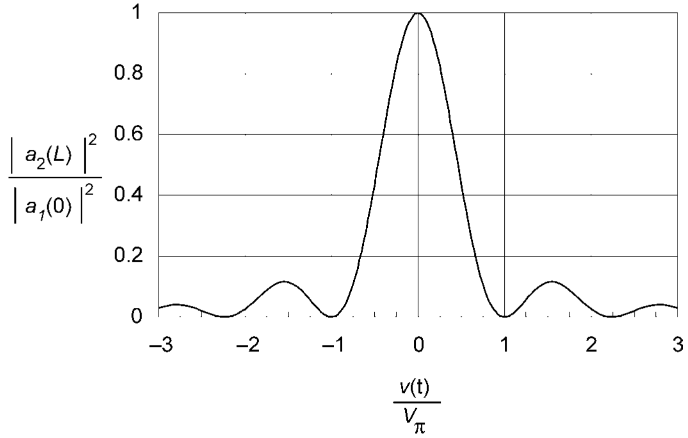


Figure B4.3. Transfer function of a directional coupler modulator.

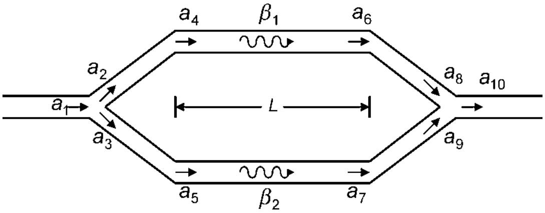

Figure B4.4. Schematic of a Mach–Zehnder interferometer.

B4.4.2 Mach–Zehnder amplitude modulators

Another commonly used amplitude modulator is a Mach–Zehnder interferometer shown in figure B4.4. This is the integrated optics version of the Michelson interferometer. The optical wave in the incoming waveguide is split into two equal parts using a Y-branch and propagates along the arms of the interferometer. At the other end waves in the two arms are combined into the output waveguide using another Y-branch. It is also possible to use 3 dB couplers in place of input and output Y-branches. For proper operation of the interferometer all the optical waveguides should be single mode. The mode amplitude in the output waveguide can be written as:

$$a_{10} = [s^2 e^{-j(\beta_1 L + 2\varphi_1)} + (1 - s^2) e^{-j(\beta_2 L + 2\varphi_2)}] a_1 \tag{B4.19}$$

where s^2 is the power splitting ratio in the Y-branch, φ_1 and φ_2 are the phase shifts along the arms of the Y-branch and β_1 and β_2 are the propagation constants of the arms of the interferometer. Any phase shift due to a length difference between the arms can also be included in φ_1 and φ_2 allowing us to assume that the arms have the same length L.

Ideally for equal power splitting $s^2 = 1/2$. However, due to imperfections during fabrication there could be slight deviations from the ideal value. In this case we can express s^2 as

$$s^2 = \frac{1}{2} + \xi.$$

Using this definition, equation (B4.19) can be expressed as

$$a_{10} = e^{-j\left(\left(\frac{\beta_1+\beta_2}{2}\right)L + (\varphi_1+\varphi_2)\right)} \left[\cos\left(\left(\frac{\beta_1 - \beta_2}{2}\right)L + (\varphi_1 - \varphi_2)\right) - 2j\xi \sin\left(\left(\frac{\beta_1 - \beta_2}{2}\right)L + (\varphi_1 - \varphi_2)\right)\right] a_1. \tag{B4.20}$$

The ratio of output power to input power is known as the transfer function of the Mach–Zehnder interferometer. Assuming that β_1 and β_2 can be perturbed with external voltages as shown in equations (B4.13) and (B4.14) and $\xi = 0$, and $\varphi_1 = \varphi_2$, the transfer function becomes

$$\frac{|a_{10}|^2}{|a_1|^2} = \cos^2\left(\frac{\pi}{\lambda_0}(K_1 - K_2) L v(t)\right). \tag{B4.21}$$

This transfer function is periodic with respect to the applied voltage. The modulator is turned off when

$$\frac{\pi}{\lambda_0}(K_1 - K_2) L v(t) = (\text{Odd integer}) \frac{\pi}{2}.$$

The lowest required voltage to turn the modulator off is known as V_π and is given as

$$V_\pi = \frac{\lambda_0}{2L(K_1 - K_2)}. \tag{B4.22}$$

Comparing this equation with equation (B4.16), we observe that the voltage swing required to turn a Mach–Zehnder modulator from on to off state is $\sqrt{3}$ times less than that required to turn a directional coupler modulator from on to off state for a given technology. Again, V_π is minimized if $K_1 = -K_2 = K$, i.e. for a push–pull drive. In terms of this definition of V_π, the transfer function becomes

$$\frac{|a_{10}|^2}{|a_1|^2} = \cos^2\left(\frac{\pi}{2}\frac{v(t)}{V_\pi}\right). \tag{B4.23}$$

The transfer function of a Mach–Zehnder modulator under push–pull drive is plotted in figure B4.5.

An important point in understanding the operation of a Mach–Zehnder modulator is physical explanation of what is happening in the off state. In the analysis, a lossless modulator is assumed. Equation (B4.21) predicts that there is no power output from the modulator in the off state even though there is input power. Since there are no reflections and optical absorption, one wonders what causes the power loss. This question can be answered with the help of figure B4.6, which describes the operation of a Mach–Zehnder modulator. In the on state, the incoming mode of the single-mode waveguide splits with equal amplitude to both arms of the interferometer in the input Y-branch. If $\beta_1 L = \beta_2 L$, the waves in both arms arrive at the output Y-branch with equal phase and combine to form the mode of the single-mode output waveguide. However in the off state $\beta_1 L - \beta_2 L = \pi$, and the waves in the both arms arrive at the output Y-branch with a π phase shift as shown in figure B4.6(*b*). As a result, when they are gradually combined by the Y-branch, in the output waveguide a mode with a null in the middle is excited. This would be the higher-order mode of the output waveguide. If the output waveguide is single mode, the higher-order mode would radiate out of the waveguide. As a result, there will not be any power left in the output waveguide after a certain length. This explanation shows that in the off state power is not lost. It simply radiates out of the output waveguide. This explanation also shows for proper operation the waveguides in the interferometer should be single mode, and the output waveguide should

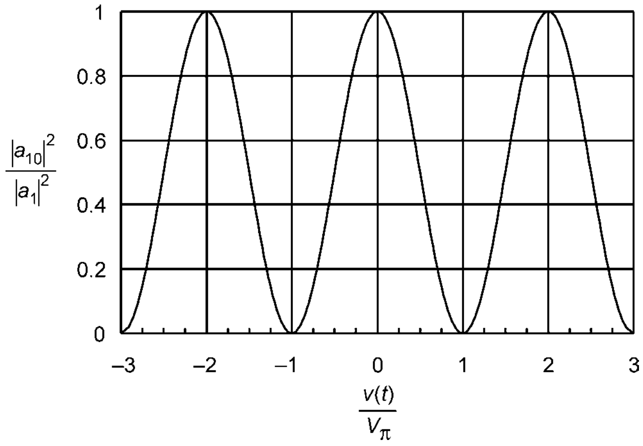

Figure B4.5. Transfer function of a Mach–Zehnder interferometer.

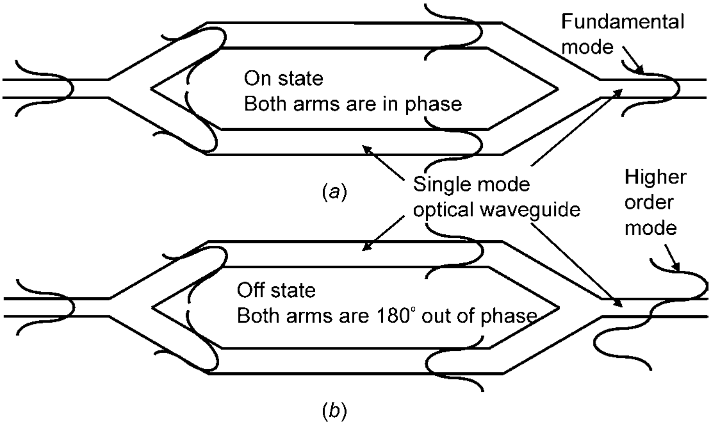

Figure B4.6. The physical description of a Mach–Zehnder modulator. (*a*) On state and (*b*) off state.

be sufficiently long for the radiation to take place in the off state. If the waveguides are not single mode in the off state only mode conversion between the fundamental and the higher-order mode takes place.

Examining equation (B4.20), it is observed that if $\xi = 0$ and $\varphi_1 = \varphi_2$

$$a_{10} = \mathrm{e}^{-\mathrm{j}\left(\frac{\beta_1+\beta_2}{2}\right)L}\left[\cos\left(\left(\frac{\beta_1-\beta_2}{2}\right)L\right)\right]a_1. \tag{B4.24}$$

If the drive is push–pull so that $(\beta_1 + \beta_2)/2$ is constant during modulation, the phase of the output signal does not change. Hence, chirp free operation results. Therefore, a push–pull driven Mach–Zehnder intensity modulator has no chirp.

B4.4.3 Electroabsorption amplitude modulators

In some materials the absorption at a given wavelength can be controlled using external voltages. Hence, it becomes possible to change the transmission through a waveguide with external voltages. This results in a very simple modulator, which is typically a short waveguide with an electroabsorption layer in it. However, critical control of the material composition and thickness are required. These devices are described in detail in section B4.7.1

B4.5 Travelling wave modulators

In optical modulators, the physical effects used to create index changes are very weak. As a result the K coefficients used in equations (B4.18) and (B4.22) are very small. This necessitates making the modulator electrode very long in order to have low drive voltages that can be supplied at high frequencies. Typical electrode lengths for electro-optic modulators are at the order of several centimetres. However, this increases the capacitance of the electrode drastically. The resulting RC product limits the bandwidth of modulation to less than a few gigahertz. These conflicting requirements on the electrode length can be eliminated using the travelling wave electrode concept. In this approach, the electrode is designed as a transmission line. Therefore, the electrode capacitance is distributed and does not create an RC limit on the modulator speed. A schematic of a travelling wave Mach–Zehnder modulator is shown in figure B4.7.

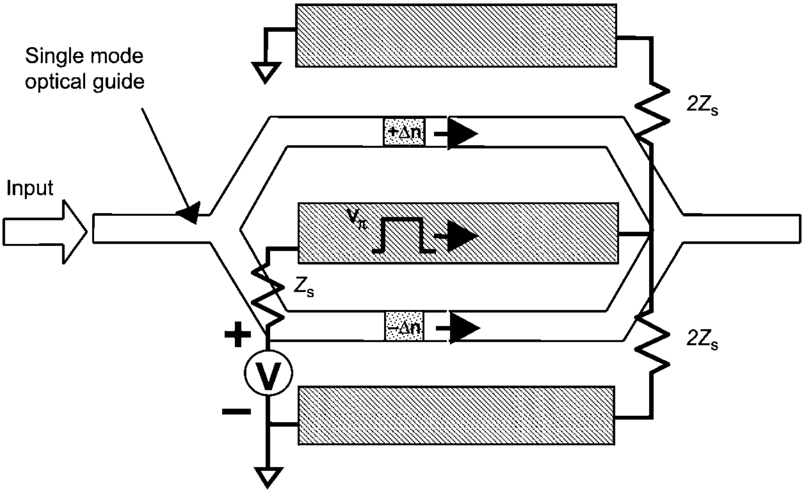

Figure B4.7. Schematic of a travelling wave Mach–Zehnder modulator.

In this figure, the electrode is designed as a coplanar waveguide. Electrical signal is applied from a voltage generator of internal impedance $Z_s\ \Omega$. In this case, signal is an electrical pulse. Both the electrical pulse and the CW optical signal travel in the same direction. On the part of the electrode where the voltage is present the index of the material is modified. In this case a push–pull drive is considered, hence index is increased a certain amount in one arm of the interferometer and decreased the same amount on the other arm. Clearly if the optical signal travels at the same velocity as the electrical signal it will experience the same index change all along the electrode. Hence, the phase shift it experiences will be integrated over the electrode length. Therefore, a very small index change may create a large phase shift. Any velocity mismatch between the electrical and the optical signals will reduce the net phase shift. The small signal modulation response of a travelling wave modulator whose electrode is terminated by its characteristic impedance is given as [8]

$$M(f) = \mathrm{e}^{-\left(\frac{\alpha_m L}{2}\right)} \left[\frac{\sinh^2\left(\frac{\alpha_m L}{2}\right) + \sin^2\left(\frac{\pi f (n_\mu - n_o) L}{c}\right)}{\left(\frac{\alpha_m L}{2}\right)^2 + \left(\frac{\pi f (n_\mu - n_o) L}{c}\right)^2} \right]^{\frac{1}{2}} \tag{B4.25}$$

where α_m and L are the loss coefficient and the length of the electrode, respectively. f is the electrical frequency and c is the speed of light in vacuum. n_μ and n_o are the microwave and optical indices and are related to the microwave and optical velocities through well-known expressions. The electrical waveform applied to the electrode of the modulator has a certain shape and contains many frequency components. The CW light that enters the modulator also becomes phase modulated as soon as it starts to interact with the electrical signal and exhibits a spectral range. As a result, the centre of gravity of both the electrical and optical signals should match [9]. That requires group velocity matching, hence the microwave and optical indices defined above should be the group indices. Usually, the modulator electrode is a quasi-TEM transmission line and has no or very little dispersion. That makes the group and the phase velocities on the electrode the same. If the electrode exhibits significant dispersion complications may arise. For example if the electrode is driven by a CW microwave signal, as in a pulse generation application, microwave phase and optical group velocities should be matched. However, if a digital electrical signal is applied to the electrode, optical and microwave group velocities should be matched. This can create velocity mismatch depending on the application. Furthermore, optical group velocity may change due to material dispersion. For example, a modulator velocity matched at 1.5 μm can be mismatched at 1.3 μm [10, 11]. This is especially a problem for semiconductor modulators, where material dispersion is much more significant compared to $LiNbO_3$.

Even in the case of perfect velocity matching, bandwidth is limited by the microwave loss of the electrode. At high microwave frequencies the microwave loss increases, which reduces the voltage on the line. Hence modulation is no longer as effective as it was at lower frequencies where microwave loss was lower. Based on equation (B4.25) if there is no velocity mismatch 3 dB bandwidth will be at the frequency where the total electrode loss becomes 6.34 dB. Therefore, a low loss and velocity matched electrode is essential for the realization of a very wide-bandwidth travelling wave modulator. Another very important consideration is impedance matching the modulator electrode. If the electrode is terminated with impedance having a value different than the electrode impedance, there is an impedance mismatch at the end of the modulator. This mismatch creates a reflected voltage wave travelling in the opposite direction. The reflected wave interferes with the wave travelling in the same direction as the optical wave and a standing wave is formed on the electrode. As a result, voltage on some parts of the electrode is higher than the rest. These parts modulate more effectively, whereas modulation is less effective on the parts having less voltage amplitude. Variation of the standing wave voltage is frequency dependent and the modulation efficiency could significantly vary as a function of frequency. In modulators with long electrodes the counter-propagating part of the standing wave is badly mismatched and contributes to modulation only at low frequencies. In these cases, modulation efficiency drops rapidly over a few gigahertz.

Based on this discussion the following requirements should be satisfied to take full advantage of the travelling wave idea:

(a) Propagation loss of the optical guide should be low so that a long modulator can be realized. This helps to significantly reduce the drive voltage.

(b) The microwave electrode mode should be quasi-TEM hence the phase and the group velocities are the same for the electrode.

(c) Microwave and optical group velocities should be matched.

(d) The electrode microwave loss coefficient should be low, so that a long modulator can be realized. As described before total electrode loss should be lower than 6.34 dB at the desired 3 dB bandwidth point.

(e) The electrode should be terminated by its characteristic impedance so that there is no standing wave on the electrode. It is desirable to have an electrode characteristic impedance of 50 Ω, but this may not always be possible.

B4.6 Physical effects used in optical modulators

The physical mechanisms used in optical modulators are change in absorption and the index of refraction under external perturbations. Change in absorption and the index of refraction are fundamentally related. The most commonly used external perturbation is an externally applied electric field, which can be generated electronically by applying voltages to the material. Modulators utilizing index changes and absorption changes under an external electric field are known as electro-optic and electroabsorption modulators, respectively. Index and absorption changes can also be generated using pressure or strain and magnetic fields. The strain is typically generated using acoustic waves.

Modulators using acoustic waves to induce index changes due to strain are known as acousto-optic modulators. Similarly, modulators using magnetic fields to induce index changes due to magneto-optic effect are known as magneto-optic modulators. Absorption is most important in III–V compound semiconductors, such as GaAs, AlAs, InP, and their alloys AlGaAs and InGaAsP.

B4.6.1 Change of absorption in semiconductors under external electric fields

In semiconductors, the sources of optical absorption are band-to-band transitions, free carriers, intraband transitions, excitons, transitions between band tails, transitions between bands and impurities, and acceptor to donor transitions. Of these band to band absorption, free carrier absorption, intraband absorption and excitonic absorption are the most dominant processes in good quality material. These processes can be perturbed by external electric fields. They are briefly described below.

Band to band absorption and Franz–Keldysh effect

In semiconductors, an incoming photon can excite an electron from the valence band to the conduction band under certain conditions as shown in figure B4.8. Since the photon momentum h/λ, where h is Planck's constant and λ is the wavelength of the light, is much smaller than the crystal momentum h/b, where b is the lattice constant, momentum conservation requires that the momentum of the initial and final states remain unchanged. Hence, only vertical transitions are allowed. Furthermore, in order to absorb a photon the initial state in the valence band should be filled and the final state in the conduction band should be empty. The energy of the photon should be larger than the energy difference between the filled initial state and the empty final state of the semiconductor. This energy difference is typically the bandgap of the material, but depending on the doping type and level, the required photon energy could be larger than the bandgap. The absorption coefficient α due to band-to-band absorption in a direct bandgap semiconductor can be expressed as

$$\alpha = A|R(h\nu)|^2 \rho_r(h\nu)(F_1 - F_2)$$

where R is the matrix element, $h\nu$ is the photon energy, F_1 and F_2 are the Fermi factors for the valence and conduction bands, respectively, ρ_r is the reduced density of states and A is a coefficient that depends

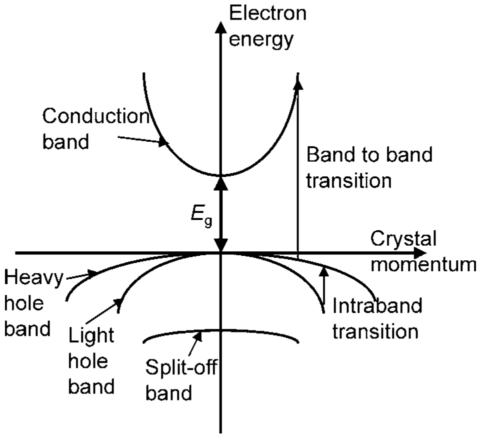

Figure B4.8. Band structure of a typical III–V compound semiconductor in the vicinity of the zone centre. Various possible transitions responsible for dominant optical absorption are also illustrated.

on fundamental constants [12]. The matrix element R is proportional to the overlap of the electronic wave functions in the conduction and valence bands. The value of R depends on the material type and its dimensionality and the polarization of the optical wave. Polarization dependence typically appears in lower-dimensional systems such as quantum wells (QWs). ρ_r also depends on the material dimensionality. For bulk materials absorption can be expressed as [12]

$$\alpha = B(h\nu - E_g)^{\frac{1}{2}}$$

assuming $F_1 = 1$ and $F_2 = 0$ as in undoped bulk material. In this expression, E_g is the bandgap of the material.

In the presence of an electric field energy bands are tilted. Figure B4.9 shows the variation of the conduction band minimum and valence band maximum in space for different values of applied electric field. In the absence of an external electric field and if the material properties such as doping and composition are uniform band extremes are flat. Increasing external electric field values tilt the energy bands, which increases the penetration of the electron and hole wave functions into the bandgap as shown in figure B4.9. This in turn increases the overlap of the electron and holes in the bandgap. In figure B4.9, points A and B are the classical turning points for the electron and hole wave functions. In other words at these points the wave functions change from oscillatory to exponentially decaying behaviour. Due to penetration of the wave functions into the bandgap it is possible to excite an electron from the valence band to conduction band with a photon of energy $h\nu$ as seen in figure B4.9. This energy is clearly less than the bandgap of the material. Hence, it becomes possible to absorb at photon energies less than the bandgap energy and this absorption increases with increasing external field. As a result, the absorption tail extends to shorter energies or longer wavelengths. This phenomenon is known as the Franz–Keldysh effect [13, 14]. It is possible to modulate the absorption from low to high absorption in

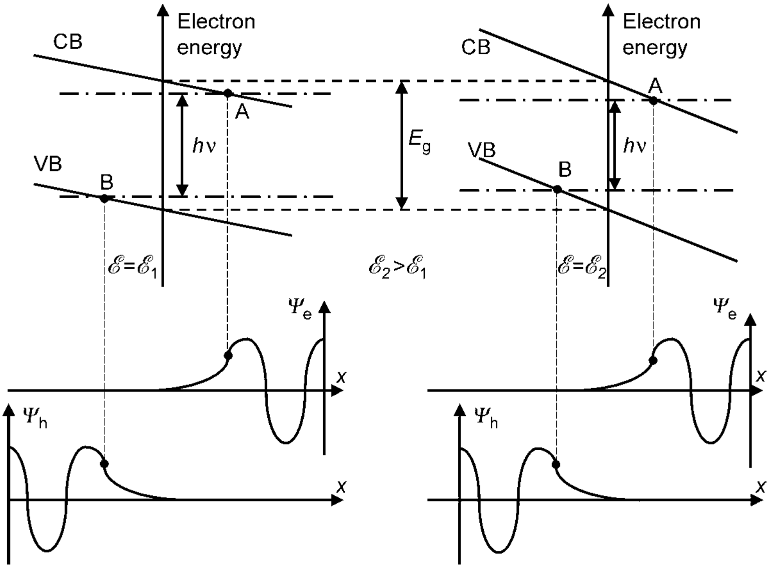

Figure B4.9. Variation of the conduction band minimum and valence band maximum under different applied external electric fields for a material with uniform doping and composition. Penetration of the electron and hole wavefunctions (Ψ_e and Ψ_h) into the bandgap is also illustrated.

the long-wavelength side with external fields. This situation is similar to tunnelling through a potential barrier under an applied electric field. In this case increasing external electric field effectively reduces the width of the barrier due to more and more penetration of the wave functions into the bandgap. The absorption coefficient under an external applied field, α_{E}, can be expressed as [15, 16]

$$\alpha_{\mathrm{E}} = B\sqrt{h\nu_{\mathrm{E}}}\pi\int_{\frac{E_{\mathrm{g}}-h\nu}{h\nu_{\mathrm{E}}}}^{\infty} \mathrm{A}i(x)^2 \mathrm{d}x$$

where

$$\nu_{\mathrm{E}} = \left(\frac{e^2\mathscr{E}^2\hbar^2}{2m_{\mathrm{r}}}\right)^{\frac{1}{3}}.$$

In this equation Ai(x) is the Airy function and m_{r} is the reduced effective mass. The absorption is also modified for photon energies larger than the bandgap energy. In this case, absorption becomes oscillatory since above the bandgap electron and hole wave functions are oscillatory. Therefore, bringing them closer changes their overlap in an oscillatory manner. Below the bandgap the wave functions were exponentially decaying, hence bringing them closer increased their overlap monotonically. The absorption changes above the bandgap are not used for modulation due to large background absorption.

Excitonic absorption in bulk and quantum well material and the quantum confined Stark effect

In a material free electrons and holes attract one another and form a bond similar to a hydrogen atom. This is called an exciton. An exciton has a strong absorption somewhat similar to an atomic absorption. In an exciton electron–hole interaction is treated as a Coulomb interaction between two point charges. Using the hydrogen atom model the binding energy for an exciton can be expressed in electron volts as $E_{\mathrm{x}n} = (13.6/n_{\mathrm{x}}^2)\ (m_{\mathrm{r}}/\varepsilon_{\mathrm{r}}^2)$ where n_{x} is an integer representing different energy levels, i.e. the quantum number, m_{r} is the reduced effective mass, and ε_{r} is the relative dielectric constant. Another important parameter is the exciton dimension. Again using the hydrogen atom model exciton radius can be expressed in Å as $a_{\mathrm{x}n} = 0.53(\varepsilon_{\mathrm{r}}/m_{\mathrm{r}})n_{\mathrm{x}}^2$. In a bulk compound semiconductor, $E_{\mathrm{x}1}$ is about 5 meV and $a_{\mathrm{x}1}$ is about 150 Å. As a result a bulk exciton covers many lattice sites and is weakly bound. Therefore, it is observed only at low temperatures. However, in a QW, electrons and holes are confined in the same physical space. As a result, they overlap and interact strongly and form an exciton confined in the QW. This strong confinement increases the binding energy or the energy required to ionize an exciton into an electron–hole pair. For a purely two-dimensional exciton the increase in the binding energy would be a factor of four [17]. However, in a QW the exciton wave function penetrates into the barriers and the dimensionality of the exciton is somewhere in between two and three. For a very thin QW this penetration could be excessive and the exciton behaves like a three-dimensional exciton. The increase in the binding energy due to quantum confinement makes the binding energy of the exciton larger than the broadening due to phonon scattering at room temperature. As a result, excitonic absorption is observed at room temperature. Spectra of such strong excitonic absorption are very sharp, and are localized in the vicinity of wavelengths corresponding to the bandgap of the QW. This energy is larger than the bandgap of the QW material due to quantization of electron and hole energy levels as shown in figure B4.10. When an external electric field is applied the electron and hole are forced to opposite ends of the QW and are physically separated as seen in figure B4.10. The applied field shifts the energy levels in the QW. This situation is similar to the shift in the energy levels of an atom under an applied electric field, which is known as the Stark effect. Hence, the corresponding transition energy shift in a QW is known as the quantum confined Stark effect (QCSE). In the QCSE, the spatial overlap or interaction of the electron

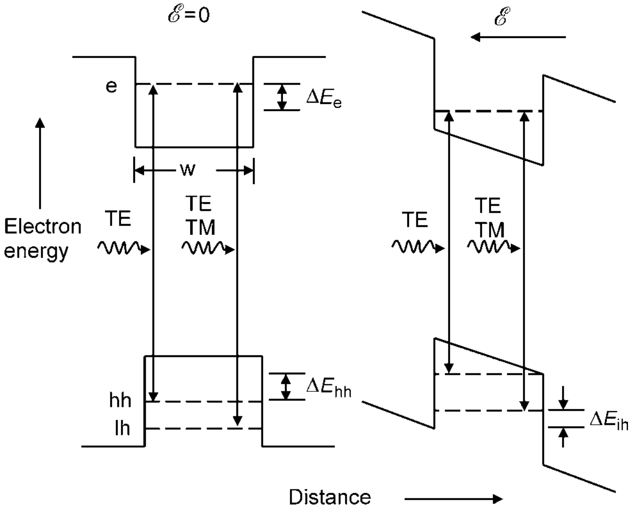

Figure B4.10. Schematic of an unstrained QW energy diagram with and without an applied electric field ℰ. e, hh, and lh designate energy levels for electrons, heavy holes and light holes, respectively. After [1] figure 3. Reproduced by permission of IEEE.

and the hole is reduced and excitonic absorption is decreased and broadened. This makes it possible to modulate the absorption very strongly with external fields around a narrow wavelength range.

Figure B4.11 shows the photocurrent spectra of an unstrained MQW material as a function of wavelength at different applied voltages [18], where device photocurrent is proportional to optical absorption. Two peaks are resolved in the absorption spectra. These are due to excitons formed between electrons and heavy holes (hh) and electrons and light holes (lh). Transition energies of hh and lh excitons are different due to different effective mass of lh and hh as seen in figure B4.11. Furthermore, the excitons interact with different optical polarizations. The hh excitons interact with TE polarized light and lh excitons interact with both TE and TM polarized light. In figure B4.11, the first absorption peak has a lower transition energy or higher optical wavelength and corresponds to the lowest hh exciton indicated in figure B4.10. The second absorption peak corresponds to the lh exciton. As bias voltage increases absorption characteristics broaden and peak absorption decreases and moves towards longer

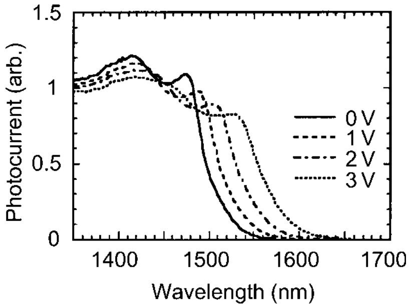

Figure B4.11. Photocurrent spectra of an unstrained MQW modulator as a function of bias voltage. The incident light is TE polarized. After [30] figure 2. Reproduced by permission of IEEE.

wavelengths. For example, at 1.55 μm absorption is modulated strongly when bias changes between 0 and 3 V. For low bias voltages, the shift in the ground state energy ΔE_{i} of a particle in a QW can be approximated as [19]

$$\Delta E_{\mathrm{i}} = C m_{\mathrm{i}} w^4 \mathscr{E}^2 \quad \mathrm{i} = \mathrm{e}, \mathrm{hh}, \mathrm{lh} \tag{B4.26}$$

where m_{i} is the effective mass of the particle, w is the width of the QW and C is a constant. Hence, wide QWs are desired for efficient operation.

Free carrier absorption

Free carriers are electrons and holes free to move in the conduction and valence bands. They can interact with photons and make transitions to a higher energy in the same band by absorbing a photon. This is known as an intra-band absorption. Since such transitions are not vertical, they require additional interactions to conserve momentum. The required momentum change can be provided by phonons or scattering from ionized impurities. There is no energy threshold for this transition; its spectrum is typically monotonic and covers a very wide range. Using a simple Drude model, which models an electron in an oscillatory field as a damped oscillator, absorption coefficient due to free carriers, α_{f}, can be expressed as [20]

$$\alpha_{\mathrm{f}} = \frac{N q^2 \lambda^2}{8 \pi^2 m^* n c^3 \tau} \tag{B4.27}$$

where N is the electron concentration, τ is the carrier relaxation time, m^* is the effective mass, n is the index of refraction, c is the speed of light in vacuum and λ is the free space wavelength. Other formulations in which the momentum is provided by acoustic phonons, optical phonons or ionized impurities yield a wavelength dependence of λ^p, where p can range from 1.5 to 3.5 [20]. Since one of the elements that affect τ is ionized impurity concentration, its value depends on the doping level and type. At high doping concentrations the carrier concentration dependence of α_{f} could be more like $N^{3/2}$. Around 1.55 μm, $\alpha_{\mathrm{f}} = 1 \times 10^{-18} N\,(\mathrm{cm}^{-3})$ in GaAs [21]. The situation is similar for intra-band absorption involving holes. However, there is another source of absorption due to possibility of transition between light and heavy hole bands in p type material. The most likely source for this absorption is vertical or near vertical transitions at longer wavelengths. Such absorption is known as intra-band absorption and is indicated schematically in figure B4.8.

Electro-optic effects

The real and imaginary parts of a complex function are related to one another if it has no poles in the lower or upper complex plane. If one describes the index of refraction of a material as a complex function, the real and imaginary parts will be related. In this representation, the real and imaginary parts of the complex index of refraction are the index of refraction and the absorption of the material. As a result, a change in absorption will generate a change in the refractive index and vice versa. This relationship is known as the Kramers–Kronig relation and can be expressed as

$$\Delta n(\mathscr{E}', \mathscr{E}) = \frac{hc}{\pi} \int_0^\infty \frac{\Delta\alpha(\mathscr{E}', \mathscr{E})}{\mathscr{E}'^2 - \mathscr{E}^2} \,\mathrm{d}\mathscr{E}'. \tag{B4.28}$$

Hence any effect that creates an absorption change $\Delta\alpha$ under an applied electric field $\mathscr{E}$ at photon energy E will also create an index change Δn. These index changes are known as electro-optic effects and are described below.

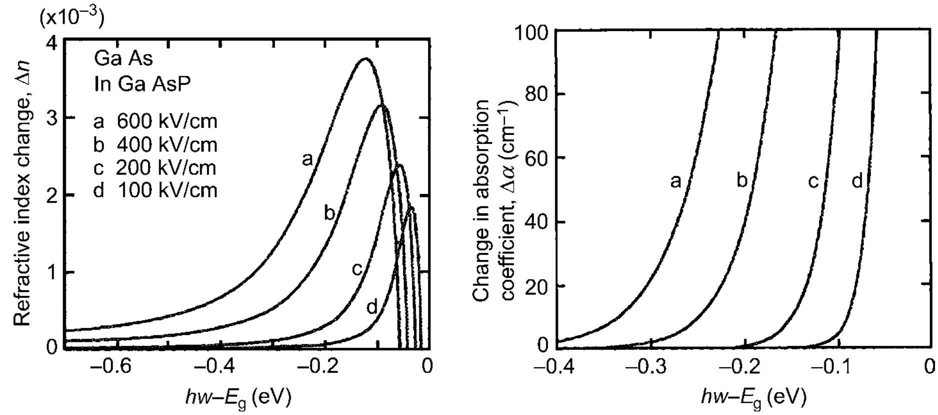

Figure B4.12. The calculated change in the index of refraction and absorption coefficient as a function of photon energy for GaAs and InGaAsP at different electric field strengths. After [22] figures 1 and 5. Reproduced by permission of AIP.

Electrorefractive effect

The electrorefractive effect is the index change accompanied with Franz–Keldysh and QCSE. Electrorefraction in bulk GaAs and InGaAsP was calculated in [22]. The calculated change in the index of refraction and absorption coefficient as a function of photon energy for GaAs and InGaAsP at different electric field strengths are shown in figure B4.12.

Index change increases rapidly towards the bandgap. The peak of the increase shifts away from the band edge with increasing electric field. For wavelengths very close to the bandgap index change decreases and it should eventually be negative. Figure B4.13 shows the change in the refractive index in

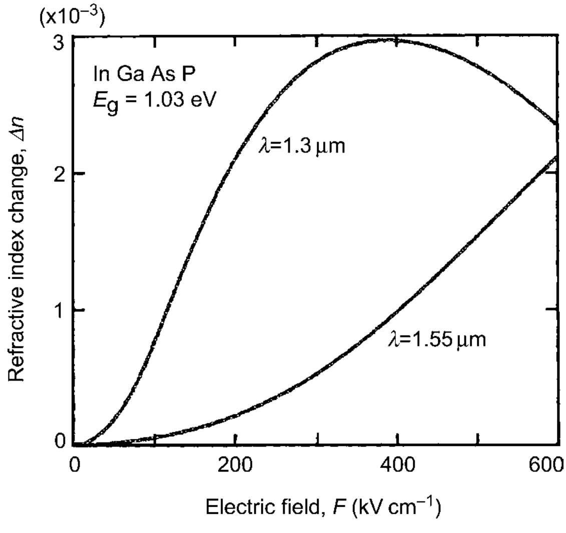

Figure B4.13. The change in the refractive index Δn in $In_{0.76}Ga_{0.24}As_{0.52}P_{0.48}$ as a function of the applied electric field at two different wavelengths. After [22] figure 3. Reproduced by permission of AIP.

$In_{0.76}Ga_{0.24}As_{0.52}P_{0.48}$ as a function of the applied electric field at two different wavelengths. For photon energies far below the bandgap the refractive index for a given electric field can be expressed as

$$\Delta n = G(\lambda)\mathscr{E}^2. \tag{B4.29}$$

There is a quadratic dependence on the electric field and the wavelength dependent coefficient $G(\lambda)$ can be expressed for GaAs as

$$G(\lambda) = 3.45 \times 10^{-16} \exp\left(\frac{3}{\lambda^3}\right)\ \mathrm{cm^2\,V^{-2}} \tag{B4.30}$$

where wavelength is expressed in micrometres [23]. For InGaAsP, $G(1.55\,\mu\mathrm{m}) = 5.8 \times 10^{-15}\,\mathrm{cm^2\,V^{-2}}$.

At high electric fields it is possible to raise the refractive index by about 3×10^{-3} at photon energies near the bandgap. However, this index change is accompanied by a large absorption change due to the Franz–Keldysh effect. In order to get predominantly an electro-optic effect absorption change should be kept to a minimum. The relative variation of the real and imaginary parts of the index of refraction with applied field is quantified using the figure of merit $\Delta n/\Delta k$, where Δk is the change in the imaginary part of the refractive index. Δk and $\Delta\alpha$ are related as $\Delta\alpha = 4\pi\Delta k/\lambda$. As described earlier, it is possible to modify the absorption in a QW close to the band edge strongly due to QCSE. This also creates an accompanying index change. Δn and $\Delta n/\Delta k$ as functions of the electric field for two MQW samples at two different wavelengths are shown in figure B4.14 [24]. In both cases, Δn shows a quadratic dependence on the applied field. $G(1.537\,\mu\mathrm{m}) = 6.73 \times 10^{-13}\,\mathrm{cm^2\,V^{-2}}$ for a 85 Å InGaAsP QW of bandgap energy 1.57 μm within 85 Å InP barriers. $G(1.306\,\mu\mathrm{m}) = 7.32 \times 10^{-13}\,\mathrm{cm^2\,V^{-2}}$ for a 70 Å InGaAsP QW of bandgap energy 1.33 μm within 250 Å InP barriers [24]. These values are more than two orders of magnitude larger than the corresponding bulk material values. But this does not necessarily make a much better modulator since the overlap of the optical mode with the QW material in a typical modulator is also a few per cent. However, the spectral width of the absorption in a QW material is much narrower compared to bulk material. Furthermore QCSE red shifts this relatively narrow resonance, hence for a given wavelength detuning $\Delta n/\Delta k$ value is larger in the QW material compared to bulk material.

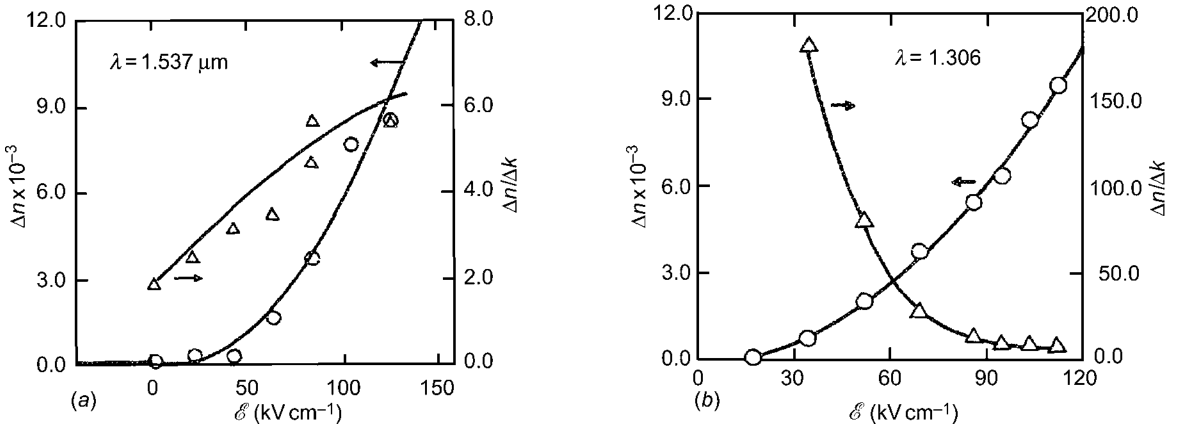

Figure B4.14. Change in the refractive index, Δn, and the ratio of the changes in the real and imaginary parts of the refractive index, $\Delta n/\Delta k$, as functions of the electric field for two MQW samples: (*a*) ten periods of 85 Å InP barriers and 85 Å InGaAsP wells of bandgap energy 1.57 μm at 1.537 μm and (*b*) five periods of 250 Å InP barriers and 70 Å InGaAsP wells of bandgap energy 1.33 μm at 1.16 μm. After [24] figure 3. Reproduced by permission of AIP.

Plasma effect

The plasma effect is the accompanying index change associated with the free carrier absorption. For n-type GaAs of carrier concentration N the index change Δn_{N} with respect to undoped material is

$$\Delta n_{\mathrm{N}} = -9.6 \times 10^{-21} \frac{N}{nE^2}$$

where n is the index of refraction and E is the photon energy. For p-type GaAs of carrier concentration P the corresponding index changes for intra- and inter-band transitions are

$$\Delta n_{\mathrm{PInter}} = -6.3 \times 10^{-22} \frac{P}{E^2} \quad \text{and} \quad \Delta n_{\mathrm{PIntra}} = -1.8 \times 10^{-21} \frac{P}{nE^2}.$$

As these expressions indicate removal of electrons or holes in a doped semiconductor reduces free carrier absorption, which in turn increases the index of refraction.

Band filling effect

In doped material, the position of the Fermi level moves depending on the doping level. In very heavily doped material, the Fermi level can move close to or even into the conduction or valence bands. Therefore, the absorption threshold could be different between the doped and undoped material. Therefore, at photon energies near the bandgap absorption could be stronger for intrinsic material compared to heavily doped material. This creates an index change due to Kramers–Kronig relationship between doped and undoped materials. This index change can be expressed as [23, 25]

$$\Delta n(E) = H(E)N.$$

The coefficient H strongly peaks around photon energy E corresponding to the bandgap of the material [23]. Below the bandgap its value is about $5 \times 10^{-21}\,\mathrm{cm}^{-3}$ for GaAs. This relationship holds as long as the semiconductor is not very heavily doped and the doping level is less than about $5 \times 10^{17}\,\mathrm{cm}^{-3}$. For heavier doping band tails that develop at the conduction band edge and bandgap shrinkage start to dominate the absorption. This increase in the absorption starts to give an index change that opposes the band filling effect [26]. For p-type material the variation of the Fermi level with doping concentration is much less due to heavier hole effective mass. Hence the band-filling effect is much weaker in p-type material.

Linear electro-optic effect

The linear electro-optic effect can be considered as the accompanying index change due to absorption at ultraviolet wavelenghts. However, the tail of absorption at such high photon energies is very weak around 1.55 μm. Hence this effect is considered as a pure index change and modelled in a different way. In a dielectric material, electric field $\vec{\mathrm{E}}$ and electric flux density $\vec{\mathrm{D}}$ are related through the dielectric tensor, which can be expressed as:

$$\begin{bmatrix} \mathcal{E}_x \\ \mathcal{E}_y \\ \mathcal{E}_z \end{bmatrix} = \frac{1}{\varepsilon_0} \begin{bmatrix} \left(\frac{1}{n^2}\right)_{xx} & \left(\frac{1}{n^2}\right)_{xy} & \left(\frac{1}{n^2}\right)_{xz} \\ \left(\frac{1}{n^2}\right)_{xy} & \left(\frac{1}{n^2}\right)_{yy} & \left(\frac{1}{n^2}\right)_{yz} \\ \left(\frac{1}{n^2}\right)_{xz} & \left(\frac{1}{n^2}\right)_{yz} & \left(\frac{1}{n^2}\right)_{zz} \end{bmatrix} \begin{bmatrix} D_x \\ D_y \\ D_z \end{bmatrix}. \tag{B4.31}$$

The index of refraction of the crystal n is defined as $n = \sqrt{\varepsilon_{\mathrm{r}}}$. This tensor has only six independent components [27]. The electric energy density W_e in a medium is given as $W_e = (1/2)\vec{E}\cdot\vec{D}$. Using the relationship shown in equation (B4.31) this can be written as

$$2\varepsilon_0 W_e = \left(\frac{1}{n^2}\right)_{xx} D_x^2 + \left(\frac{1}{n^2}\right)_{yy} D_y^2 + \left(\frac{1}{n^2}\right)_{zz} D_z^2 + 2\left(\frac{1}{n^2}\right)_{yz} D_y D_z + 2\left(\frac{1}{n^2}\right)_{xz} D_x D_z + 2\left(\frac{1}{n^2}\right)_{xy} D_x D_y. \tag{B4.32}$$

It should be noted that in equation (B4.32) $\left(1/n^2\right)_{xx} \neq \left(1/n_{xx}^2\right)$ unless the principal axes are used as the coordinate system. Since the left hand side of equation (B4.32) is a constant, the following association can be made:

$$x = \frac{D_x}{\sqrt{C}}, \quad y = \frac{D_y}{\sqrt{C}}, \quad \text{and} \quad z = \frac{D_z}{\sqrt{C}},$$

where

$$C = \sqrt{2\varepsilon_0 W_e}.$$

With this association and using the abbreviated notation in which $xx \equiv 1$, $yy \equiv 2$, $zz \equiv 3$, $yz \equiv 4$, $xz \equiv 5$, and $xy \equiv 6$, equation (B4.32) can be rewritten as

$$\left(\frac{1}{n^2}\right)_1 x^2 + \left(\frac{1}{n^2}\right)_2 y^2 + \left(\frac{1}{n^2}\right)_3 z^2 + 2\left(\frac{1}{n^2}\right)_4 yz + 2\left(\frac{1}{n^2}\right)_5 xz + 2\left(\frac{1}{n^2}\right)_6 xy = 1. \tag{B4.33}$$

In this equation x, y and z relate to the polarization of the optical field. For example, $y = z = 0$ means an x polarized optical field. Equation (B4.33) represents an ellipse and is known as the index ellipsoid or optical indicatrix. Using this equation one can find the phase velocity of an optical wave propagating in the crystal in any arbitrary direction [27].

If an external electric field is applied to the material, the coefficients of the index ellipsoid change. This external electric field is the modulating field and typically extends in frequency from DC to the millimetre wave range. This change in the coefficients is equivalent to modulating the velocity of the optical wave and is used to create the modulation of the optical wave. This change is linearly proportional to the applied field; hence the relationship between the six coefficients in equation (B4.33) and the three electric field components can be expressed as

$$\begin{pmatrix} \Delta\left(\frac{1}{n^2}\right)_1 \\ \Delta\left(\frac{1}{n^2}\right)_2 \\ \Delta\left(\frac{1}{n^2}\right)_3 \\ \Delta\left(\frac{1}{n^2}\right)_4 \\ \Delta\left(\frac{1}{n^2}\right)_5 \\ \Delta\left(\frac{1}{n^2}\right)_6 \end{pmatrix} = \begin{pmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \\ r_{41} & r_{42} & r_{43} \\ r_{51} & r_{52} & r_{53} \\ r_{61} & r_{62} & r_{63} \end{pmatrix} \begin{pmatrix} \mathscr{E}_x \\ \mathscr{E}_y \\ \mathscr{E}_z \end{pmatrix}. \tag{B4.34}$$

The 6×3 matrix multiplying the electric field vector is known as the electro-optic tensor and its elements r_{ij} are known as the electro-optic coefficients. The typical magnitude of these coefficients is of the order of $10^{-12}\,\mathrm{m\,V^{-1}}$. With these changes the index ellipsoid is written as

$$\underset{(a)}{\begin{bmatrix} 0 & -r_{22} & r_{13} \\ 0 & r_{22} & r_{13} \\ 0 & 0 & r_{33} \\ 0 & r_{51} & 0 \\ r_{51} & 0 & 0 \\ -r_{22} & 0 & 0 \end{bmatrix}} \qquad \underset{(b)}{\begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ r_{41} & 0 & 0 \\ 0 & r_{41} & 0 \\ 0 & 0 & r_{41} \end{bmatrix}}$$

Figure B4.15. Electro-optic tensor (*a*) for 3*m* crystal symmetry, and (*b*) for cubic crystal symmetry.

$$(x \quad y \quad z)\begin{bmatrix} \left(\left(\frac{1}{n^2}\right)_1+\Delta\left(\frac{1}{n^2}\right)_1\right) & \left(\left(\frac{1}{n^2}\right)_6+\Delta\left(\frac{1}{n^2}\right)_6\right) & \left(\left(\frac{1}{n^2}\right)_5+\Delta\left(\frac{1}{n^2}\right)_5\right) \\ \left(\left(\frac{1}{n^2}\right)_6+\Delta\left(\frac{1}{n^2}\right)_6\right) & \left(\left(\frac{1}{n^2}\right)_2+\Delta\left(\frac{1}{n^2}\right)_2\right) & \left(\left(\frac{1}{n^2}\right)_4+\Delta\left(\frac{1}{n^2}\right)_4\right) \\ \left(\left(\frac{1}{n^2}\right)_5+\Delta\left(\frac{1}{n^2}\right)_5\right) & \left(\left(\frac{1}{n^2}\right)_4+\Delta\left(\frac{1}{n^2}\right)_4\right) & \left(\left(\frac{1}{n^2}\right)_3+\Delta\left(\frac{1}{n^2}\right)_3\right) \end{bmatrix}\begin{pmatrix} x \\ y \\ z \end{pmatrix} = 1. \tag{B4.35}$$

Crystal symmetry imposes certain restrictions on the form of the index ellipsoid. Figure B4.15 shows the form of the electro-optic tensor for 3*m* and cubic crystal symmetries. More complete representation of the electro-optic tensor for other crystal symmetries can be found in [28].

B4.7 Specific examples of different modulator technologies

B4.7.1 Electroabsorption modulators

Lumped electroabsorption modulators

Earlier it was shown that in a QW it was possible to modulate the absorption very strongly with external fields around a narrow wavelength range due to QCSE. If such QWs are embedded in an optical waveguide, the insertion loss of this waveguide can be modulated by applying an electric field and changing the absorption of the QWs through the QCSE [29]. Figure B4.16 shows such a modulator [1, 30]. Typically, MQWs are used to increase absorption and are embedded in the i region of a reverse

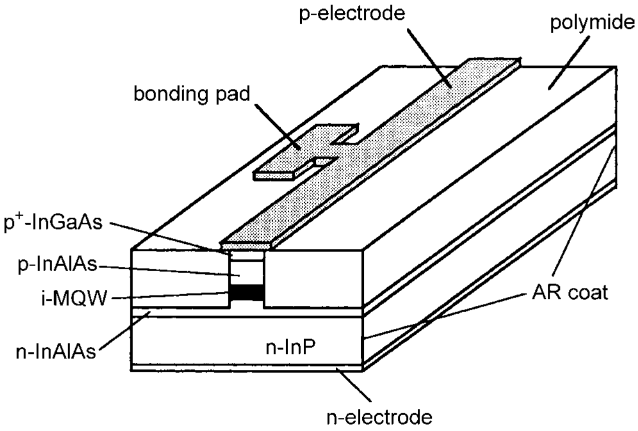

Figure B4.16. Schematic of an MQW electroabsoption modulator. After [30] figure 1. Reproduced by permission of IEEE.

biased p-i-n diode. The typical thickness of the i region, d_i, is in the 0.1–0.5 μm range. Therefore, it is possible to apply very strong electric fields with a few volts of reverse bias. In this case, well and barrier material are InGaAs and InAlAs, respectively. The index of refraction of the top p and bottom n-InAlAs is lower than that of the MQW. This forms a slab waveguide. By deeply etching this slab waveguide a channel optical guide is formed. Waveguide widths are of the order of 1–3 μm and the etch depths are about 1–2 μm. Typical device lengths are in the 50–300 μm range. Ohmic contacts are formed at the top and bottom. Etched areas underneath the bonding pads are filled with a low-dielectric-constant polyimide to reduce device capacitance. Since only the absorption modulation is utilized, the optical waveguide need not be single mode. Therefore, the profile of the optical waveguide can be optimized for improved coupling to the incoming fibre mode. However, critical control of the composition and thickness of the epitaxial layers are required.

The transmission through such a modulator as a function of applied voltage can be expressed as

$$T(V) = T_0 \exp[-\Gamma \alpha(V) L] \tag{B4.36}$$

where Γ is the overlap between the optical mode and the MQW, $\alpha(V)$ is the absorption coefficient as a function of applied voltage V, L is the length and T_0 is the coupling coefficient between the fibre and the optical waveguide. The on/off ratio of an EA modulator in decibels can be expressed as

$$10\log\left[\frac{T(V)}{T(0)}\right] = \frac{\alpha(V)-\alpha(0)}{\alpha(0)} 10\log\left[\mathrm{e}^{-\alpha(0)L}\right] = \frac{\Delta\alpha}{\alpha}[\text{Propagation loss (dB)}]. \tag{B4.37}$$

Optical propagation loss of EA modulators is large, typically in the 15–20 dB mm^{-1} range. Main components of this loss are the free carrier absorption, especially in the p layers, and band-to-band absorption, both described in earlier sections. The second loss component can be made smaller by increasing the separation between the wavelength of operation and the absorption peak, which is called detuning. Typical detuning values are about 20–50 nm. Typical $\Delta\alpha/\alpha$ values are in the 3–10 range. Large-on/off-ratio devices can be obtained using long devices, but that also increases the insertion loss. For the typical EA modulator lengths in the 50–300 μm range propagation loss is 1–3 dB. Therefore, to get large extinction ratios with low device insertion loss, $\Delta\alpha/\alpha$ should be maximized. Furthermore, efficient modulation requires a large $\Delta\alpha/\Delta v$ or $(1/d_i)(\Delta\alpha/\Delta\mathscr{E})$, where $\mathscr{E}$ is the applied electric field. In other words, large Stark shifts are required. For low bias voltages, the shift in the ground state energy ΔE_i of a particle in a QW is proportional to the fourth power of the well width as shown in equation (B4.26) [19]. Hence wide QWs are desired for efficient operation.

For fibre optic communication applications the desired wavelength is around 1.55 μm. This requires alloys of InP and GaAs as active material grown on InP substrates. Quaternary alloys such as InGaAsP and InGaAlAs can be grown lattice matched to InP and make it possible to change the bandgap energy and well thickness independently [31, 32]. Thick QWs up to 12 nm have been reported in InGaAsP/InGaAsP MQWs resulting in drive voltages as low as 1.2 V [31]. Similarly, InGaAlAs/InAlAs MQWs with well widths as large as 19.6 nm yielded very low-voltage EA modulators at 1.55 μm, requiring about 1 V for 10 dB on/off ratio [33]. Larger electron confinement due to increased conduction band discontinuity in this material system makes such wells comparable to narrower wells in the InGaAsP system. It is possible to obtain similar results using lattice matched InGaAs ternary QWs. However, as the wells get thicker the absorption edge shifts to longer wavelengths and operation around 1.55 μm becomes difficult. This difficulty in the ternary material can be eliminated by using tensile strained QWs [18]. A commonly used material design consists of a 0.6 μm n-InAlAs buffer, an undoped strained MQW absorption layer, a 2 μm p-InAlAs cladding layer and a p$^+$-InGaAs contact layer [34]. The strained MQW layer contains ten 8.8 nm $\mathrm{In_{0.48}Ga_{0.52}As}$ wells and 5 nm $\mathrm{In_{0.53}Al_{0.47}As}$ barriers. The wells are under 0.35% tensile strain and the barriers are under 0.5% compressive strain. The strain in the barriers

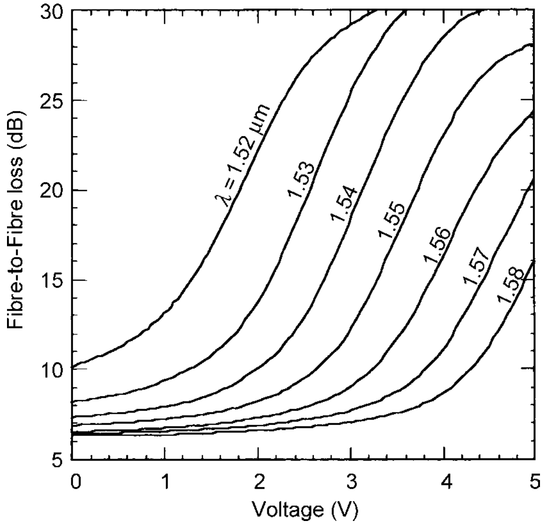

Figure B4.17. Fibre-to-fibre insertion loss of a 40 Gbit s^{-1} EA modulator for various wavelengths. The input light was TE polarized. After [34] figure 10. Reproduced by permission of IEEE.

is used for strain compensation. Proper amounts of alternating compressive and tensile strain can make the total strain in the MQW near zero, allowing large periods of strained MQWs without exceeding the critical layer thickness. Fibre-to-fibre insertion loss of a typical high-speed EA modulator as a function of external bias at different wavelengths is shown in figure B4.17 [34]. The QCSE is most pronounced for photon energies near the bandgap of the material and shows strong wavelength dependence as seen in figure B4.17. At shorter wavelengths modulation becomes more efficient, but insertion loss also increases. EA modulators are very short devices and, hence, have small device capacitance. Therefore, when driven as a lumped circuit element their speed of operation will be limited by the *RC* time constant of the circuit. Therefore, reducing the capacitance by shortening the device increases the speed of operation. Typically a 2.5 μm wide and 150 μm long device has a capacitance of about 0.33 pF, which is low enough for 20 GHz bandwidth when driven by a 50 Ω source with a 50 Ω terminating resistance across the device. Higher bandwidths are possible by using a lower terminating resistance. This reduces the *RC* time constant, hence increases the bandwidth at the expense of modulation efficiency. Electrical 3 dB bandwidths approaching 60 GHz have been reported for lumped devices [34–37]. High-speed operation requires not only a short device but also good impedance matching and proper microwave packaging. Although unpackaged devices demonstrated very high-speed operation, it was difficult to duplicate these results in packaged modules. The main source of the difficulty is cleaving and packaging devices as short as 50 μm. One solution to this difficulty is to integrate passive input and output waveguides to a very short EA section [34]. This requires etching of the MQW region outside the EA modulator section and regrowing low-loss passive waveguide sections. This technique was used to obtain overall device lengths of 1 mm, with EA modulator sections as short as 50 μm. The measured frequency response of such a 1.55 μm modulator is shown in figure B4.18, showing a 3 dB electrical bandwidth of 50 GHz. At 1.3 μm, bandwidths as large as 38 GHz have been demonstrated [38].

In unstrained material QCSE is polarization dependent. However, using strain compensated QWs polarization dependence can be significantly reduced [18, 39, 40]. The most common approach is to use about 0.5% tensile strained InGaAs wells and about 0.5% compressive strained InAlAs barriers [34, 39].

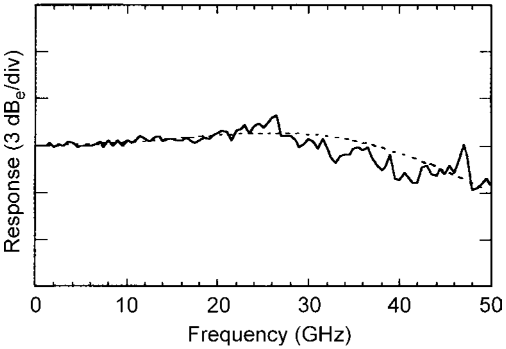

Figure B4.18. Frequency response of an EA modulator with integrated input and output optical waveguides under 1.5 V reverse bias and + 5 dBm optical input power at 1.55 μm. The dashed line shows the calculated data. After [34] figure 11. Reproduced by permission of IEEE.

Travelling wave electro-absorption modulators

One of the emerging directions in EA device research is to reduce the drive voltage and increase the bandwidth. Lumped device performance seems to be saturated around 2 V drive voltage and 50 GHz bandwidth. The main reason for that are the conflicting requirements on the length of the device. Low drive voltages require longer devices yet wide bandwidths require shorter devices. One way to address this problem is to design the device as a travelling wave modulator. As described earlier for a travelling wave device, the *RC* time constant is not the bandwidth limit and the device can be made longer without sacrificing bandwidth. However, the special structure of an EA modulator presents interesting issues. First of all, the optical propagation loss of an EA device is rather high. Therefore, increasing the length over a few hundred microns introduces excessive loss. Large device capacitance per unit length also makes it difficult to make a 50 Ω transmission line with matched velocity. Since the device is rather short, velocity matching is not an issue up to frequencies well into the sub-millimetre-wave range. The bandwidth is typically limited by the microwave loss [41]. For travelling wave electro-absorption modulator (TW-EA) electrodes, measured microwave loss coefficients of about 60–80 dB cm^{-1} at 40 GHz were reported [41]. This excessive loss is due to heavily doped layers inside the device and is another factor limiting the length of the device. Characteristic impedance values are about 25 Ω [41, 42]. However, designing the device as part of a 25 Ω transmission line makes longer devices possible and packaging easier. Recently, a 200 μm long TW-EA device with a bandwidth over 54 GHz [43] and a 300 μm long device with a bandwidth of 25 GHz [42] were reported. Both devices were polarization insensitive and operated at 1.55 μm. For 20 dB on/off ratio, drive voltages of the 200 and 300 μm devices were 3 and 1.9 V, respectively.

B4.7.2 $LiNbO_3$ modulators

Among all external modulators, $LiNbO_3$ travelling wave modulators have the most mature technology. Such modulators are commercially available from several manufacturers and are used in commercial applications. $LiNbO_3$ is a ferroelectric crystal, which is readily available commercially.

A schematic of a typical $LiNbO_3$ phase modulator is shown in figure B4.19. On the surface there are two electrodes across which the modulating voltage is applied. An optical waveguide is also formed in the crystal. The most common way of fabricating optical waveguides in $LiNbO_3$ is Ti indiffusion. Typically, Ti stripes of about 3–8 μm wide and about 0.1 μm thick are patterned on the surface of $LiNbO_3$ using liftoff. These Ti stripes are subsequently driven into $LiNbO_3$ around 1000°C for about 10 h in an oxygen

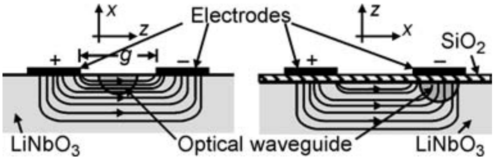

Figure B4.19. The most commonly used $LiNbO_3$ modulator configurations using (*a*) an *x*-cut, (*b*) *z*-cut crystal.

atmosphere. The resulting Ti diffusion profile translates itself into a higher index of refraction and optical guiding results. The index steps generated this way are of the order of 0.01, and typical optical propagation loss coefficients are less than $0.2\,\mathrm{dB\,cm^{-1}}$. Furthermore, the optical modes in such waveguides match rather well with the mode of a single-mode optical fibre. As a result, 5 dB fibre-to-fibre insertion is quite common for $LiNbO_3$ travelling wave modulators with 5 cm long electrodes. Other techniques of fabricating optical waveguides in $LiNbO_3$ include ion exchange, proton exchange and Ni diffusion. The effect used for modulation is the linear electro-optic effect and its specifics for $LiNbO_3$ are described next.

Electro-optic effect in LiNbO3

$LiNbO_3$ has 3*m* crystal symmetry. When an external modulating field is applied to $LiNbO_3$ its index ellipsoid is perturbed and using equations (B4.34) and (B4.35) and figure B4.15 it can be expressed as

$$(x\quad y\quad z)\begin{bmatrix} \frac{1}{n_o^2}-r_{22}\mathscr{E}_y+r_{13}\mathscr{E}_z & -r_{22}\mathscr{E}_x & r_{51}\mathscr{E}_x \\ -r_{22}\mathscr{E}_x & \frac{1}{n_o^2}+r_{22}\mathscr{E}_y+r_{13}\mathscr{E}_z & r_{51}\mathscr{E}_y \\ r_{51}\mathscr{E}_x & r_{51}\mathscr{E}_y & \frac{1}{n_e^2}+r_{33}\mathscr{E}_z \end{bmatrix}\begin{pmatrix} x\\ y\\ z\end{pmatrix}=1 \tag{B4.38}$$

where n_o and n_e are known as the ordinary and extraordinary indices of refraction, respectively. Their values are $n_e = 2.21$ and $n_o = 2.3$. The electro-optic coefficients are given as $r_{22} = 3.4\times10^{-12}\,\mathrm{m\,V^{-1}}$, $r_{13} = 8.6\times10^{-12}\,\mathrm{m\,V^{-1}}$, $r_{33} = 30.8\times10^{-12}\,\mathrm{m\,V^{-1}}$, and $r_{51} = 28\times10^{-12}\,\mathrm{m\,V^{-1}}$. In this case depending on the direction of the modulating electric field different possibilities exist. For example, if the modulating field is z directed, $\mathscr{E}_x = \mathscr{E}_y = 0$, and equation (B4.38) reduces to

$$(x\quad y\quad z)\begin{bmatrix} \frac{1}{n_o^2}+r_{13}\mathscr{E}_z & 0 & 0 \\ 0 & \frac{1}{n_o^2}+r_{13}\mathscr{E}_z & 0 \\ 0 & 0 & \frac{1}{n_e^2}+r_{33}\mathscr{E}_z \end{bmatrix}\begin{pmatrix} x\\ y\\ z\end{pmatrix}$$

$$=(x\quad y\quad z)\begin{bmatrix} \frac{1}{(n_0+\Delta n_x)^2} & 0 & 0 \\ 0 & \frac{1}{(n_0+\Delta n_y)^2} & 0 \\ 0 & 0 & \frac{1}{(n_e+\Delta n_z)^2} \end{bmatrix}\begin{pmatrix} x\\ y\\ z\end{pmatrix}=1 \tag{B4.39}$$

In this case, the index ellipsoid remains diagonal. The index of refraction for an optical wave polarized in the z direction and propagating in either the x or y direction can be found using equation (B4.39) as

$$\frac{1}{(n_e+\Delta n_z)^2}=\frac{1}{n_e^2}+r_{33}\mathscr{E}_z \quad\text{or}\quad (n_e+\Delta n_z)=\frac{n_e}{\sqrt{1+r_{33}n_e^2\mathscr{E}_z}}.$$

Since $r_{33}n_e^2E_z \ll 1$, $(n_e + \Delta n_z) \approx n_e\left(1 - \frac{1}{2}r_{33}n_e^2E_z\right)$, hence

$$\Delta n_z = -\frac{1}{2}r_{33}n_e^3E_z. \tag{B4.40}$$

Since r_{33} is the largest electro-optic coefficient, this arrangement generates the largest index change, while keeping the index ellipsoid diagonal. For this reason a z-directed modulating field, modulating a z-polarized optical wave, is the most commonly used arrangement for $LiNbO_3$ electro-optic modulators.

The two most commonly used configurations taking advantage of this arrangement are shown in figure B4.19. For x-cut crystals the optical waveguide is in the y crystal orientation. A horizontal electric field parallel to the surface of the crystal, i.e. an electric field along the z-axis, is utilized. This configuration modulates the TE polarized optical mode, in which the main electric field component of the optical waveguide mode is parallel to the surface of the crystal, i.e. it is along the z-axis of the crystal. For z-cut crystals an electric field vertical to the surface of the crystal is used. Optical waveguides are along the y-axis of the crystal as shown in figure B4.19. This field modulates the TM polarized optical mode most efficiently. For TM modes the main electric field component of the optical waveguide mode is also perpendicular to the surface of the crystal, i.e. it is along the z-axis of the crystal. For both configurations, the modulating external field and the main electric field component of the optical mode are parallel to each other and to the z-axis of the crystal. In the case of a z-cut crystal usually a low-index buffer layer, such as SiO_2, is used under the electrode. This buffer layer is used to isolate the optical mode from the metal electrode to keep the optical propagation loss low.

The presence of the applied electric field modifies the index of the material as described earlier. This in turn modifies the propagation constant of the optical mode. Since the effect is very small this perturbation can be found using a perturbation analysis. The result is [12]

$$\Delta\beta = (2\pi/\lambda)\Delta n_{\mathrm{eff}} \ \text{ with } \ \Delta n_{\mathrm{eff}} = \iint \Delta n_z |Y|^2\,\mathrm{d}S$$

where Y is the normalized electric field of the optical mode. The integration is carried out over the entire optical mode. Substituting the value of Δn_z derived in equation (B4.40) we obtain

$$\Delta n_{\mathrm{eff}} = \frac{1}{2}r_{33}n_e^3 \iint E_z |Y|^2\,\mathrm{d}S. \tag{B4.41}$$

Multiplying and dividing this equation by v/g, where v is the applied voltage and g is the electrode gap, we obtain

$$\Delta n_{\mathrm{eff}} = \frac{1}{2}r_{33}n_e^3\frac{v}{g}\left[\frac{g}{v}\iint E_z|Y|^2\,\mathrm{d}S\right] = \frac{1}{2}r_{33}n_e^3\frac{v}{g}\Gamma \tag{B4.42}$$

where Γ is known as the overlap integral and is expressed as

$$\Gamma = g\iint \frac{E_z}{v}|Y|^2\,\mathrm{d}S. \tag{B4.43}$$

Γ is proportional to the overlap of the magnitude squared normalized optical mode electric field and the normalized z-component of the applied modulating field. With this definition, we can express the K-coefficients defined in equation (B4.13) and (B4.11) as

$$K = \frac{1}{2}r_{33}n_e^3\frac{\Gamma}{g}. \tag{B4.44}$$

Therefore, the V_π of a push–pull driven $LiNbO_3$ directional coupler modulator is given as

$$V_\pi = \frac{\sqrt{3}}{2}\frac{\lambda_0}{L}\frac{g}{r_{33}n_e^3\Gamma}. \tag{B4.45}$$

Similarly that of a push–pull driven $LiNbO_3$ Mach–Zehnder modulator is

$$V_\pi = \frac{1}{2}\frac{\lambda_0}{L}\frac{g}{r_{33}n_e^3\Gamma}. \tag{B4.46}$$

Obviously in order to have a low drive voltage a large electro-optic coefficient, a large index of refraction, a large overlap integral, a long electrode length and a small electrode gap are desired. A simple back of the envelope calculation indicates that unless L is very long it is not possible to achieve low-drive-voltage modulators. However, long electrode length necessitates a travelling wave configuration as described earlier. For this reason, all practical $LiNbO_3$ electro-optic modulators are travelling wave modulators. Such modulators are described in the next section.

Travelling wave $LiNbO_3$ electro-optic modulators

A schematic of a typical $LiNbO_3$ travelling wave modulator is shown in figure B4.20 [44]. The optical structure is a Mach–Zehnder interferometer. The electrode length is of the order of centimetres, hence velocity matching is essential in such a modulator.

The dielectric constant of $LiNbO_3$ shows a large amount of dispersion going from microwave to optical frequencies due to a large ionic contribution to its dielectric constant. For *z*-cut crystals the

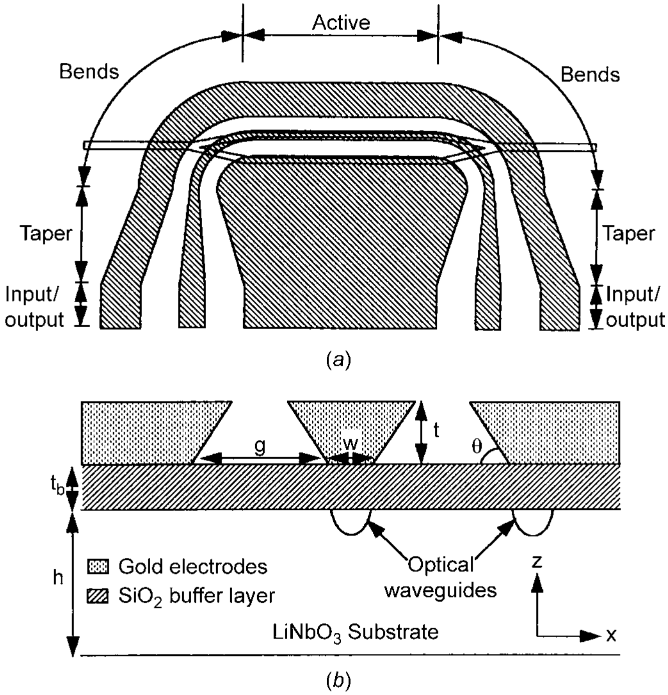

Figure B4.20. (*a*) Top view, (*b*) cross sectional schematics of a *z*-cut *y*-propagating $LiNbO_3$ travelling wave modulator. After [44] figure 1. Reproduced by permission of IEEE.

microwave relative dielectric constants of $LiNbO_3$ parallel and perpendicular to the crystal are $\varepsilon_{ry} = 43$ and $\varepsilon_{rz} = 28$, respectively. For a transmission line running along the y-direction one can define an effective relative dielectric constant under the quasi-static approximation as [45]

$$\varepsilon_{\text{reff}} = \sqrt{\varepsilon_{ry}\varepsilon_{rz}} \tag{B4.47}$$

which is around 35. The most commonly used electrode for such modulators is the coplanar transmission line (CPW). The effective microwave index of a CPW on $LiNbO_3$ with zero conductor thickness and top dielectric as air is [46]

$$n_{\mu} = \sqrt{\frac{\varepsilon_{\text{reff}} + 1}{2}} = \sqrt{\frac{\sqrt{\varepsilon_{ry}\varepsilon_{rz}} + 1}{2}}. \tag{B4.48}$$

This value is larger than 4. On the other hand, the commonly assumed effective index of an optical mode in a Ti indiffused $LiNbO_3$ optical waveguide is 2.15. As a result, an electrical signal applied to the electrode will travel significantly slower than the optical wave. Therefore, velocity matching in $LiNbO_3$ modulators requires increasing the velocity of propagation of the microwave electrode.

The most common way of achieving this is to use a SiO_2 buffer layer under the electrode and to increase the thickness of the conductors. The characteristic impedance, Z_0, and the velocity of propagation, v_{μ}, of a transmission line are given as

$$Z_0 = \sqrt{\frac{l}{C}} \quad v_{\mu} = \frac{1}{\sqrt{lC}}, \tag{B4.49}$$

where l and C are the inductance and capacitance per unit length of the transmission line, respectively. Under the quasi-static approximation, l is found using exactly the same line geometry in which the dielectrics are replaced by air. Since electro-optic materials used are nonmagnetic, l of this air line is the same as the l of the original line. But the capacitance per unit length of the airline, C_a, is different. Such a line with uniform air dielectric supports a TEM mode with velocity of propagation the same as the speed of light in air, c. Hence

$$c = \frac{1}{\sqrt{lC_a}} \quad \text{or} \quad l = \frac{1}{c^2 C_a}. \tag{B4.50}$$

Combining these equations together we find that

$$v_{\mu} = c\sqrt{\frac{C_a}{C}} \quad \text{and} \quad Z_0 = \frac{1}{c\sqrt{CC_a}}. \tag{B4.51}$$

The relative dielectric constant of SiO_2 is 3.9, which allows filling part of the transmission line with a low-index medium. This in turn reduces C hence v_{μ} and Z_0 are increased. Placing a dielectric like SiO_2 under the metal electrode also helps to reduce the overlap of the optical mode with the metal electrode as described earlier. This helps to reduce the optical propagation loss significantly especially for z-cut devices. However, thick SiO_2 layers are not desirable since part of the electrode voltage that drops across this layer reduces the electric field intensity in $LiNbO_3$ and hence the modulation efficiency of the device. Typical SiO_2 layer thickness is about 1 μm. The additional velocity increase is typically achieved by increasing the conductor thickness. Increasing the conductor thickness increases the electric field strength in the slots between the conductors. This in turn increases C_a, hence v_{μ} increases and Z_0 decreases. Typical conductor thicknesses range from 10 to 20 μm. For such thick electrodes, the slope of the sidewalls starts to affect the electrode characteristics [44]. Although it is possible to achieve velocity matching this way, the undesirable side effect is the reduction in the characteristic impedance of the electrode. It is possible to adjust the gap and the width of the centre conductor of the CPW to match v_μ and Z_0 simultaneously, but this requires rather narrow gap and width values [47]. As a result microwave electrode loss increases and becomes the limiting factor for the bandwidth. This difficulty was solved by introducing the ridge structure [48].

Figure B4.21 illustrates the basic idea behind this approach [48]. Compared to the conventional modulator, the ridge removes the high-microwave-dielectric-constant $LiNbO_3$ between the conductors. As a result, C reduces and both v_μ and Z_0 are increased simultaneously. This allows velocity matching without sacrificing impedance matching. Furthermore, a high dielectric constant in the ridge helps to confine the electric field lines under the electrode such that field becomes almost vertical under the electrode. As a result, the desired vertical component of the electric field overlaps better with the optical mode improving the efficiency of the modulator. This is especially true for the *z*-cut devices. Detailed analysis of this modulator geometry was reported in [49].

Travelling wave $LiNbO_3$ modulators with very wide bandwidths have been demonstrated. The frequency dependence of the modulation response of a modulator fabricated using the ridge structure is shown in Figure B4.22.

For this modulator $t_b = 1.0\,\mu m$, ridge height, $t_r = 4.0\,\mu m$, $t_m = 20\,\mu m$, $L = 2\,cm$, $W = 8\,\mu m$, and $G = 25\,\mu m$. The measured electrical and optical bandwidths are 75 and 110 GHz, respectively, and V_π is 5.1 V [50]. If the length of the same device is increased to 3 cm, V_π decreases to 3.5 V but the electrical and optical bandwidths also decrease to 30 and 45 GHz, respectively. Recently, a careful loss measurement up to 110 GHz revealed that up to 20 GHz loss is dominated by conductor losses [51]. Above 20 GHz

dielectric and radiation losses become important. The SiO_2 buffer layer is found to have a loss tangent four times higher than that of the $LiNbO_3$ substrate [51]. Therefore, the quality of this buffer layer needs to be carefully controlled. Another loss component is the coupling to substrate modes in a CPW structure [52]. The usual technique to eliminate this loss is to thin the $LiNbO_3$ substrate. Typical substrate thickness used is less than 0.5 mm. The thinner the substrate, the higher the frequency at which this coupling occurs. Also keeping a large part of the substrate covered with metal helps to eliminate this coupling. CPW electrodes provide an advantage in this regard. In the measurements in [51], several narrowband electrode loss increases at 85, 95 and 105 GHz were reported. This observation was attributed to coupling to substrate modes in the electrical connectors.

The recent results in the bandwidth of $LiNbO_3$ modulators are impressive. However, drive voltages required to drive such modulators at high frequencies are still high. Present day electronics is expected to generate about 3.5 V drive voltages at 40 GHz and even less at higher frequencies. That means the drive voltages of existing modulators need to be reduced even further. One obvious way is to increase the electrode length. In a recent work, a reflection type travelling wave modulator was reported [53]. This approach reflects the electrical and optical signals from the cleaved and polished edge of the substrate. The reflection doubles the interaction length with the electrode. For an electrode and interaction length of 5.3 and 10.6 cm, respectively, V_π was 0.89 V at 1.3 μm.

$LiNbO_3$ is susceptible to what is known as photorefractive effect [54]. Under optical illumination, electrons from ionized impurity centres (typically Fe^{2+}) are excited to the conduction band. Then they move around until they are recaptured by traps. This creates charge separation, which creates large electric fields inside the material. These electric fields change the index through the electro-optic effect. Propagation loss also changes. This is a time dependent process depending on the charge dynamics and changes in the illumination levels. This effect is most significant at wavelengths shorter than about 870 nm [55]. It becomes less of an issue at infrared wavelengths like 1.55 μm for typical power levels used in communication applications. It is shown that photorefractive sensitivity of Ti indiffused $LiNbO_3$ modulators can be reduced significantly using high-temperature O_2 anneals [56]. Annealed modulators were operated at 1.3 μm at input optical powers as high as 400 mW up to 168 h with only a 3.5° drift in the modulator bias point. There was no measurable change in the bias point at 100 mW. It is also shown that annealing at high temperatures in N_2 and Ar ambient increases the sensitivity to the photorefractive effect significantly [56].

Bias stability of modern day $LiNbO_3$ devices is very good. They can operate at constant bias for thousands of hours under the control of automatic biasing circuitry. However, when bias voltages change suddenly, bias drifts with time constants from hours to many days may be observed. The major source of bias point drift was attributed to flow and redistribution of electrical charge under the application of applied voltages. The conductivity of SiO_2 buffer and $LiNbO_3$ are very high but finite. Usually a certain amount of low-mobility charge exists in these materials, at their interface or on their surface. These charges could be process related or can be generated with optical or thermal excitation during the operation of the device. When voltages are applied to the electrodes, charge starts to move and modifies the electric field applied to the optical guides. As a result, modulation characteristics change. This behaviour can be modelled using an electrical network approach [57]. Each layer in the device can be modelled by an equivalent resistance representing the flow of charge through it and each interface can be modelled by a capacitance representing the potential for charge storage. Such models are able to describe experimental observations successfully [57]. The usual method of preventing such drift involves controlling the resistivity of the buffer and matching it to the resistivity of waveguide layers and modifying the $LiNbO_3$ surface before depositing the buffer layer.

The electro-optic effect in $LiNbO_3$ depends on the polarization of the light and high-speed modulators are polarization dependent. However, polarization independent $LiNbO_3$ has been demonstrated. This usually takes advantage of the anisotropic electro-optic tensor of $LiNbO_3$. One approach relies on TE/TM mode coupling via off-diagonal elements of the electro-optic tensor [58]. In another approach, a $\Delta\beta$ coupler is used [59]. There have been other novel approaches using crossing waveguides and specially designed directional couplers [60, 61]. Digital optical switches can also be used as polarization independent modulators [62]. Polarization independent modulators usually require special crystal cuts and electrode geometries. As a result, the electro-optic coefficient used is not the largest and the electrode is not suitable for high-speed operation. This makes the efficiency and speed of such devices low.

B4.7.3 III–V compound semiconductor electro-optic modulators

Electro-optic effect in III–V compound semiconductors

III–V compound semiconductors such as GaAs, InP and their alloys have excellent optical properties due to their direct and tunable bandgap and are materials of choice in many optoelectronic components such as lasers and detectors. They also lack inversion symmetry and possess an electro-optic coefficient. It is also possible to utilize other electro-optic effects described earlier if the wavelength of operation is close to the material bandgap. As a result they are also used in modulator applications. The most commonly used optical structure is a Mach–Zehnder interferometer. There are many different ways of making optical waveguides in III–V compound semiconductors. It is possible to adjust the index of refraction of these materials by controlling the composition of their alloys. For example increasing Al composition x in an $Al_xGa_{1-x}As$ compound semiconductor decreases its index of refraction. Furthermore, $Al_xGa_{1-x}As$ is lattice matched to GaAs for all x values. By growing such layers epitaxially using techniques such as molecular beam epitaxy (MBE) or metal organic chemical vapour deposition (MOCVD), it is possible to sandwich a higher-index material between two lower-index materials. This forms a slab waveguide and provides waveguiding in the vertical direction. The most common approach to provide lateral waveguiding is to etch a rib and form what is known as a rib waveguide. The effective index under the rib is higher than the effective index outside the rib in the etched regions. This provides a lateral index step and a two-dimensional waveguide is formed. There are many other ways to provide waveguiding which include proton implantation, buried heterostructures, pn junctions and disordering. However, rib waveguides are almost the universal choice since vertical and lateral index profiles and dimensions can be independently and precisely controlled. Typical rib widths are in the 2–4 μm range and rib heights are typically less than 1 μm.

III–V compound semiconductors have $\bar{4}3m$ or zinc blende crystal structure. When an external modulating field is applied, the index ellipsoid is perturbed and using equations (B4.34) and (B4.35) and figure B4.15 it can be expressed as

$$(x \quad y \quad z)\begin{bmatrix} \frac{1}{n^2} & r_{41}\mathscr{E}_z & r_{41}\mathscr{E}_y \\ r_{41}\mathscr{E}_z & \frac{1}{n^2} & r_{41}\mathscr{E}_x \\ r_{41}\mathscr{E}_y & r_{41}\mathscr{E}_x & \frac{1}{n^2} \end{bmatrix}\begin{pmatrix} x \\ y \\ z \end{pmatrix} = 1. \tag{B4.52}$$

The refractive index value for compound semiconductors is around 3.5 at 1.55 μm. This value can be adjusted over a wide range by changing the composition of the material. The electro-optic coefficient is given as $r_{41} = 1.4 \times 10^{-12}\,\mathrm{m\,V^{-1}}$ [63]. In this case, depending on the direction of the modulating electric field different possibilities exist. For example, if the modulating field is z directed, $\mathscr{E}_x = \mathscr{E}_y = 0$, and equation (B4.52) reduces to

$$(x \quad y \quad z)\begin{bmatrix} \frac{1}{n^2} & r_{41}\mathscr{E}_z & 0 \\ r_{41}\mathscr{E}_z & \frac{1}{n^2} & 0 \\ 0 & 0 & \frac{1}{n^2} \end{bmatrix}\begin{pmatrix} x \\ y \\ z \end{pmatrix} = 1 \tag{B4.53}$$

In this case, the index ellipsoid is no longer diagonal. It can be diagonalized using a simple coordinate transformation in the xy-plane as shown in figure B4.23. The new $x'y'$-axes are simply rotated 45° with respect to the xy-axes. In the new $x'y'z$ coordinate system index ellipsoid can be written as

$$(x' \quad y' \quad z)\begin{bmatrix} \frac{1}{n^2} - r_{41}\mathscr{E}_z & 0 & 0 \\ 0 & \frac{1}{n^2} + r_{41}\mathscr{E}_z & 0 \\ 0 & 0 & \frac{1}{n^2} \end{bmatrix}\begin{pmatrix} x' \\ y' \\ z \end{pmatrix}$$

$$= (x' \quad y' \quad z)\begin{bmatrix} \frac{1}{(n+\Delta n_{x'})^2} & 0 & 0 \\ 0 & \frac{1}{(n+\Delta n_{y'})^2} & 0 \\ 0 & 0 & \frac{1}{n^2} \end{bmatrix}\begin{pmatrix} x' \\ y' \\ z \end{pmatrix} = 1. \tag{B4.54}$$

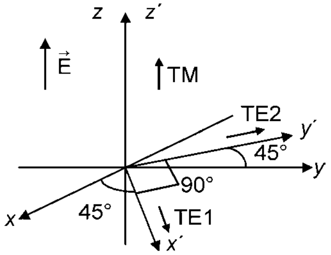

Figure B4.23. The axes of the index ellipsoid for an III–V compound semiconductor in the case of a z-directed external electric field. The dielectric tensor is diagonal in x, y, z and x', y', z' coordinate systems in the absence and the presence of the electric field, respectively. TE1, TE2, and TM show the direction of the main optical field of the two orthogonal TE and TM modes, respectively.

In this case, there is no index change for an optical wave polarized in the z-direction. The index of refraction for an optical wave polarized in the x'-direction and propagating in the y'-direction can be found using equation (B4.54) as

$$\frac{1}{(n+\Delta n_{x'})^2} = \frac{1}{n^2} - r_{41}\mathscr{E}_z \quad \text{or} \quad (n+\Delta n_{x'}) = \frac{n}{\sqrt{1-r_{41}n^2\mathscr{E}_z}}.$$

Since $r_{41}n^2\mathscr{E}_z \ll 1$, $(n+\Delta n_{x'}) \approx n\left(1+\frac{1}{2}r_{41}n^2\mathscr{E}_z\right)$, hence

$$\Delta n_{x'} = \frac{1}{2}r_{41}n^3\mathscr{E}_z. \tag{B4.55}$$

Similarly the index of refraction for an optical wave polarized in the y'-direction and propagating in the x'-direction can be found as

$$\Delta n_{y'} = -\frac{1}{2}r_{41}n^3\mathscr{E}_z. \tag{B4.56}$$

In practice, the z-axis is along the 001 crystal plane. Then the x'- and y'-axes are along 110 and $1\bar{1}0$ crystal axes. Therefore, in such material a vertically applied electric field in the 001 direction increases the index of refraction by $\Delta n_{x'}$ in the 110 direction and decreases it by $\Delta n_{y'}$ in the $1\bar{1}0$ direction. In other words, the index increases along one of the two mutually orthogonal directions parallel to the surface of the crystal. It decreases by the same amount in the other orthogonal direction. These directions correspond to the cleavage planes of the 001 oriented material. No index change is observed in the 001 direction, which implies that a vertically applied electric field to a 001 oriented crystal will only modulate the TE mode of the optical waveguide in which the main electric field component of the optical mode is either in 110 or $1\bar{1}0$ directions, in other words it is tangential to the surface. No modulation will result for the TM mode, which has its main electric field component in the 001 direction, i.e. normal to the surface of the crystal. The electro-optic coefficient in compound semiconductors is about 20 times less than that of $LiNbO_3$; however, the net index change for a given electric field is only about five times less due to the higher index of refraction of the semiconductor. It is possible to enhance this index modulation using other physical effects described earlier.

Lumped III–V compound semiconductor modulators

Electric fields that exist in the depletion regions of either pn junctions or Schottky barriers are used to modify the index of compound semiconductors. Figure B4.24 shows a phase modulator using the electric field in the reverse biased pn junction of a GaAs/AlGaAs bulk heterostructure.

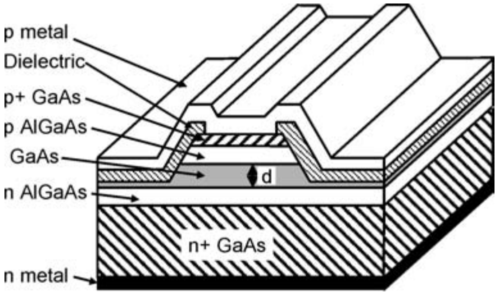

Figure B4.24. Schematic of a III–V compound semiconductor waveguide phase modulator.

The high-index GaAs layer of thickness *d* in between two lower-index AlGaAs layers provides vertical waveguiding. For lateral confinement etching the layers outside the rib of width *w* forms a rib waveguide. Ohmic contacts are formed to the top p^+ GaAs contact layer and to the backside of the n^+ substrate. A dielectric isolation layer, such as SiO_2, covers the sidewalls and the etched regions. By reverse biasing the pn junction a large electric field is generated in the depletion region. Typically the core of the waveguide, in this case the GaAs layer, is undoped. Hence, a fairly constant electric field is generated across the core of the waveguide. This electric field generates an index change through the electro-optic effects described earlier. These are the linear electro-optic effect, electrorefractive effect, plasma effect, and band filling effects. QWs in place of bulk material are also used to enhance the electrorefractive effect. We can express the resulting effective index change using equations (B4.29), (B4.42) and (B4.55) as

$$\Delta n_{\mathrm{eff}} = \left(\frac{1}{2} r_{41} n^3 \frac{v}{g} \Gamma + G(\lambda)\left(\frac{v}{g}\Gamma\right)^2\right). \tag{B4.57}$$

In equation (B4.57) it is assumed that the linear electro-optic and electrorefractive effects are the dominant effects. The basic phase modulator shown in figure B4.24 can easily be extended into an amplitude modulator using either a Mach–Zehnder or directional coupler design. The presence of doped layers may increase the optical insertion loss. One of the doped layers can be eliminated by replacing one side of the junction with a Schottky barrier. As a matter of fact totally undoped material can be used if Schottky barriers replace both doped layers. One such modulator was fabricated using substrate removal [64]. The top and cross sectional schematic of a substrate-removed modulator is shown in figure B4.25.

In this case an undoped GaAs/AlGaAs epilayer grown on a GaAs substrate is etched to form rib waveguides. An AlAs etch stop layer is also grown between the substrate and the epilayer. Then an Schottky barrier is formed on top of the rib. Next the entire wafer is glued onto a transfer substrate using a polymer bonding layer. In this case the polymer is benzocyclobutane (BCB). After this bonding the growth substrate is etched away. The substrate etch stops on the AlAs etch stop layer. Next the etch stop layer is also etched away. This exposes the backside of the epilayer. Another Schottky electrode is formed on the backside. Hence in between two electrodes on either side of the epilayer two back-to-back Schottky diodes are formed. A voltage applied to the electrodes reverse biases one of the Schottky diodes and the electric field formed in its depletion region generates index changes. The thin undoped

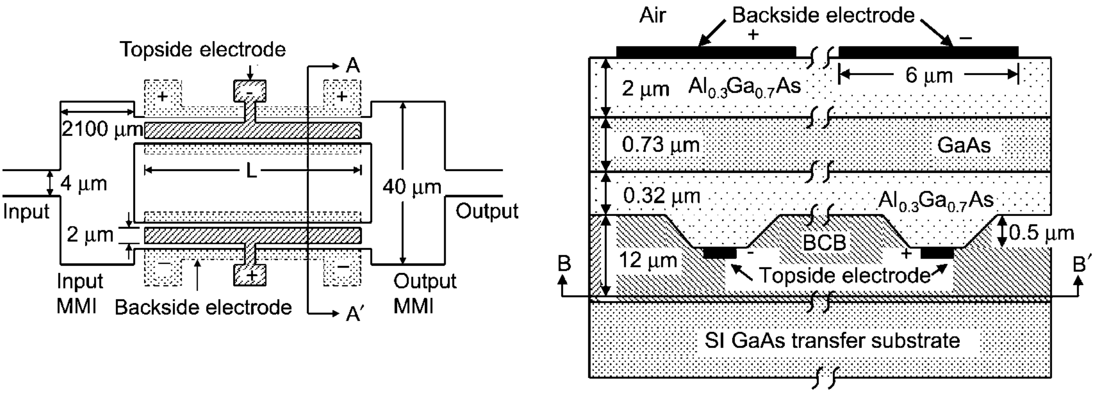

Figure B4.25. The top and cross sectional schematic of a substrate removed GaAs/AlGaAs electro-optic modulator. After [64] figures 1 and 2. Reproduced by permission of IEEE.

GaAs/AlGaAs layers self-deplete due to Fermi level pinning at the surfaces and behave effectively as a dielectric material with electro-optic properties. One big advantage of such a design is the ability to bias both arms of the interferometer independently. As a result true push–pull operation is possible. This creates a zero-chirp modulator. Using appropriate bias on both arms any amount of chirp can be obtained. The modulator reported in [64] had V_π of 8.7 and 17.8 V cm when driven push–pull or single arm, respectively.

Travelling wave III–V compound semiconductor modulators

For high-speed operation travelling wave designs are used. The index of the bulk compound semiconductors is isotropic. Furthermore, the refractive index variation between microwave and optical frequencies is rather small. The optical index of refraction is around 3.4 and the relative dielectric constant at microwave frequencies is about 13, which corresponds to an index of 3.6. Since it is a lot easier to form electrodes on the surface of the crystal the most commonly used electrode is either a CPW or a CPS structure. The optical signal is entirely confined in the semiconductor, which has a refractive index of about 3.4. On the other hand, the microwave and millimetre wave electric field fringes into the air and experiences an effective index between that of the air and semiconductor. For example, for a coplanar line of zero conductor thickness the effective dielectric constant is the arithmetic mean of the dielectric constants of the air and the semiconductor as indicated earlier in equation (B4.48). Therefore, the effective dielectric constant is around 7, which corresponds to a microwave index of about 2.65. Therefore, there is about 38% of index mismatch between the optical and microwave signals. This requires about 23% velocity reduction. Therefore, in III–V compound semiconductors velocity matching requires slowing down of the microwave signal. The most commonly used technique to slow the microwave signal is to use a slow wave transmission line [10, 65–67]. Such lines are obtained by periodically loading a uniform transmission line. The loading element is typically a capacitor. This can be achieved using either doped or undoped epitaxial layers.

Figure B4.26 shows the schematic of a travelling wave Mach–Zehnder modulator using doped layers [65]. The optical structure is a Mach–Zehnder interferometer utilizing multimode interference sections at the input and output for power splitting and combining. A GaAs/AlGaAs epitaxial layer is grown on a semi-insulating (SI) GaAs substrate. Underneath the GaAs core there is a buried n^+ layer which acts as a ground plane. The main electrode is a coplanar strip line. This electrode is periodically loaded by narrow and small capacitive elements. In [65], the capacitive elements used are the reverse biased capacitance of a Schottky–i–n junction as shown in figure B4.26. The advantage of this approach is to utilize the large vertical electric field existing in the reverse biased Schottky–i–n junction. This field overlaps very well with the optical mode enabling low drive voltages. Furthermore, these capacitive elements do not carry any of the axial currents in the transmission line. Hence increase in the microwave loss of the electrode due to loading is marginal.

Such devices with a total of 1 cm electrode length and loading segment lengths of 0.5, 0.6 and 0.7 mm were fabricated and characterized [65]. DC V_π values at 1.15 μm for 0.5, 0.6 and 0.7 mm segment-length electrodes were 5.7, 4.25 and 4.24 V, respectively. Corresponding bandwidths were >26.5, 25.0 and 22.5 GHz, respectively. Recently, such a device demonstrated an electrical 3 dB bandwidth of 50 GHz and V_π of 13 V at 1530 nm [66].

Another approach for GaAs travelling wave modulator design is to use unintentionally doped epitaxial layers [10, 68]. Such GaAs/AlGaAs layers self-deplete due to Fermi level pinning at the surface and the depletion originating at the semi-insulating substrate interface and behave very similarly to low-loss dielectric materials. As a result, optical and microwave losses become very low. The required velocity slowing can be achieved using a properly designed electrode. A schematic of such a device is shown in figure B4.27. The optical structure is a Mach–Zehnder interferometer. A (001) oriented

GaAs/AlGaAs heterostructure grown by MBE on semi-insulating GaAs provides vertical optical waveguiding. The lateral waveguiding is obtained by etching ridges down into the top AlGaAs layer. The microwave electrodes form Schottky contacts with the epitaxial layers. A voltage applied between the electrodes biases two back-to-back Schottky diodes. The conductivity of self-depleted epilayers is so low that, for frequencies larger than 1 MHz, the epilayers start to behave like slightly lossy dielectrics. Hence, the situation becomes identical to electrodes on an insulating dielectric. This makes it possible to

apply mainly (001) directed electric fields of opposite polarity on the optical guides as shown in figure B4.27. This generates phase shifts of opposite sign on both arms through the linear electro-optic effect, creating a net differential phase shift between the arms of the interferometer. Hence, push–pull modulation results. The device electrode is a modified coplanar line, in which T-rails stem from either side of the centre conductor and from the inner side of the both ground planes [69]. These T-rails form tiny capacitors, which periodically load the line, increase its capacitance per unit length, and, thus, slow the microwave signal propagating on the electrode. For this structure, axial transmission line currents cannot flow along these T-rails. Only displacement current flows in these tiny capacitors. Therefore, the distance between the centre conductor and the ground plane of the unloaded line determines current crowding and the microwave loss. One can make that gap large to keep microwave loss low [69]. On the other hand, the gap between the T-rails determines the field applied to the optical guides for a given voltage. In this design this gap can be reduced significantly with a very small increase in the microwave loss [69]. As a result the electrode gap has been decoupled from the electrode loss. The small-signal electrical bandwidth of this device at 1.55 μm is in excess of 40 GHz.

Polarization independent operation of III–V electro-optic modulators can be achieved either designing the material using an appropriate amount of strain, or using novel device ideas. Strain may provide equal electro-optic coefficients for TE and TM modes making the operation the same for two orthogonal polarizations. In bulk material it is possible to get TE/TM coupling for certain applied field orientations. In one approach polarization dependence was obtained using near degenerate TE and TM modes and controlling the coupling between them [70]. In this case electrodes were suitable for travelling wave operation [71] and such a device has potential for broadband polarization independent operation.

B4.7.4 Polymer modulators

Organic polymers have many attractive features for integrated optical applications [72]. It is possible to form multilayer polymer stacks by spin deposition and curing on a large variety of substrates or even on fabricated circuits [73]. They can be patterned using several different techniques such as photo-bleaching and reactive ion etching. They present good optical properties, such as low propagation loss and low index of refraction very close to that of the single-mode fibre. They also have low dielectric constant, which is important for high-speed devices. These properties resulted in passive low-loss polymer optical waveguides that can couple to single-mode optical fibres very efficiently [74, 75].

Polymers can also be made electro-optic and used in active devices. Certain molecules known as chromophores possess large ground state electric dipole moments and exhibit large optical nonlinearities. This microscopic nonlinearity can be converted to a macroscopic nonlinearity by mixing them with polymers and aligning their dipole moments. The most common method is to take a chromophoric polymer film and apply a strong electric field across it while keeping the film heated at a high temperature near its glass transition temperature. At such high temperatures randomly aligned individual chromophores are able to move in the polymer and align themselves with the externally applied electric field due to their dipole moments. After this alignment if the film is cooled to room temperature while applied electric field is present ordering of chromophores is achieved. This creates a macroscopic nonlinearity that can be used for electro-optic modulation. This process is known as high-temperature poling. Poling temperatures and fields depend on the particular film, but are typically about 100–200°C and 100–200 V μm^{-1}.

Most common techniques of poling a polymer film are either corona or electrode poling. In corona poling, corona discharge is used to create large poling fields over large areas. In electrode poling one approach is to spin coat the lower cladding and core on a ground electrode. Then poling electrodes are formed on top of the cladding. After poling these electrodes are removed and the upper cladding is spin coated. Alternatively, whole stack can be spin coated, followed by poling electrode formation, poling and removal of poling electrodes. The conductivity of upper and lower cladding regions of the polymer waveguide should be larger than the core of the waveguide for most of the poling voltage to drop across the electro-optic core and result in effective poling. Usually, the electro-optic coefficient increases linearly with poling field but so does the optical loss and birefringence.

After poling electro-optic activity is observed. For modulating fields applied in the poling field direction, two different electro-optic coefficients are observed depending on the polarization of the optical mode. The coefficient for TM polarization, i.e. when the optical field is polarized in the modulating field direction, is r_{33}. The coefficient for TE polarization, i.e. when the optical field is polarized perpendicular to the modulating field direction, is r_{13}. Typically for polymers r_{33} is about three times larger than r_{13}. At the present time, for most of the reported modulators, r_{33} values range between 1 and 20 pm V^{-1} although values as high as 67 pm V^{-1} have been reported [76]. The index change for an applied electric field is given by equation (B4.42). Polymer indices of refraction are around 1.6, which makes a polymer with $r_{33} \cong 12$ pm V^{-1} equivalent to bulk GaAs as far as index change is concerned. To take advantage of high r_{33}, modulating field should be applied in the poling field direction and the optical mode should be polarized in the same direction. For these considerations the most commonly used electrode is microstrip and the optical polarization is TM.

Figure B4.28 shows a travelling wave polymer modulator [79]. The optical structure is the Mach–Zehnder interferometer. The optical waveguides were fabricated by spin coating three layers of polymers that act as claddings and the core of the optical waveguide onto a high-resistivity Si wafer which was coated with a patterned gold plated film. Exposing the polymer film to a high-intensity light at the appropriate wavelength reduces the refractive index in the exposed areas, which is known as photo-bleaching. After poling, photo-bleaching was used to form channel optical waveguides. The thickness of the polymer stack was 6.5 μm. Tapered coplanar lines were used to couple in and out of the 12 mm long microstrip electrode. V_π of this modulator was 10 V. Low dielectric constant and low dielectric constant dispersion of polymers from microwave to optical frequencies offer an advantage in the design of travelling wave modulators. It is possible to get very good velocity matching using a microstrip electrode. For example, using a commonly quoted value of 1.6 for the optical index and 2.9 for the microwave relative dielectric constant and a 10 μm thick polymer stack, a 50 Ω microstrip line would have about 25 μm strip width and less than 5% velocity mismatch. In the case of the modulator shown in figure B4.28 index mismatch was estimated to be 0.03. The bandwidth is wider than 40 GHz. Other polymer modulators with

bandwidths wider than 40 GHz have been reported [77, 78]. Furthermore, polymer modulators operating in the W band (75–110 GHz) have been reported demonstrating intrinsic high-frequency response of electro-optic polymers [77, 78].

If corona poling or a single poling electrode is used, chromophores in both arms of the Mach–Zehnder are aligned in the same direction. This makes it difficult to make a push–pull modulator using a single microstrip electrode and usually only one arm of the interferometer is phase modulated [79, 80]. It is possible to use two electrodes driven 180° out of phase on both arms of the interferometer to get push–pull operation and halve the drive voltage. This requires broadband 3 dB microwave hybrid and makes only half the power available to each arm without considering the loss of the hybrid. Another way of obtaining push–pull operation is to pole the arms of the Mach–Zehnder in opposite directions as shown in Figure B4.29 [81]. In this case poling electrodes had to be closely spaced in order to form a 50 Ω microstrip line. The polymer stack is about 10 μm thick, which makes the required microstrip width about 30 μm, and implies that the separation between the arms of the interferometer should be less than that. Therefore, the poling electrodes should be less than 30 μm apart. Since voltages approaching 1000 V must be applied to create poling fields in the range of 100 V μm^{-1} across the 10 μm film, the air breakdown between closely spaced poling electrodes becomes an issue. In this case, this difficulty was addressed by using a fused silica piece on top of the poling electrodes to modify the field distribution in the gap and the sample was placed in an inert gas (SF_6) ambient to increase the breakdown field. Modulators with 2 cm long microstrip electrodes had V_π values of 40 and 20 V for one-arm and push–pull operation, respectively, at 1.3 μm [81]. This corresponds to an r_{33} value of about 7 pm V^{-1}. The typical loss of a pigtailed modulator was about 12 dB. Loss of 6 dB was attributed to the on-chip optical loss of the 3 cm long interferometer and the rest was due to mode mismatch between the fibre and the optical waveguide. The additional processing associated with poling electrode formation can be eliminated if device electrodes can be used as poling electrodes. By applying 180° out of phase pulsed voltages to the electrodes, it is possible to pole both arms of the interferometer sequentially [82]. In this way, the maximum voltage between the electrodes is reduced from $2V_p$ in the case of DC poling to V_p in the case of pulse poling, where V_p is the poling voltage applied across one arm of the interferometer. The field strength between the device electrodes during poling can be further reduced by increasing the separation between electrodes. One approach uses two parallel microstrip lines of 100 Ω characteristic impedance each [83]. This way it was possible to get a separation of 200 μm between the arms of the interferometer.

Chromophores used in electro-optic polymers have certain optical transitions in the wavelength range used in optical applications. For example, it is reported that Disperse Red 19 (DR19) chromophores have a peak absorption wavelength around 470 nm corresponding to $\pi-\pi^*$ transition [84]. Therefore any optical energy present around this wavelength excites the chromophore which loses its orientation when it relaxes. This results in photoinduced relaxation, which reduces the electro-optic coefficient, absorption and the optical index. This effect is shown to be polarization dependent due to large optical dipole moment associated with the chromophore. At wavelengths away from the absorption peak this effect decreases significantly. However, optical nonlinearity of the material results in second-harmonic generation, which in turn generates optical power within the absorption band even for near infrared excitations [85]. Typically, second-harmonic generation efficiency in commonly used optical waveguides is very low due to poor phase matching. Nevertheless, this places an upper limit on the maximum power handling capacity of the optical waveguide. For example, at 1320 nm for 10 mW in a 10 μm^2 cross section waveguide, device lifetime is estimated to be larger than 10^4 h for a 30% decay in the electro-optic efficiency [84]. On the other hand, lifetime at 1064 nm was estimated to be ~1 h due to the 532 nm second harmonic [84]. Recently double-end cross-linked polymers were found to be stable when exposed to 250 mW at 1.32 μm for 1 week [86]. They were also found to be thermally stable when baked at 100°C in air for more than 2000 h. r_{33} of these materials are quoted to be 6 pm V^{-1}.

Long-term bias stability is another very important concern. Polymer layers have finite conductivity which affects electrical response under DC and AC applied biases. This effect was studied using an equivalent network approach [57, 87, 88]. Every layer of the optical waveguide can be modelled as a parallel *RC* circuit. The resistance and capacitance of each layer depend on its conductivity, σ, and dielectric constant, ϵ, respectively. At low frequencies and low DC biases, the fraction of the applied voltage across the electro-optically active core layer depends on the relative conductivity of the layers. For low-bias operation, conductivity of the electro-optic layer is desired to be much smaller than other layers. This condition is also required for effective poling. However, it is shown that this would generate a bias drift that depends on the amplitude of the AC voltage swing. This could be a problem in practical operation requiring continuous bias point monitoring and adjustment. This effect has a ω^{-1} dependence and can be made zero by matching the relaxation constants (σ/ε) for all layers [87].

Today, the electro-optic polymer topic is a very intense research area. One direction is to improve material stability and electro-optic properties of polymers. Another direction seems to be the elimination of high-temperature electric field poling. This would enable room-temperature processing, but requires electro-optically active, or ordered, material to start with. This can be achieved by depositing the polymer film monolayer by using Langmuir–Blodgett films and relying on self-ordering of the chromophores in each monolayer.

B4.8 Summary

Optical modulators are key components for fibre optic networks. This chapter has described the basic modulator specifications; phase and different types of amplitude modulators, as well as physical effects used in modulators. In addition, examples from different competing modulator technologies are given. Of these electro-absorption modulators offer compact size, low drive voltage and high bandwidth. However, modulation characteristics depend critically on wavelength and temperature. Furthermore, material preparation requires critical layer thickness and composition control. Lumped EA modulator modules with electrical bandwidths approaching 60 GHz and drive voltages around 2 V for 20 dB extinction have been demonstrated at 1.55 μm. Their fibre-to-fibre insertion loss is around 10 dB and polarization independent operation has been achieved. Drive voltage and bandwidth can be improved further using the TW-EA modulator approach. $LiNbO_3$ has the most mature technology. $LiNbO_3$ travelling wave modulators are commonly used in industrial applications. They have higher drive voltages, which requires a modulator driver. Such modulators with electrical bandwidths as high as

75 GHz and V_π around 5 V have been demonstrated. Their fibre-to-fibre insertion loss is around 5 dB. Further V_π reduction is being pursued. III–V compound semiconductor electro-optic modulators offer excellent bandwidth at the expense of higher drive voltages and insertion loss. Electrical bandwidths up to 50 GHz have been realized. V_π values are around 15 V and fibre-to-fibre insertion loss is in the 10–15 dB range. Efforts to reduce the drive voltage and fibre-to-fibre insertion using novel processing techniques are under way. Polymers offer the promise of low-cost technology and presently are an active research area. High-speed capability of electro-optic polymers has been demonstrated. Polymer modulators with electrical bandwidths exceeding 40 GHz has been reported. V_π values are around 10 V and fibre-to-fibre insertion loss is about 10 dB. In all technologies drive voltage reduction while improving the speed of operation remains as a challenge.

B5
Optical amplifiers

Johan Nilsson, Jesper Lægsgaard and Anders Bjarklev

B5.1 Background

From the first demonstrations of optical communication systems, a primary drive in the research activity has been directed towards constant increase in system capacity. Over the past 25 years, it has been an alternating activity to overcome the fundamental fibre limitations of either attenuation or dispersion, and on the basis of the limiting term of the transmission link, systems have been denoted as either *loss limited* or *dispersion limited*. In the mid-1980s the international development had reached a state at which not only dispersion-shifted fibres were available but also spectrally pure signal sources emerged. The long-haul optical communication systems were, therefore, clearly loss limited and their problems had to be overcome by periodic regeneration of the optical signals at repeaters applying conversion to an intermediate electrical signal, which was a complex technology with lack of flexibility.

The technological challenge was to develop a practical way of obtaining the needed gain, that is, to develop relatively simple and flexible optical amplifiers, which would be superior to the electrical regenerators. Several means of doing this had been suggested in the 1960s and 1970s, including direct use of the transmission fibre as amplifying medium through nonlinear effects [1], semiconductor amplifiers with common technical basis in the components used for signal sources [2], or doping optical waveguides with an active material (rare-earth (RE) ions) that could provide the gain [3]. First, however, with the pronounced technological need for optical amplifiers and the spectacular results on erbium-doped fibre amplifiers (EDFAs) [4], an intense worldwide research activity on optical amplifiers was initiated. This resulted in the appearance of commercially available packaged EDFA modules in 1990.

EDFAs operate at signal wavelengths around 1550 nm, i.e. in the so-called third optical transmission window of silica fibres used in telecommunication systems. With the availability of efficient optical amplifiers in this wavelength region, which allowed for cost-effective transmission of optical signals (almost independent of modulation format and bit-rate), the development of multi-channel—wavelength-division-multiplexed (WDM)—systems became possible and a very rapid development of improved amplifier technologies has followed over the past 10 years. EDFAs have truly revolutionized optical telecommunications. By contrast, other optical amplification technologies such as Raman amplification, semiconductor amplifiers, planar amplifiers, and various RE-doped amplifiers for different wavelength regimes have yet to make a significant impact on deployed optical communication systems.

In this chapter, we will provide a short review of the general properties and limitations of optical amplifiers. Thereafter, the specific technologies available for the realization of optical amplifiers are reviewed, and their key parameters are compared. However, since the area of optical amplifiers is extremely broad, we do not attempt to cover all details of the latest development; rather, a selection of recent research and development results will be presented. This selection includes an overall discussion of amplification bands, cladding-pumped amplifiers for high-power amplification, recent results on high-concentration erbium doping in silica glass, and planar optical amplifiers in silica-on-silicon technology.

By and large, we restrict our discussion to amplifiers used in optical transmission systems. There are many other uses for optical amplifiers, in other types of system for other types of application. While all optical amplifiers used in optical transmission systems are waveguiding ones (fibre amplifiers in particular), there are also nonguiding ('bulk') amplifiers. These are primarily used for high-power amplification and amplification of high-energy pulses. Bulk amplifiers have many disadvantages compared to waveguiding ones, including a low gain efficiency and generally a low gain. Furthermore, in the case of a crystalline host, the bandwidth is narrow. Bulk amplifiers are not used in optical transmission systems and will not be discussed here. See, for example, reference [31] for further details.

B5.2 General amplifier concepts

In this section, we discuss some basic concepts common to all optical amplifiers. Due to the general nature of this first part of the chapter, this first part will follow the description given in [13].

Ideally, an optical amplifier would amplify the signal by adding, in phase, a well-defined number of photons to each incident photon. This means that a bit sequence (or analogue optical signal) simply would increase its electromagnetic field strength, but not change its shape by passage through the optical amplifier. Figure B5.1 shows the basics of optical amplification. In a perfect amplifier, this process would take place independent of the wavelength, state of polarization, intensity, (bit) sequence, and optical bandwidth of the incident light signal, and no interaction would take place between signals, if more than one signal were amplified simultaneously. In practice, however, the optical gain depends not only on the wavelength of the incident signal, but also on the electromagnetic field intensity, and thus the power, at any point inside the amplifier. Details of wavelength and intensity dependence of the optical gain depend on the amplifying medium.

An amplifying medium needs to be pumped. For example, a sufficient number of erbium ions must be excited so that a population inversion is reached, otherwise the erbium ions will attenuate rather than amplify the beam. All amplifiers described here need to be optically pumped, with the exception of semiconductor optical amplifiers. Laser diodes are the only acceptable pump sources for telecom applications, because of their efficiency, reliability, and small size. The development of suitable pump diodes has therefore been an integral part of the development of optical amplifiers. However, this will not be discussed here.

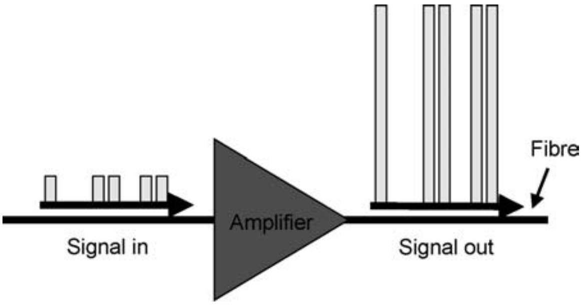

Figure B5.1. Optical amplification. In this case, the amplifier is fibre coupled, so that the input and output signals propagate in an optical fibre.

Next, some general concepts of practical optical amplifiers will be outlined. First, we consider a case in which the amplifying medium is modelled as a homogeneously broadened two-level system. In such a medium, the gain coefficient (i.e. the gain per unit length) can be written as [5]:

$$g(\omega) = \frac{g_0}{1 + (\omega - \omega_0)^2 T_2^2 + P_s/P_{sat}}. \tag{B5.1}$$

Here g_0 is the peak value of the gain coefficient determined by the pumping level of the amplifier, and ω is the optical angular frequency of the incident signal, related to its vacuum wavelength λ by $\omega = 2\pi c/\lambda$. Furthermore, ω_0 is the atomic transition angular frequency. P_s is the optical power of the signal and P_{sat} is the saturation power, which depends on amplifying medium parameters such as fluorescence lifetime and the transition cross section at the signal frequency. The parameter T_2 in equation (B5.1) is normally denoted as the dipole relaxation time [5].

Two important amplifier characteristics are described in equation (B5.1): First, if the signal power ratio obeys $P_s/P_{sat} \ll 1$ throughout the amplifier, the amplifier is said to be operated in the unsaturated region. The gain coefficient is then maximal when the incident angular frequency ω coincides with the atomic transition angular frequency ω_0. The gain reduction for angular frequencies different from ω_0 is generally given by a more complex function than the Lorentzian profile, but this simple example allows us to define the general property of the gain bandwidth. This is normally defined as the full width at half maximum (FWHM) value of the gain coefficient spectrum $g(\omega)$. For the Lorentzian spectrum, the gain bandwidth is given by $\Delta\omega_g = 2/T_2$ (figure B5.2).

From a communication system point of view, it is more natural to use the related concept of amplifier bandwidth (often determined by the 3 dB points) instead of the gain bandwidth, which is related to a point within the amplifying medium. The difference becomes clear, when we consider the linear gain of the amplifier G defined as

$$G = \frac{P_s^{out}}{P_s^{in}} \tag{B5.2}$$

where P_s^{in} is the input power and P_s^{out} is the output power of a continuous wave (cw) signal being amplified. The amplifier gain G may be found by using the relation

$$\frac{dP}{dz} = gP \tag{B5.3}$$

where $P(z)$ is the optical power at a distance z from the amplifier input end. If the gain coefficient $g(\omega)$, for simplicity, is considered constant along the amplifier length, the solution of equation (B5.3)

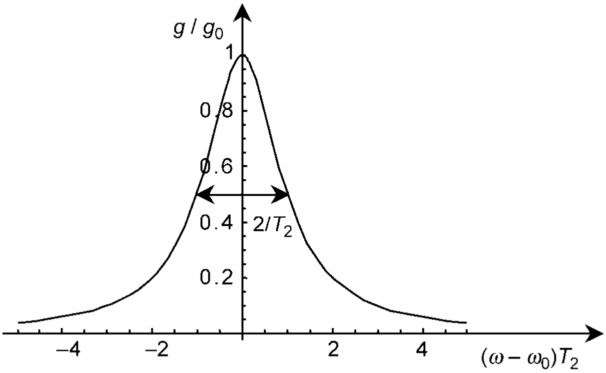

Figure B5.2. Lorentzian gain profile with bandwidth $\Delta\omega_g = 2/T_2$ (FWHM, full width at half maximum). The unsaturated gain is shown, with $P_s \ll P_{sat}$.

is an exponentially growing signal power $P(z) = P_s^{in}\ \exp(gz)$. For an amplifier length L, we then find that

$$G(\omega) = \exp[g(\omega)L]. \tag{B5.4}$$

Equation (B5.4) illustrates the frequency dependence of the amplifier gain G, and shows that $G(\omega)$ decreases much faster than $g(\omega)$ with the signal detuning $(\omega - \omega_0)$, because of the exponential dependence of G on g. Having said that, in many cases the gain spectrum is tophat-like (e.g. supergaussian) rather than Lorentzian, and then, the difference between gain bandwidth and amplifier bandwidth, which is smaller, is reduced. The limited amplifier bandwidth results in signal distortion in the cases where a broadband optical signal is transmitted through the amplifier. In practical optical transmission systems, a very important consequence of a restricted bandwidth relates to WDM signal amplification: different signals at different wavelengths are amplified by different amounts if the amplifier bandwidth is too narrow. The deviation from a flat gain is referred to as gain ripple. The problem of gain ripple is exacerbated in a long-distance transmission system employing many cascaded amplifiers. Any systematic differences in amplification of the different channels then add up, leading to high requirements on gain flatness. To meet this requirement many amplifiers incorporate gain-flattening filters that equalize the gain over a range of wavelengths [38]. While most gain-flattening filters are static, dynamic ones have been developed for demanding applications. In any case, the bandwidth of optical amplifiers is extremely large and one of their principal attractions, maybe around 1 THz even in the simplest amplifier and exceeding 10 THz in state-of-the art, gain-flattened, ones.

Another limitation of the nonideal amplifier is expressed in the power dependence of the gain coefficient. This property, which is known as gain saturation, is included in the example of equation (B5.1), and it appears in all cases where the term P_s/P_{sat} is non-negligible. Since the gain coefficient is reduced when the signal power P_s becomes comparable to the saturation power P_{sat}, the amplification factor (or amplifier gain) G will also decrease. This limits an amplifier's maximum signal output power, known as the saturated output power. Gain saturation might be seen as a serious limitation for multi-wavelength optical communication systems. However, gain-saturated amplifiers have practical use because of their self-regulating effect on the signal output power in links of many concatenated amplifiers. Furthermore, the saturated output power of modern EDFAs is high enough not to be a practical limitation.

Besides the bandwidth and gain saturation limitations of practical optical amplifiers, there is another important limitation in practical amplified systems. Optical amplifiers, in general, will add spontaneously emitted or scattered photons to the signal during the amplification process, and this will consequently lead to a degradation of the signal-to-noise ratio (SNR). The SNR degradation is quantified through a parameter F, normally denoted as the amplifier noise figure, which is defined as the SNR ratio between input and output [6]:

$$F = \frac{\mathrm{SNR_{in}}}{\mathrm{SNR_{out}}}. \tag{B5.5}$$

It should be noted that it is common practice to refer the SNR to the electrical power generated when the optical signal is converted to electrical current by using a photodetector. The noise figure as defined in equation (B5.5), therefore, in general, would depend on several detector parameters, which determine the shot noise and thermal noise associated with the practical detector. However, the influence of detector parameters will not help us to clarify the amplifier noise properties, and it is, consequently, advantageous to consider an ideal detector, whose performance is limited by shot noise only [6].

In practice, the spontaneous emission is reduced by optical filtering of the received signal, by rejecting light at frequencies away from the signal. Therefore, the SNR generally also will be dependent on the bandwidth of the optical filters and the spectral power distribution of the spontaneous emission from the amplifier. However, since this filtering is a process independent of the amplifier properties, it is also common practice to eliminate this ambiguity by considering an ideal filter [5]. Such an ideal filter is introduced only to allow the signal and the spontaneous emission within the signal bandwidth to pass to the detector. Therefore, it will only be the spontaneous emission spectral power density at the signal wavelength that enters the ideal detector, and the noise figure becomes independent of the spectral shape of the spontaneous emission. Note that since the amplifier deteriorates the SNR, that is, $\mathrm{SNR}_{\mathrm{in}} > \mathrm{SNR}_{\mathrm{out}}$, the noise figure will always obey the relation $F > 1$. In fact, conventional, so-called phase-insensitive, amplifiers like the EDFA always have a noise figure of at least 2 (i.e. 3 dB) in the limit of high gain. This is known as the quantum limit. We emphasize that the common interpretation that the output SNR is always at least 3 dB worse than the input SNR is only correct for high-gain amplifiers when the input SNR is shot-noise limited. Though the coherent state emitted from an ideal laser is shot-noise limited, far from all input signals fulfil this. In particular, it is not true for an input signal that has already been amplified.

The noise contribution of an amplifier can also be understood as arising from a fundamentally stochastic nature of the amplification process (stimulated emission). Absorption can also occur in an amplifier, again in a fundamentally stochastic manner that adds to the noise. In order to minimize the noise contribution of an amplifier, one should maximize the stimulated emission to absorption ratio—preferably there should be no absorption at all.

Though the SNR at the output of the amplifier is degraded, the high power of the amplified signal means that additional noise added further down the transmission line will have less impact. Thus, the amplifier improves the SNR of the transmission line as a whole.

A phase-insensitive amplifier operates independently of the optical phase of the signal. In contrast, its counterpart, the phase-sensitive amplifier, provides amplification that does depend on the phase of the signal. A phase-sensitive amplifier does not necessarily degrade the SNR (i.e. it can have a noise figure of unity) [12]. Phase-sensitive amplifiers are used for squeezed-state amplification in research applications, but are not in common use because of practical difficulties.

For a practical communication system, the amplifier spontaneous emission may have another influence besides that described through the noise figure (i.e. besides the effect that it adds fluctuations to the amplified optical signal power, which are converted to current fluctuations during the photo-detection process). This additional influence is that the spontaneous emission, which is emitted from the amplifier input end, may enter the signal source (a semiconductor laser), where it can result in performance disturbances. Therefore, it is often necessary to include isolation between amplifier and light source to avoid additional noise in the system. Therefore, it must be considered that the optical communication system has to be protected against undesired emission from the amplifier. These may also transmit residual pump power onto the transmitter and/or detector. The actual effect of this will be strongly dependent on the spectral properties of the pump light and whether the signal source or detector is sensitive to such radiation.

Another property that has to be evaluated for the optical amplifier is the polarization sensitivity. A high polarization sensitivity means that the amplifier gain G differs for different polarization states of the input signal. Since optical communication systems normally do not include polarization control, and because the polarization state is likely to vary due to external factors such as mechanical pressure, acoustic waves, and temperature variations, the amplifier polarization sensitivity is an undesired property in most cases. Therefore, for amplifiers that are inherently polarization sensitive, it has been a primary goal to reduce or even eliminate the amplifier output power variation due to changes in the signal input polarization state. Fortunately, the dominating EDFA has a negligible intrinsic polarization dependence of the gain.

All of the limiting properties which we have previously discussed are not surprisingly distinctly different for different types of amplifier. This is also the case for the crosstalk limitation that relates to multi-channel applications of optical amplifiers. In contrast to the ideal case, where all signal channels (or wavelengths) are amplified by the same amount, undesired nonlinear phenomena may introduce inter-channel crosstalk (i.e. the modulation of one channel is affected or modified by the presence of another signal channel). We will return to the more specific nature of these nonlinear phenomena in connection with the discussion of the different optical amplifiers.

Other factors such as polarization mode dispersion, multi-path interference, and nonlinearities may also degrade an amplifier.

The final limiting factors that should be mentioned here are closely related to the physical environment in which the amplifier is placed. These may include sensitivity toward vibrations, radioactive radiation, chemicals, pressure, and temperature. However, since at least amplifiers for optical communication systems generally are placed in controlled environments, we will not go further into a detailed discussion of such properties.

The relative importance of the different limiting factors as just discussed depends on the actual amplifier application. One application is the replacement of electronic regenerators; in such cases the amplifiers are placed at a considerable distance from the transmitter and receiver and they are denoted as in-line amplifiers (figure B5.3(*a*)). The optical amplifier may also be used to increase the transmitter power by placing an amplifier just after the transmitter (figure B5.3(*b*)). Such amplifiers are called power amplifiers, or boosters, because their main purpose is to boost the transmitted power. Long-distance systems may also be improved by the inclusion of the so-called preamplifiers, which are placed just before the receiver (figure B5.3(*b*)). Effectively, they improve the sensitivity of the receiver, so that lower-power signals can be detected, thus increasing the distance over which a signal can be transmitted. Furthermore, optical amplifiers can be used in local area networks in which they can compensate for distribution losses (figure B5.3(*c*)). Thereby, the number of nodes in the networks may be increased. Amplifiers can also compensate for the loss of various components, thus enabling the use of lossy optical components such as optical add–drop multiplexers and switches (figure B5.3(*d*)).

It is interesting to note that the most important parameter of an amplifier, its gain, is not a limiting factor, at least not for EDFAs in optical communication systems. They can easily reach a gain of 10 000 (40 dB). However, because of noise limits and nonlinear limits in the transmission system, there is no need for such high gain in a well-designed system. Thus, EDFAs can be designed to reach the gain required in an optically amplified system relatively easily.

B5.3 Different classes of optical amplifiers

The most important factors that limit the performance of practical optical amplifiers have now been identified. The next task is to investigate the technologies available for obtaining real-world amplifiers. Basically, six different ways of obtaining optical amplification are considered: fibre-Raman and fibre-Brillouin amplifiers, semiconductor optical amplifiers (SOAs), RE-doped fibre amplifiers, RE-doped waveguide amplifiers, and optical parametric amplifiers (OPAs). The aim of the following description is to present the basic physical properties of these amplifiers. The properties of the different amplifiers are summarized in table B5.1.

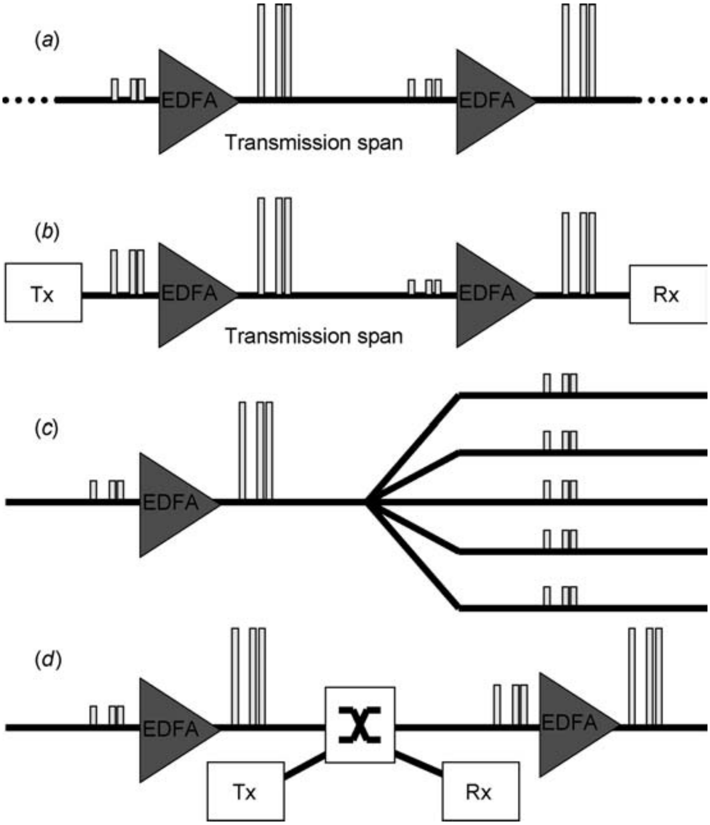

Figure B5.3. Amplification of optical signals with erbium-doped fibre amplifiers (EDFAs) in various optical transmission fibres. (*a*) In-line amplifiers are used periodically in a link comprising several fibre spans. (*b*) A booster amplifier is used after a transmitter (Tx) and a pre-amplifier is used before a receiver (Rx) in a simple repeaterless link. (*c*) A signal is amplified before being split up in a distribution network. (*d*) Amplifiers enable the use of optical add–drop multiplexers and other lossy optical components. Similarly, signals can be amplified in high-power EDFAs to the point where nonlinear optical effects can be utilized, e.g. for all-optical regeneration.

B5.3.1 Fibre-Raman amplifiers

Raman amplification is currently a very active field of research. The fibre-Raman amplifier works through the nonlinear process of stimulated Raman scattering (SRS) occurring in the fibre itself. Like most optical amplifiers, a fibre Raman amplifier must be optically pumped, preferably by a semiconductor laser diode (LD) or a fibre laser. As early as 1962, it was observed that for very intense pump waves a new phenomenon of SRS can occur in which the Stokes wave grows rapidly inside the medium such that most of the pump energy appears in it. SRS is an interaction between light and the vibrational modes of silica molecules that converts a fraction of the incident power from one optical beam (the pump) to another optical beam (the signal, or Stokes wave) at a frequency down-shifted by an amount determined by the vibrational modes (phonon energy) of the medium. A phonon is a quantized vibration of the surrounding medium. SRS involves the so-called optical phonons. Optical phonons of a given energy exist with a broad range of momenta, so that momentum conservation (phase matching) is guaranteed. As a consequence, Stokes waves are generated both co-propagating and counter-propagating with the incident beam. See, e.g. reference [1] for a discussion of SRS.

Table B5.1. Characteristics of optical amplifiers for telecom applications, with an emphasis on commercially available amplifiers.

	EDFA	EDWA	Other RE-doped amplifiers	Fibre Raman	Semiconductor	Fibre OPA	Fibre Brillouin	Comment
Amplifying medium	Er-doped fibre	Er-doped planar waveguide	Rare-earth doped fibre or waveguide	Any fibre; lumped Raman amplifier should use optimized fibre; distributed Raman amplification uses transmission fibre	Semiconductor, e.g. InGaAsP for 1550 nm operation	Dispersion-shifted fibre (zero-dispersion wavelength must coincide with pump wavelength)	Any fibre	
Status, deployment	Widely deployed in commercial systems	Commercially available but not deployed	Some amplifiers commercially available (e.g. Tm and Pr-doped fluoride fibre amplifiers); not deployed	Lumped Raman amplifiers not deployed; small-scale deployment of distributed Raman amplification	Commercially available but not deployed	Not commercially available or deployed; not active R&D area	Not commercially available or deployed; not active R&D area	
Pumping	Optical, at 980 or 1480 nm; typical pump power a few hundred milliwatts	Optical, at 980 or 1480 nm; typical pump power a few hundred milliwatts	Optical; typical pump power a few hundred milliwatts	Optical, e.g. at ~ 1450 nm for amplification at 1550 nm; typical pump power 1 W	Electrical; typical pump current a few hundred milliamperes	Optical, at wavelength near signal wavelength; typical pump power > 1 W	Optical, ~10 GHz above signal frequency	
Gain	20–30 dB typical, 40 dB readily obtainable	20 dB (typical)	20 dB (typical)	15–20 dB optimum for distributed Raman amplification	10–30 dB (typical)	40 dB obtainable; uni-directional if pump is uni-directional	Sufficient; uni-directional if pump is uni-directional	30 dB sufficient for telecom applications; even 10–20 dB is sufficient in many cases

Noise performance	Good (e.g. 4 dB noise figure)	Reasonable (noise figure typically 5–7 dB)	Varying (good in many cases)	Reasonable for lumped RFAs; excellent for distributed Raman amplification	Reasonable (6–10 dB noise figure typical)	Good	Poor	For nonfibre amplifiers, fibre coupling loss degrades the noise figure
Maximum output power	From 10 dBm up to 23–27 dBm in high-power EDFAs, limited by pump power (50 dBm has been demonstrated [63])	Typically 10–15 dBm	Varying	25 dBm (typical)	8–17 dBm (typical)	Typically up to 30 dBm	Depends on pump power	Generally maximum output power depends on pump power, which is high for Raman and parametric amplifiers
Operating wavelengths	1480–1620 nm (C-band 1528–1562 nm, L-band 1570–1620 nm, S-band 1480–1520 nm)	1530–1560 nm	Tm, 1450–1520 nm (S-band); Pr, 1300 nm (2nd telecommunications window); Nd, 1300 nm	Any wavelength, determined by pump wavelength and fibre composition	Any wavelength (determined by bandgap of given material and structure); 1200–1650 nm demonstrated	Any wavelength (near zero-dispersion wavelength of fibre)	Any wavelength, determined by pump wavelength and fibre composition	
Bandwidth	1–10 THz (single band) 8–18 THz (split band)	1–4 THz	1–2 THz	~ 3 THz with single-wavelength pumping, up to ~ 10 THz with broadband pumping; 20 THz possible with tellurite fibres	Up to ~ 10 THz	Typically 1–2 THz (25 THz with pulsed pumping)	Intrinsically below 0.1 GHz	
Polarization dependence of gain	Negligible	Small with appropriate waveguide design	Negligible in fibres (small in appropriately designed planar waveguides)	Small with polarization multiplexed or scrambled pump, otherwise high	Small with appropriate waveguide design (e.g. 0.5 dB)	Intrinsically high, but smaller with a polarization multiplexed or scrambled pump	Small with polarization multiplexed or scrambled pump, otherwise high	

(*continued*)

Table B5.1. (Continued)

	EDFA	EDWA	Other RE-doped amplifiers	Fibre Raman	Semiconductor	Fibre OPA	Fibre Brillouin	Comment
Gain response time	0.1–1 ms	~1 ms	Varying, 0.1 ms typical	Instantaneous	Sub-nanosecond	Instantaneous	Nanosecond	Depends on gain medium, waveguide design, and operating conditions
Extractable energy stored in gain medium	Large	Large	Large	None	Small	None	None	The small energy stored in SOAs and their short response time leads to signal distortion in saturation
Transient behaviour	Transients potentially severe because saturated gain, often suppressed with electronic pump power control	Gain often not saturated, in which case transients are small	Varying	Gain normally not saturated, transients therefore small	OK in special designs (gain-clamped, 'linear', amplifiers)	Gain normally not saturated, transients therefore small		
Gain efficiency	High (a few dB mW^{-1} in C-band)	Reasonable	Varying	Low (up to $\sim 50\,\mathrm{dB\,W}^{-1}$ for distributed Raman amplification in standard single-mode fibre)	High	Low	High	Gain efficiency less important for high-power devices
Power conversion efficiency	Good	Often poor	Varying	Good	Good	Good	Good	Important for high-power devices

In an amplifier context, if the signal angular frequency ω_s and pump angular frequency ω_p are chosen with a difference $\Omega_R = \omega_p - \omega_s$ (the Stokes shift) corresponding to the vibrational energy of the molecules, the signal may experience Raman gain via SRS. Thus, with a proper choice of pump wavelength, Raman amplification is possible at any signal wavelength (e.g. 1300 nm, 1550 nm, ...), limited only by the transparency of the material. Since phase-matching is automatically fulfilled, Raman gain is independent of the pump direction. Another significant feature of the Raman gain in silica fibres is that it extends over a large frequency range (up to 40 THz) with a broad dominant peak near 13 THz with a typical FWHM width of 6 THz (figure B5.4). This is due to the amorphous nature of fused silica in which the molecular vibrational frequencies spread out into bands overlapping each other and creating a continuum (depending on the fibre core composition). The bandwidth of a Raman amplifier would normally be narrower than the intrinsic Raman gain, but it can be extended by using multiple pumps at different wavelengths. Each pump creates Raman gain with a peak down-shifted by ~13 THz. With an appropriate choice of pump wavelengths, the Raman gain spectra of the individual pumps will overlap. Thus, the combined amplification spectrum can be significantly broader, with a low ripple. This is shown in figure B5.5. Thus, Raman amplification bandwidths exceeding 10 THz can be obtained in silica fibres, and with careful optimization, the gain ripple can be below 0.5 dB [54]. In this kind of system there is significant stimulated Raman scattering between the pumps, that redistributes the pump power and therefore needs to be taken into account [57]. However, the pump beams can be time multiplexed in order to suppress the interaction [56]. Also SRS between signals at different wavelengths is a concern in high-power, broadband systems. For bandwidths beyond ~10 THz, the signal and pump beams would have to overlap spectrally with silica fibres. This leads to severe signal degradation, and is why the bandwidth of silica fibre Raman amplifiers is limited to ~10 THz, even though amplification can be obtained at any wavelength with the right pump.

The large bandwidth of fibre Raman amplifiers and a very large saturation power (typically 0.1–1 W) makes them attractive for optical communication systems. Also their noise properties are good, with a noise figure close to 3 dB being obtainable. While stimulated Raman scattering leads to gain, the pump beam will also cause spontaneous Raman scattering. The scattered light is Stokes shifted by the Raman frequency shift, so it will overlap spectrally with the signal. Since spontaneous Raman scattering is a stochastic process, it effectively adds noise to the signal, though the noise addition can be close to the 3 dB quantum limit.

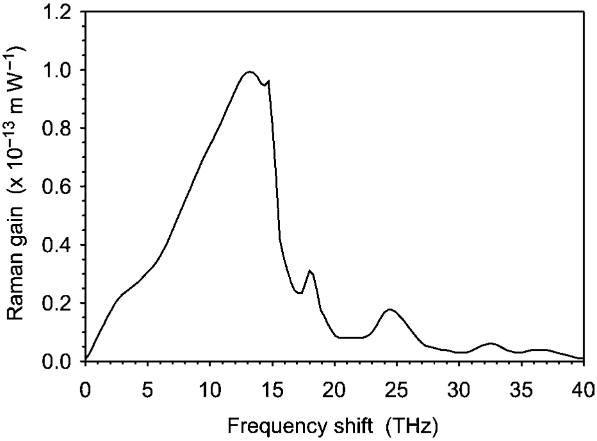

Figure B5.4. Raman gain in fused silica for parallel polarizations, with a pump wavelength of 1064 nm. The Raman gain coefficient scales approximately inversely with the pump wavelength. After [65].

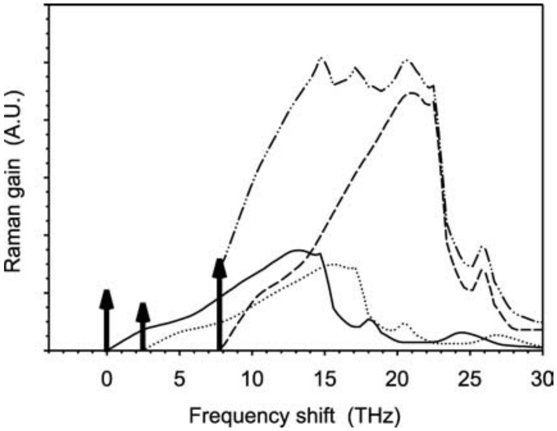

Figure B5.5. Schematic illustration of how several pumps (three in this case) at different wavelengths combine to create a broadened Raman gain.

SRS requires long fibres and high pump powers because it is a weak process. Starting with the Raman gain coefficient shown in figure B5.4, the actual Raman gain can be obtained by dividing the gain coefficient by the effective area (e.g. 50 μm^2) and multiplying it by the effective fibre length (up to ~20 km). Despite the weakness of SRS, with the present development of powerful solid-state pump lasers, sufficient power levels are obtainable from fibre lasers as well as directly from laser diodes. A pump power of 1 W can be enough to generate a gain of up to 50 dB in standard single-mode fibre. For amplification at 1550 nm, a pump wavelength of ~1450 nm is preferable, and suitable laser diodes have been developed at that wavelength. In addition, since SRS will be more efficient if the pump and signal beams are more tightly focused, efficient Raman amplification is possible in fibres shorter than 10 km with optimized designs. In highly nonlinear fibres such as small-core holey fibres, device lengths can be of the order of 100 m.

The weak nature of SRS is actually an advantage for distributed Raman amplification: since Raman gain takes place directly in a silica fibre, it can also occur in the transmission fibre itself. Thus, it is possible to turn the transmission fibre itself into an amplifier, and with an appropriate pump source, it is possible to distribute the gain over several tens of kilometres of transmission fibre. That way amplification can be realized many kilometres away from the pump injection point (often at the receiver end of a transmission link). This leads to a better SNR, since the signal starts to be amplified before it has experienced the full loss of the transmission link (in the absence of Raman gain). Most of the recent record-breaking transmission experiments have indeed utilized distributed Raman amplification in the transmission line [58].

Raman amplification is limited by Rayleigh scattering. At too high gain multiple Rayleigh scattering leads to multi-path interference, which degrades the signal. Optimum distributed Raman on–off gain is in the range 15–20 dB.

Polarization is another concern for Raman amplification. The gain in a polarization orthogonal to the pump polarization is only a few percent of the gain for parallel polarization [53,66,67]. Thus, the polarization properties must also be taken into account when evaluating the Raman gain in a fibre [67]. Because polarization control is not normally employed in optical communication systems, this property introduces an additional complexity. In practice, the polarization dependence can be mitigated with pump polarization scrambling or multiplexing.

The numbers quoted so far refer to silica and germanosilicate fibres. Recently, however, Raman amplifiers have been demonstrated in tellurite fibres. Tellurite is a nonsilica glass with a significantly broader bandwidth. An amplification bandwidth of 20 THz, from 1490 to 1650 nm, has so far been demonstrated, which is a record for a single-band cw amplifier [52].

B5.3.2 Brillouin amplifiers

Because of severe limitations such as narrow linewidth, Brillouin fibre amplifiers are not practical and will not be treated henceforth. See, e.g. reference [1] for details on Brillouin amplifiers.

B5.3.3 Semiconductor optical amplifiers

The SOA is fabricated in a material and structure very different from the silica transmission fibre. It incorporates a waveguide within a semiconductor gain medium. For 1550 nm amplification, InGaAsP SOAs are often used. The major attraction of SOAs is the potential for low cost and the direct electrical pumping.

Since an SOA is not a fibre device, the coupling of light from fibre to SOA and vice versa is difficult. There are inevitably significant coupling losses which degrade the noise figure. Furthermore, intrinsically, the SOA itself also will experience relatively large feedback due to reflections occurring at the cleaved end facets (32% reflectivity due to refractive index differences between semiconductor and air), resulting in sharp and highly disadvantageous gain reduction between the cavity resonances of the Fabry–Perot resonator. Therefore, it is generally necessary to design travelling wave (TW) type SOAs by suppressing the reflections from the end facets; a common solution is the inclusion of antireflection coating of the end facets. It turns out that to avoid the amplifier bandwidth being determined by the cavity resonances rather than the gain spectrum itself, it becomes necessary to require that the facet reflectivities satisfy the condition [5]:

$$G\sqrt{R_1R_2} < 0.17. \tag{B5.6}$$

Here, G is the single-pass amplification factor, and R_1 and R_2 are the power reflection coefficients at the input and output facets, respectively. For an SOA designed to provide a 30 dB gain, this condition will mean that $\sqrt{R_1R_2} < 0.17 \times 10^{-3}$, which is difficult to obtain in a predictable and reproducible manner by antireflection coating alone. Additional methods to reduce the reflection feedback include designs in which the active-region stripe is tilted from the facet normal and introduction of a transparent window region (nonguiding) between the active-layer ends and the antireflection coated facets. Thereby, reflectivities as small as 10^{-4} may be provided, so that the SOA bandwidth can be determined by the amplifying medium rather than by the narrower resonance peaks of the cavity. Typically, 3 dB amplifier bandwidths of 60–80 nm may be obtained. Another attractive spectroscopic property of SOAs is that, with appropriate composition and design, gain can be realized over a very wide range of wavelengths from 1200 to 1650 nm (though limited to, say, 80 nm in a given device with a specific bandgap).

The gain in an SOA depends on the carrier population, which changes with the signal power and the injection current. To reiterate, the SOA is pumped electrically. By contrast, alternative optical amplifiers are optically pumped. Typical pump currents are a few hundred milliamperes. An important property is the very short effective lifetime of the injected carriers (e.g. of the order of 100 ps). This property becomes specifically relevant for multi-channel applications of SOAs, where crosstalk limitations arise. This crosstalk originates from two nonlinear phenomena: cross-saturation and four-wave mixing. The former appears because the signal in one channel through stimulated recombinations affects the carrier population and, thereby, the gain of other channels. This significant problem may only be reduced by operating the amplifier well below saturation, but this is not an easy task due to the relatively limited saturation output power of the order of 10 mW. Four-wave mixing also appears because stimulated recombinations affect the carrier number. More specifically, the carrier population may be found to oscillate at the beat frequencies between the different channels, whereby both gain and refractive index are modulated. The multi-channel signal, therefore, creates gain and index gratings, which will introduce inter-channel crosstalk by scattering a part of the signal from one channel to another.

Despite these difficulties, the so-called gain-clamped (‘linear’) SOAs for multi-wavelength amplification have been realized [36, 37]. Because of their linear (power-independent) characteristics, channel cross talk and four-wave mixing can be avoided. For instance, a linear SOA with 10 dBm output power, up to 25 dB gain, and 8 dB noise figure is offered commercially by Genoa [32].

As with other types of optical amplifier, the stimulated emission is accompanied by spontaneous emission, which leads to noise. The noise properties of the SOA are determined by two factors. One is the emission due to spontaneous decays and the other is the result of nonresonant internal losses α_{int} (e.g. free carrier absorption or scattering loss), which reduce the available gain from g to $(g - \alpha_{\mathrm{int}})$. The nonzero absorption then increases the noise figure. Also residual facet reflectivities increase the noise figure, via loss of signal input power and via multi-path interference. Typical values of the noise figure for SOAs are 6–10 dB.

Another undesirable characteristic of early SOAs is the polarization sensitivity, which appears because the amplifier gain differs for the transverse-electric (TE) and transverse-magnetic (TM) modes in the semiconductor waveguide structure. However, intense research in the early 1990s has reduced the problem, and SOAs with polarization sensitivity reduced to less than 0.5 dB have been reported [7]. Other methods of using serial or parallel coupled amplifiers or two passes through the same amplifier are also suggested. Although such schemes increase complexity, cost, and stability requirements, they may add attractive properties applicable in optical signal processing (e.g. in optical wavelength conversion [7]).

To conclude the discussion of the SOA, it is important to note that the major drawbacks are polarization sensitivity, interchannel crosstalk, and large coupling losses. These drawbacks have been overcome to some extent, but the resulting performance is still significantly worse than that of EDFAs. Therefore, the impact of SOAs on real systems has been small so far. In favour of the SOA are the large amplifier bandwidth, the possibility of amplification at any wavelength in the range 1200–1650 nm (at present), and the possibility of monolithic optoelectronic integration, especially within the receiver, where the input signal powers are weak enough to avoid undesired nonlinearities. It should also be mentioned that the SOA itself can be used as an amplifier and a detector at the same time, because the voltage across the pn-junction depends on the carrier density, which again interacts with the optical input signal. Promising results for transparent channel drops, channel monitoring, and automatic gain control have been demonstrated [7]. Note that possible future applications of SOAs are not limited to amplification alone; they can also be used as wavelength conversion elements and optical gates [7].

B5.3.4 Rare-earth-doped fibre amplifiers

Parallel to the maturation of SOAs, another development has taken place, with a revolutionary impact on optical communication systems. With a point of reference in work on RE-doped glass lasers initiated as early as 1963 [3], the first low-loss, single-mode, RE-doped fibre amplifiers (as possible useful devices for telecommunication applications) were demonstrated in 1987 [4]. Progress since then has multiplied to the extent that amplifiers today offer far-reaching new opportunities in telecommunication networks. We will in the following sections discuss some of the recent results on RE-doped fibre amplifiers.

The possible operational wavelengths of RE-doped fibre amplifiers are determined by the emission spectra of the RE ions, moderately dependent on the host material in which they are embedded. Only a few RE materials become relevant for optical communication purposes, primarily erbium, which may provide amplification in the 1550 nm wavelength band (the third telecom window), and praseodymium, which may be operated around the 1300 nm band (the second telecom window). Note that also ytterbium and thulium have shown important features in amplifier development over the past few years.

The absorption spectrum holds accurate information about the location of possible pump wavelengths that can be used to excite the RE ions to higher energy levels. From this higher energy level the ion can relax to the ground state, transferring its packet of energy either radiatively or nonradiatively. The most prominent nonradiative de-excitation mechanism, known as multi-phonon relaxation, involves the creation of phonons. The maximum energy of a phonon is limited in any given host, for example, in silica to approximately 1100 cm^{-1} (corresponding to a frequency of 33 THz). Thus, the larger the energy gap that is to be bridged via multi-phonon relaxation, the more phonons need to be created. However, this becomes an increasingly improbable process. At energy gaps exceeding around six times the maximum phonon energy, multi-phonon relaxation becomes insignificant. Then, other processes, notably radiative decay, will dominate the relaxation process. Figure B5.6 shows the energy levels, possible pumping wavelengths (980 and 1480 nm), and emission processes for erbium. Quite fortuitously, the phonon energy in silica is such that the 980 nm pump level ($^4\mathrm{I}_{11/2}$) relaxes via rapid multi-phonon relaxation to the metastable level ($^4\mathrm{I}_{13/2}$), while multi-phonon relaxation from $^4\mathrm{I}_{13/2}$ is virtually absent. Instead, the decay from the meta-stable level to the lower energy level (the ground state $^4\mathrm{I}_{15/2}$) is radiative. Thus, it leads to the emission of a photon, either via spontaneous or stimulated emission. Spontaneous emission always takes place, when an amplifying medium such as a collection of ions is in an excited state; therefore, spontaneously emitted light cannot be avoided in a fibre amplifier. Stimulated emission is the process that allows signal amplification to take place and, therefore, is the desired property of the fibre amplifier. The process may be explained as follows: a photon incident on the medium, with an energy equal to the difference in energy of the ground state and an excited metastable state, promotes de-excitation, with the creation of a photon that is in phase with the incident photon.

Radiative transitions within triply ionized RE ions are actually relatively weak because they are ‘forbidden’ for reasons of symmetry (the normally dominant electrical dipole transition is not allowed for the relevant intra-4f transitions). Because of the weak nature, the involved lifetimes in the upper laser level (a measure of the spontaneous decay) are many orders of magnitude larger than the nonradiative lifetimes of the higher energy levels, and many orders of magnitude larger than the radiative lifetime of states that can decay via electric dipole transitions (typical, e.g. for transition metals). In Er^{3+}, the upper-level lifetime is typically 10–14 ms.

The absorption and emission cross-sections for Er^{3+} are shown in figure B5.7. Their size is the measure of the probability for a photon to interact with an Er^{3+} ion in the ground state or metastable

state. They are wavelength dependent, and allow absorption and stimulated emission in Er^{3+} to be described quantitatively.

EDFAs are commercially available and are widely deployed. For this reason, we will describe the EDFA in some detail.

EDFAs have revolutionized optical communication by removing the loss limit from optical transmission systems, enabling simultaneous amplification of a large number of optical channels, and facilitating the use of lossy components, as well as nonlinear components that only work at high powers. Hence, more complex links and networks with vastly higher capacity are made possible. As shown in figure B5.7, EDFAs operate in the third transmission window around 1550 nm. Figure B5.8 illustrates a simple EDFA. An input signal is launched into the erbium-doped fibre via an isolator and a wavelength-selective coupler. A pump beam from a pump diode is combined with the signal beam in the coupler, and also launched into the erbium-doped fibre. There, it is absorbed by the erbium ions, which thereby are excited to the metastable state. Thus, the erbium-doped fibre can amplify the signal via stimulated emission. The amplified signal exits the amplifier through a second isolator. The isolators only transmit

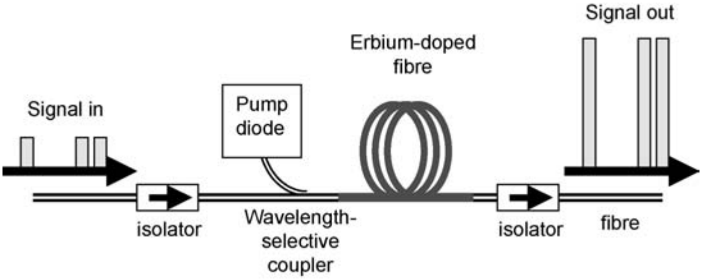

Figure B5.8. Schematic of an erbium-doped fibre amplifier.

light in one direction, and protect the amplifier from external feedback from reflections. Though the isolators and pump diode are discrete components, they are all fibre pigtailed so that the amplifier can be fusion-spliced together.

Real EDFAs are more complicated than the simple one shown in figure B5.8. They often consist of two amplifier stages, and may incorporate a gain-equalizing filter (figure B5.9). Furthermore, the input and output signal powers are monitored, and the pump power is controlled to maintain a constant gain. The pump power control must be fast enough to suppress transients that can arise in amplified systems and destroy them. Telemetry systems need to be implemented, too. For demanding applications, the erbium-doped fibre may be temperature controlled.

An EDFA may be fabricated using a silica glass host, and semiconductor pump sources have been successfully used to pump amplifiers in the 800, 980, and 1480 nm absorption bands. In addition, pumping at shorter wavelengths is also possible, but less interesting due to the lack of practical pump sources [8]. Basic differences exist between the application of the three mentioned pump choices. First, it should be noted that amplification occurs according to a three-level scheme when 800 or 980 nm pumping is applied, but the erbium ion works as a two-level system when 1480 nm pumping is used. Furthermore, 800 nm pumping is much less efficient than 980 nm pumping due to a pronounced excited-state absorption (ESA) of pump photons [8]. Because of these differences, today only 980 and 1480 nm pumping are considered in practical system applications. In cases, where very low noise figures are required, 980 nm pumping is the preferred choice, since the three-level nature of the system makes excitation of essentially all erbium ions (full inversion) possible, resulting in a noise figure very close to 3 dB. For 1480 nm pumping only around 70% of the erbium ions may be excited to the upper laser level. Ions in the ground state absorb the signal and thus degrade the noise figure. Noise figures down to 5 dB are generally obtainable with 1480 nm pumping. However, 1480 nm pumping still provides highly efficient amplifiers.

EDFAs readily provide small-signal gain in the order of 30–40 dB, and values as high as 54 dB have been achieved [9]. The EDFA also provides high saturation powers, and signal output powers of more than 500 mW have been demonstrated; multi-watt output power is even possible in cladding-pumped, ytterbium-sensitized, EDFAs [63]. In such power amplifier applications, 80% or more of the pump photons may be converted to signal photons, indicating the high efficiency of the EDFA. A 30 nm bandwidth of the EDFA may easily be obtained, and is available in commercial amplifiers.

The long lifetime in the upper laser level makes the EDFA an excellent energy reservoir, and it is important to note that, with the power levels used in modern optical communication systems, one signal

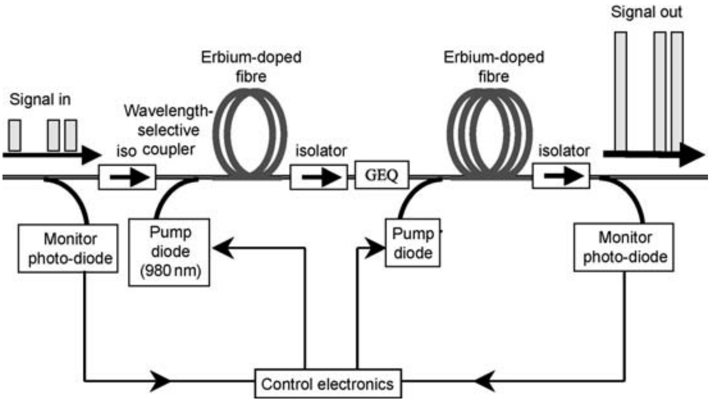

Figure B5.9. Two-stage erbium-doped fibre amplifier with gain-flattening filter (GEQ) and control electronics.

pulse will only interact with a very small fraction of the erbium ions within the EDFA. The following pulse is, therefore, very unlikely to interact with the same erbium ions, and it will remain unaffected by other pulses. For this reason, in practice no crosstalk will be seen in fibre amplifiers. The EDFA is also essentially insensitive to polarization variations of the signal, and only systems with cascaded amplifiers have lately demonstrated degradation due to polarization effects. A typical gain variation of 0.1 dB was found [10], when the polarization state of the signal is switched between orthogonal linearly polarized states. Finally, it should be mentioned that since the EDFA is an optical fibre itself, very low coupling losses (comparable to ordinary splice losses) are involved in the application of EDFAs.

It should be stressed that EDFAs work very well, and well-engineered EDFAs are available commercially. Performance-wise, EDFAs can provide more power, and more gain, than what is required in a telecom system. The noise figure can be very near the quantum limit of 3 dB of traditional (phase-insensitive) amplifiers. There is essentially no polarization dependence. They are very efficient. In these aspects, there is no need, or it is fundamentally impossible, to improve the EDFA.

EDFAs with larger bandwidth would arguably be desirable. Most EDFAs, and all of those used in real systems, are made with silica fibres, often Er-doped aluminosilicate. Therefore, this article is focused on silica EDFAs. Other types of EDFA, made, e.g. with fluoride, tellurite, or bismuth glass may offer some performance advantages, especially in terms of bandwidth. Unfortunately fibres from such glasses are vastly inferior to silica fibres in properties such as durability and strength, and are much more difficult to fabricate and splice. Furthermore fluoride glasses are hygroscopic. In fact, silica EDFAs have been engineered to the point where they outperform other types of EDFA in all important respects, and the over 30 nm bandwidth available in typical broadband commercial silica EDFAs is sufficient for the vast majority of today's transmission systems. Furthermore bandwidths of up to 48 nm have been demonstrated in an antimony silicate EDFA operating at around 1550 nm [50]. This bandwidth is still not quite as large as that of the SOA, but the bandwidth can be extended if one considers other amplification bands: during the first years of the EDFA research and commercial employment, the primary interest was focused on the spectral band from ~1530 to ~1560 nm, because limited lengths of erbium-doped fibres allow for very efficient amplification in this frequency range, and because this range coincides with the loss minimum of silica fibres. Hence, this band has been denoted as the 'conventional' band or just C-band. This use of names naturally indicates that other bands have emerged. Indeed, differently designed EDFAs allow for amplification in the 1570–1620 nm wavelength range, where the loss of silica fibres is still quite low. Such EDFAs are generally said to operate in the long-wavelength or L-band. For example, Codemard *et al* [59] report an unflattened amplification band from 1555 to 1620 nm in a cladding-pumped ytterbium-sensitized phosphosilicate EDFA. L-band amplification can be realized by operating the EDFA at a low inversion level (with only a small fraction of the Er ions excited). This leads to a ground-state absorption in the C-band, which suppresses gain there. At longer wavelengths, the transition becomes quasi-four level (with insignificant ground-state absorption), so a low but finite gain can be realized even with a low inversion level. Long fibres must then be used in order to reach a sufficient gain.

Amplifiers operating on the short-wavelength side of the C-band (from around 1450 to 1520 nm) are defined by the International Telecommunications Union (ITU) to belong to the class of S-band amplifiers. Sometimes the range 1450–1480 nm is called the S^+-band. Transmission in the S-band, at wavelengths between the second and third telecom windows, is possible due to the low loss at those wavelengths in newly developed low-OH silica fibres. High-gain EDFA have also been demonstrated in the S^+-band, down to 1480 nm [51]. In order to realize an S^+-band EDFA one must operate at a high inversion level in order to bleach the large erbium absorption in the S^+-band. Furthermore, a distributed filter is required to suppress the C-band gain, which otherwise saturates the amplifier. Note that S^+-band EDFAs are generally considerably more complicated than C- and L-band EDFAs. All these types of amplifier have been realized with silica fibres.

Thulium-doped fibre amplifiers (TDFAs) are in fact dominating in the S-band while S-band EDFAs are a later development. Typically, TDFAs provide amplification in the 1450–1480 nm window [14], though TDFAs gain-shifted to longer wavelengths within the S-band have been demonstrated. Thus, TDFAs can access the whole S-band. Another option for extending the gain to longer wavelengths is to cascade a TDFA with a discrete Raman amplifier, e.g. to a total bandwidth of 40 nm [15]. Still, compared to (C-band) EDFAs, TDFAs have several disadvantages. The energy-level diagram of triply ionized thulium ions (Tm^{3+}) is quite complicated, and many levels play important roles in S-band TDFAs. One problem is that the upper laser level is quenched in silica fibres by multi-phonon relaxation. Therefore, nonsilica glasses with lower maximum phonon energy such as fluoride and, recently, tellurite glasses are used instead. Another problem is that the lower laser level needs to be depopulated in order to maintain population inversion and avoid the so-called self-termination. Because of this, complicated pumping schemes, including two-wavelength pumping schemes, are employed. Nevertheless, TDFAs are commercially available, and high-gain (20–30 dB), high-output-power (e.g. 20 dBm), and low-noise operation (~5 dB noise figure) has been demonstrated.

Though transmission at around 1550 nm is currently the dominating technology, historically, large-scale deployment of systems in the second transmission window at 1300 nm predates this development. As a result, there has been a large demand for amplifiers at 1300 nm. Unfortunately, RE-doped fibre amplifiers for the second transmission window at 1300 nm have to deal with a number of difficulties, and their applicability is quite limited. The neodymium-doped fibre amplifier is limited by excited-state absorption to wavelengths that are too long (around 1340 nm and beyond) for real systems (at ~1310 nm), and so the best RE candidate in the 1300 nm wavelength band is the praseodymium-doped fibre amplifier (PDFA). The primary difficulty is that also praseodymium has to be placed in a host material other than silica, with a lower phonon energy, since otherwise, the upper energy level of the transition in question will be quenched by multi-phonon relaxation, and no net gain will appear [8]. Until now the most promising host materials have been different compositions of fluoride glasses, with problems such as low strength and hygroscopy. Another problem is that the 1300 nm amplifiers normally have lower pump efficiency than EDFAs. However, pump efficiency as high as 4 dB mW^{-1} for praseodymium-doped amplifiers is shown together with noise figures in the 5–8 dB range.

B5.3.5 Rare-earth-doped waveguide amplifiers

RE-doped waveguide amplifiers are only fundamentally different from fibre amplifiers in the respect that the RE material is embedded in a planar optical waveguide and not a fibre. This means at first glance that only another waveguide geometry has to be considered. However, several important factors have to be considered in the design of RE-doped waveguide amplifiers. First, the background loss is several orders of magnitude larger in a planar waveguide (around 0.01–0.05 dB cm^{-1}) than in a fibre, and second, a much higher RE-dopant concentration is necessary to achieve high gain in the relatively short planar waveguides. This raises the problem of energy transfer between the RE ions and results in a lower amplifier efficiency. Not surprisingly, the focus has been on the erbium-doped planar waveguide amplifiers in silica, and integration with a 980/1530 nm wavelength division multiplexer was presented early in the development [11]. In this component a maximum gain of 13.5 dB for a 600 mW pump power was shown, but gain values up to 20 dB have been demonstrated in other amplifiers. Recent results by Hübner *et al* [64] also demonstrate that boundaries between active and passive regions may be fabricated with transition losses below 0.03 dB/transition and back reflections suppressed more than 70 dB. However, it is not realistic to expect that the RE-doped waveguide amplifier will completely replace EDFAs as high-performance amplifiers in optical communication systems, but their advantages have to be found in the ability for integration of several functionalities, e.g. splitting and amplification on the same component. In addition, planar waveguide amplifiers can be realized in a wider range of materials than fibres. We may consider host materials such as lithium niobate, which is electro-optic, and new applications besides optical communication. Furthermore, Nd-doped planar waveguides in fluoro-aluminate glass remain a possibility for 1310 nm amplification [55]. We will return to more detailed descriptions of properties of Er-doped planar waveguide amplifiers and high-concentration doping in the following sections.

B5.3.6 Optical parametric amplifiers

An OPA utilizes a so-called wavemixing process, in which pump photons at one wavelength are converted directly to signal photons at another wavelength through a lossless nonlinear interaction in a medium. At the same time, idler photons are created in an idler beam at yet another wavelength to satisfy requirements on energy and momentum conservation. It is referred to as a parametric process as it originates from light-induced modulation of a medium parameter such as the refractive index. Its origin lies in the nonlinear response of bound electrons of the material to an applied optical field. Optical parametric amplification is traditionally realized via three-wave mixing (or three-photon mixing) in electro-optic materials such as lithium niobate with a second-order nonlinearity. However, it is also possible in media without a second-order nonlinearity, such as silica [33, 44]. In this case, a third-order nonlinearity (the nonlinear refractive index) leads to amplification. This is now a four-photon process (i.e. a four-wave-mixing process), involving two pump photons, a signal photon, and an idler photon. Two pump photons, from a single or from two different pump beams, are annihilated, and a signal photon and an idler photon are created. Thus, the idler becomes an image of the signal. This allows OPAs to be used for signal wavelength conversion. Because of energy conservation, the signal and idler photons are created at optical frequencies located symmetrically on opposite sides of the frequency (or frequencies) of the pump beam(s). Though four-wave mixing in silica is intrinsically a much weaker process than three-wave mixing in electro-optic materials, the low loss (allowing for long interaction lengths) and tight modal confinement of silica fibres enhances nonlinear interactions and thus compensates for the intrinsic weakness of the four-wave mixing process.

Interestingly, OPAs can be configured both as conventional phase-insensitive amplifiers as well as phase-sensitive ones [34]. In the case of a phase-sensitive fibre OPA, powerful pump as well as idler beams need to be injected into the amplifier. The pump and idler beams interact to create gain for a signal beam of a particular optical phase. Any signal beam with opposite phase would be attenuated, in a process in which a signal and an idler photon combine to create two pump photons. The difficulties in tracking and controlling optical phases are major practical drawbacks of phase-sensitive OPAs.

There is no idler beam injected into a phase-insensitive OPA. Instead, the idler is created in the four-wave mixing process, with an optical phase that depends on the phase of the signal. Because of this, the signal can be amplified independently of its phase, and there is no need to control the optical phase of any beam. Nevertheless, there are many challenges with a phase-insensitive OPA (which also apply to phase-sensitive ones). The main difficulty is that phase matching of the interacting pump, signal, and idler waves has to be maintained along the fibre. This means that fibres with tailored dispersion properties must be used, and the pump wavelength must be near the zero-dispersion wavelength of the fibre. Four-wave mixing depends on the polarization of the interacting waves, so in a typical system without control of signal polarization, the pump beam should be unpolarized, polarization scrambled, or polarization multiplexed. Furthermore, a high-pump-power requirement is a serious limitation. Still, for example, the pump power needed to reach a certain gain with OPAs may be less than half of what is needed in a Raman amplifier. Thus, an OPA has a higher gain efficiency, though its power conversion efficiency may be lower. In addition, an OPA does not require long fibres as a Raman amplifier does. Phase-insensitive fibre OPAs were first demonstrated with 49 dB peak fibre gain for 32.2 dBm of launched pump power [33]. The amplification bandwidth was approximately 10 nm on both sides of the pump wavelength of 1562 nm (parametric gain occurs symmetrically, in wavelength ranges on both sides of the pump wavelength in a phase-insensitive parametric fibre amplifier). The noise figure was inferred to be similar to that of an EDFA. The bandwidth of OPAs increases with pump power, and Ho *et al* recently demonstrated a pulsed fibre OPA with more than 200 nm of total bandwidth using only 20 m of highly nonlinear fibre [35]. High gain, high output power, and low noise figure (e.g. 4 dB) have been confirmed in several recent experiments.

Parametric amplifiers have several attractions, but they are at present not developed to the level of erbium-doped, semiconductor, or Raman optical amplifiers. See, e.g. reference [60] for a recent summary on fibre OPAs.

B5.4 Challenges in fibre amplifier application and development

To reiterate, the performance of EDFAs is sufficient for transmission applications, and there is not much reason to improve performance. A major challenge is instead to cut cost, e.g. by reducing the cost of pump diodes and other EDFA components. A lower cost would increase the proliferation of EDFAs in the network, and include uses for which the specifications are not so demanding. This allows for further cost reductions. Other cost-reduction strategies include a higher degree of parallelization and integration (e.g. by employing planar technology), as well as cladding pumping, both to be discussed further below.

The only performance limitation of EDFAs is its limited wavelength range. Still, the EDFA bandwidth is sufficient for today’s systems. Nevertheless, the limited bandwidth may well become a bottleneck some day. Since the available amplification bandwidth—as indicated—may not be extended significantly beyond the C- or L-band using established EDFA technology, and since the RE-doped S-band amplifiers still are complex (including S-band EDFAs), researchers have begun seeking alternative enabling techniques wider than those that can be managed by erbium- (or even thulium-) doped amplifiers. In this context, broadband, wavelength-agile technologies such as SOAs and Raman amplifiers, discussed above, are attractive options. Also from a cost perspective, SOAs are potentially very attractive, but they still require further development before they can be widely deployed.

Distributed Raman amplification directly in the transmission line can provide the best overall system performance, and offer the longest reach of optical networks. Still, the cost, dominated by the pumping system, must be reduced before Raman-amplified systems will be widely deployed.

B5.5 Cladding-pumping

Early fibre amplifiers were pumped by large laser systems requiring many kilowatts of electrical power, with an overall EDFA power conversion efficiency (‘wallplug efficiency’) of the order of one in a million. EDFAs only became practical with the realization of suitable semiconductor laser diodes for pumping. These pump-LDs improved the wallplug efficiency to the per cent level and above. In most EDFAs, the optical pump beam is injected into the core, which implies that a (transversally) single-mode pump source must be used. Though single-mode pump diodes are being developed rapidly, they are still limited in power to less than a watt. While an EDFA is typically pumped by more than one LD, this power limitation still means that, in practice, traditional core-pumped EDFAs are limited in power to less than 1 W (i.e. 30 dBm). This power is more than enough for most applications in optical communications, but higher powers can be used in free-space communication and in distribution networks in which the transmitted power (e.g. 1 W from an EDFA) is divided and distributed in a large number of different fibre branches.

Cladding-pumping is a method of overcoming the power limitation of core-pumped EDFAs. Cladding-pumped fibre devices utilize multi-mode pump-LDs rather than single-mode ones.

Multi-mode diodes are more powerful and often cheaper than single-mode ones. They come in many shapes for a wide range of power ranges, up to several kilowatts, but the simplest, lowest-cost multi-mode diode is the broad-stripe diode, typically generating up to a few watts of output power.

Standard RE-doped fibres cannot be cladding-pumped. Instead, special fibres known as double-clad fibres are used. These comprise a secondary, multi-mode waveguide into which the multi-mode pump beam can be launched. Typically, this structure is realized with a secondary cladding ('outer cladding') surrounding the original cladding ('inner cladding'). The outer cladding has a lower refractive index than the inner cladding, so that the pump beam can be guided within the inner cladding via total internal reflection. There is still a core for guiding signal light. It resides in the inner cladding and is similar to the core of a core-pumped EDFA, i.e. it is doped with erbium (or another RE) and has a higher refractive index than the surrounding inner cladding (figure B5.10). A single-mode core is preferred for amplifiers in optical transmission systems. The pump light still reaches the RE-doped core and excites the RE ions, so that gain is created and the signal can be amplified.

Thus, a cladding-pumped fibre amplifier has a potential not only for higher power, but also lower cost, than a core-pumped one. However, there are challenges with this technology. While the pump has a high power, its intensity (power density) is much lower than it is with core pumping. This is a problem since erbium ions require a minimum pump intensity to reach gain. A related problem is that because the overlap between the pump beam and the RE-doped region is small, the pump absorption is low. Since the intrinsic absorption of Er^{3+} is already quite low, and since the maximum Er^{3+} concentration is relatively limited, this can lead to excessively long Er-doped fibres, e.g. 100 m or even more if special care is not taken. For this reason a small inner cladding is preferred for EDFAs, significantly smaller than 100 μm diameter [39], but this makes it more difficult to launch the pump light into the fibre. Another proposed [40] and recently demonstrated [41] design modification is to dope the erbium in a ring around the core, since this reduces reabsorption and signal-induced gain-compression. The most common approach, however, is to co-dope (sensitize) the erbium with ytterbium [42]. In an ytterbium-sensitized EDFA, pump photons are initially absorbed by Yb^{3+} ions, which are thus excited. Then, the energy is transferred nonradiatively from Yb^{3+} ions to Er^{3+} ions, resulting in de-excitation of the Yb^{3+} ions and excitation of the Er^{3+} ions. Ytterbium has a larger absorption cross-section than erbium, as well as a much broader absorption band, from 910 to 980 nm. Significantly, the broad absorption can alleviate the requirement of pump wavelength stabilization via temperature control of the pump-LD. Furthermore, Yb^{3+} is comparatively resistant to a reduction of efficiency at high Yb concentrations (concentration quenching), and can therefore be incorporated in much higher concentrations than Er^{3+}. In total, this means that a high gain can be obtained with much lower pump intensities than without sensitization, and even in fibres with a large inner cladding, a fully adequate pump absorption of several decibels/metre can be reached. However, so far, efficient Yb-sensitized EDFAs require a host glass with a high phosphorus content. Unfortunately, this leads to a relatively narrow gain spectrum, so Yb-sensitized EDFAs have not been able to cover the whole C-band. This is a very important aspect.

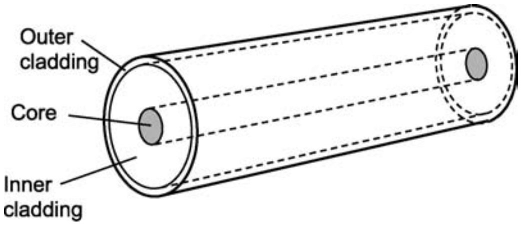

Figure B5.10. Schematic drawing of a double-clad fibre, comprising an RE-doped core, and an inner and an outer cladding.

Ytterbium-free EDFAs do not suffer from this problem—their gain spectrum even defined the extent of the C-band. But, because of the poor pump absorption, Yb-free cladding-pumped EDFAs are relatively inefficient and of low output power. With cladding-pumping, the L-band actually appears more attractive than the C-band, for Yb-sensitized EDFAs because the gain spectrum is wider there, and for Yb-free EDFAs because the pump absorption is higher.

The pump launch is another challenge with cladding-pumped EDFAs. Wavelength-selective fused fibre couplers used to combine the signal and pump beams in core-pumped EDFAs do not work with multi-mode beams. Micro-optic couplers do work and have been used for cladding-pumping. However, these rely on lenses and wavelength-selective reflectors with free-space (unguided) beam propagation to combine the beams, and require precise assembly and alignment. They are much more complex and therefore more costly than fused fibre couplers. Their power-handling capability is also worse, which is a distinct disadvantage for cladding-pumped EDFAs designed for high powers.

Instead of launching the pump through the end of the erbium-doped fibre, together with the signal, one can launch it through the side of the fibre. We will describe three such side-pumping schemes.

One scheme utilizes several (typically three) parallel fibres combined into a common fibre assembly. The fibres are embedded in a polymer coating with a low refractive index so that the fibres themselves can guide pump light. Furthermore, the fibres are in optical contact with each other, meaning that pump light can couple from one fibre into another. One (or several) of the fibres contain a core doped with erbium, typically sensitized with ytterbium. Figure B5.11 shows an example of such a multi-fibre assembly, known as a GTwave fibre. In the GTwave fibre, the fibre with a doped core can be spliced to any fibre carrying a signal. The signal is then launched into the erbium-doped core and amplified in the GTwave fibre. The fibres without a core constitute pump fibres, to which pigtailed pump diodes can be spliced, as many as one to each end of each pump fibre. Once in the pump fibre, the pump light will couple over to the Er-doped fibre and excite the ions in the core.

GTwave fibre devices take simplicity to the limit in that no other components, bar pump-LDs, are required to realize an EDFA (though practical amplifiers do include isolators and, optionally, gain-flattening filters). Another attractive feature is the possibility to include several parallel Er-doped fibres in a multi-port amplifier for parallel amplification. Amplification in eight parallel fibres has been demonstrated [43]. Single-channel GTwave amplifiers can reach well over 1 W of output power with high gain and noise characteristics typical for EDFAs. Broadband versions have been realized both in the C- and L-band [44, 45].

V-groove side-pumping (VSP) is another approach to cladding-pumping, that offers many of the advantages that GTwave fibres provide, with comparable performance [46, 47]. An additional advantage is that VSP amplifiers can be made with any double-clad fibre. On the other hand, while conceptually simple, the fabrication of the v-groove as well as the pump launch are relatively complex issues. A v-groove is fabricated in the side of a double-clad fibre, penetrating into the inner cladding but leaving the (erbium-doped) core intact. Then, pump light from a laser diode is launched through the

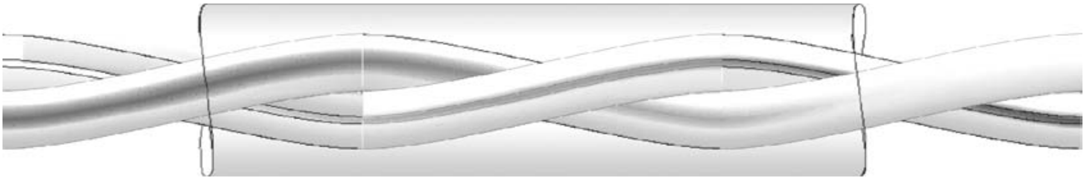

Figure B5.11. A GTwave fibre assembly consisting of a single pump fibre and a single signal fibre, surrounded by a polymer coating. Pump light (red) is launched into the pump fibre, and couples over to the signal fibre. Here, it excites the erbium in the core, leading to amplification of the signal light.

opposite side of the fibre, and hits the v-groove from within the fibre. The light is then deflected off the v-groove facet by ~90°, along the fibre axis and inside the inner cladding, via total internal reflection. Thus, the pump light is launched into the inner cladding of the double-clad fibre, while signal-carrying fibres can be spliced to its ends.

Finally, multimode couplers offer a convenient and widely used way of launching pump light into a double-clad fibre through its side. For example, the tapered fibre bundle is a multi-port version of such a coupler [62].

Despite the success of GTwave, VSP, and multimode couplers, the difficulty of combining high output power, efficient operation, and broadband gain (over the whole C-band) in cladding-pumped EDFAs remains. High-power cladding-pumped ytterbium-doped fibre lasers emitting at 980 nm have therefore been developed as a pump source for EDFAs [48, 49, 61]. This is an alternative way of combining cladding-pumping with EDFAs that is compatible with conventional core-pumped EDFAs, including fused fibre couplers. The EDFA is powered by laser diodes, albeit in an indirect way. Thus, the high-power advantage of cladding-pumping can be realized without compromising amplification bandwidth or reliability. Cladding-pumped ytterbium-doped fibre lasers can generate several watts of output power at 980 nm in a single-mode beam.

B5.6 Planar erbium-doped optical amplifiers

The development of integrated optical amplifiers has been intensified due to the demand for more compact and lower-cost solutions for the DWDM systems, in which the vast majority of erbium-doped fibre-based amplifiers have found commercial use. The commercialization of other planar lightwave components (PLCs) such as AWGs, power splitters and optical switch blocks has resulted in a maturing of the PLC manufacturing with silica-on-silicon being the most widely used technology. The next logical step in the evolution of optical components and subsystems is to combine functions realized in passive PLCs with amplifiers, realizing loss-less or amplifying components of high complexity and functionality that at the same time can be mass produced and offer the overall component size to be reduced significantly compared to the fibre- or bulk optic based counterparts.

In recent years, the development of the planar amplifiers has thus moved from the university and research labs into industry, where it is presently being commercialized in a number of different technologies such as erbium-doped silica-on-silicon, ion-exchange in erbium-doped glass, and as SOAs. At the same time, the fibre-based optical amplifiers are decreasing rapidly in size, the smallest now being less than the size of a credit card. Comparing the technologies, the silica-on-silicon technology potentially has the advantages of the erbium-doped fibre-based amplifier (low noise figure, low polarization dependence, and low gain cross-modulation). In addition, it allows monolithic integration of components known from the passive PLC technology. The main obstacles for the planar erbium-doped amplifier remain the propagation loss and the limited length of the waveguide that requires the erbium concentration to be increased with a factor of 10–100 compared to that in normal erbium-doped fibre. As we describe in section B5.7, the efficiency of the amplifier strongly depends on the erbium concentration and at high concentration it is reduced due to the ion–ion energy transfer that is increasing rapidly with concentration and even more as the erbium ions tend to form clusters at high concentrations. This is known as concentration quenching.

The propagation loss of high-quality waveguides has been reduced to a minimum of 1–3 $\mathrm{dB\,m^{-1}}$, which is still orders of magnitude larger than for fibres, but sufficiently low to allow the use of a long waveguide and hence a relatively low erbium concentration. The fact that the propagation loss is non-negligible, however, means that a planar erbium-doped waveguide amplifier will never be as efficient as the fibre-based amplifiers. On the other hand, the pump laser technology has led to high-power pump lasers at significantly reduced prices. This enables the less efficient planar amplifier technology to be used instead of the fibre-based technology, if it offers other advantages in terms of functionality, performance, manufacturability, cost, or size.

The focused development of the erbium-doped silica-on-silicon technology has led to planar amplifiers with sufficiently high gain and low noise figures to be applicable in commercial long-haul or metro systems. On the picture on figure B5.12, a wafer with four PLC chips, each containing 10 individual waveguide amplifiers, is shown. Each of the amplifiers consists of an erbium-doped waveguide section that is curled up in a spiral to achieve sufficient length. 980/1550 nm combiners on all amplifier inputs and outputs are included for pump multiplexing and removal of excess pump power.

These waveguide amplifiers were produced by a modified plasma-enhanced chemical vapour deposition (PECVD) process, in which the erbium precursors and other co-dopants are introduced directly into the core deposition process. This technique allows detailed control of the glass composition, and enables highly uniform glass layers to be deposited. In contrarst to fabrication processes not involving etching of the waveguide core, such as the ion exchange process, the PECVD-based silica-on-silicon manufacturing process allows the erbium doping to be confined to the waveguide core, where the pump intensity is high. Hence, the erbium ions are easily inverted, leading to a low threshold pump power for amplification. A typical gain spectrum for such a waveguide chip is shown in figure B5.13 for a pump power of 100 mW at 976 nm. For this device, a net gain exceeding 14.5 dB has been achieved over the entire C-band. The performance of such amplifiers typically results in noise figures between 4 and 4.5 dB at low input signal powers.

As for all erbium-doped amplifiers, the performance is strongly dependent on the selected amplifier length, erbium concentration and pump power. For optimized waveguide parameters, gain in excess of 16 dB over the C-band is reached for 100 mW of pump power, and for 200 mW pump power more than 25 dB of gain can be achieved over the C-band, while maintaining the low noise figures. Such gain values will suffice for most applications, and thus represent a viable alternative to the fibre-based amplifiers.

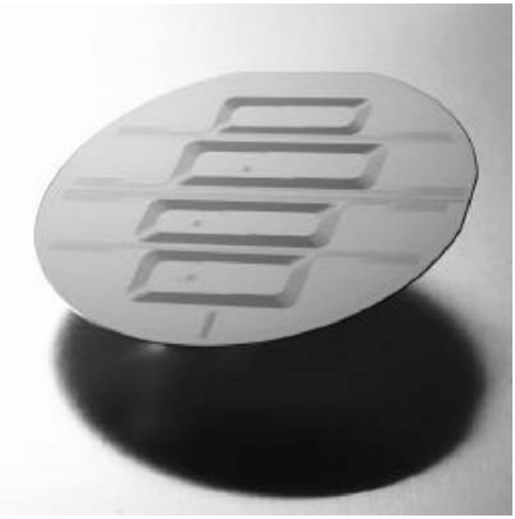

Figure B5.12. Picture of a wafer with four PLC chips, each containing 10 individual waveguide amplifiers. Each amplifier consists of a curled-up erbium-doped waveguide section, and 980/1550 nm combiners on all inputs and outputs for pump multiplexing and removal of excess pump power. The picture is kindly provided by NKT Integration A/S.

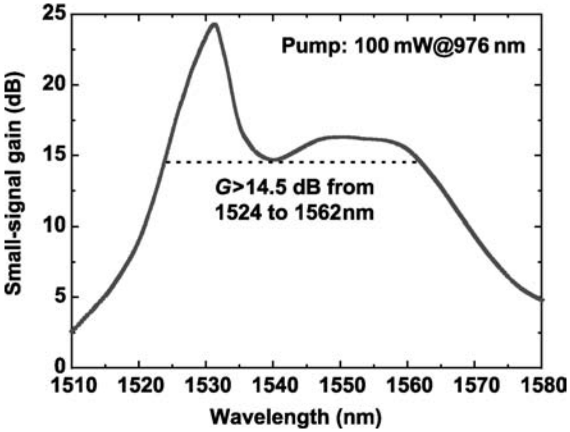

Figure B5.13. A typical gain spectrum for a waveguide chip obtained for a pump power of 100 mW at 976 nm. The results are kindly provided by NKT Integration A/S. Similar gain spectra can be obtained with EDFAs, albeit typically with a higher gain. For WDM applications, the strong gain variations would have to be equalized with a gain-flattening filter.

B5.7 Rare-earth incorporation in silica glass

Practical use of RE-doped silica for amplification purposes typically requires RE concentration levels above 10^{18}–10^{19} cm^{-3}, and elimination of quenching processes. The main sources of quenching are multi-phonon processes associated with O–H bonds and the so-called ‘concentration-quenching’ arising from electrostatic interactions between RE ions. These effects lead to the requirement of a ‘dry’ silica (i.e. with a low hydrogen content) with well-dispersed RE ions. The content of hydrogen in as-fabricated samples can be substantial depending on the fabrication process, but it may be straightforwardly eliminated by subsequent heat treatment and chlorine drying if necessary [17]. Concentration quenching is a more difficult problem to overcome. The root of the problem is that excited RE ions can de-excite each other through electrostatic dipole–dipole interactions, whose magnitudes decay with distance as r^{-6} so that the interaction between neighbouring RE ions in the glass network may be substantial. This problem is particularly severe in the case of erbium, where the energy of the upper laser level ($I_{13/2}$) is close to half the energy of the $I_{9/2}$ level so that a near-resonant upconversion process can take place between close-lying Er ions. Because of its fundamental nature this problem sets an ultimate limit to the useful RE concentration in many systems such as Er- and Nd-doped silica glasses. The problem is magnified by the low solubility of RE ions in the pure SiO_2 matrix, which leads to strong RE clustering during post-production annealing, and in practice it is this effect which limits the usable RE concentrations [18, 19]. This is particularly critical in the case of integrated optics, where the limitations on device dimensions put a lower limit (around 10^{19} cm^{-3}) on the Er concentrations needed to obtain useful signal amplification.

Co-doping of silica glass with aluminium or phosphorus increases the RE solubility and is therefore often used to counter RE cluster formation. Such glasses are known as aluminosilicate and phosphosilicate. Aluminium doping has proven very effective, ensuring essentially complete cluster dissolution at RE concentration levels in the range 10^{19}–10^{20} cm^{-3} (approximately 0.1–1% by weight) when the Al/RE concentration ratio is around 10 or higher. Furthermore, Al doping broadens the emission spectrum of erbium, which is highly desirable. Using P as a co-dopant a slightly higher ratio of about 15 is needed [20]. Nevertheless, with sufficient P content, phosphosilicate glass has a very high RE solubility. This is also true for phosphate glasses (free from silica), in which RE contents of 35% by weight have been realized (however with severe quenching). However, the gain spectrum of phosphosilicate EDFAs is narrower than that of aluminosilicate EDFAs.

At RE concentration levels encountered in Er-doped amplifiers (say, up to 1% by weight), the macroscopic properties of the silica glass are not strongly affected by the co-doping and integration with other glass-based components is a straightforward matter. This suggests that the mechanism underlying the cluster dissolution is a local interaction between RE and co-dopant ions rather than an overall modification of the SiO_2 network structure. Whereas the effect of P codoping is not well understood on a microscopic level there is some experimental [21] and theoretical [22] evidence for this hypothesis in the case of Al codoping. General thermodynamic arguments suggest that cluster dissolution should be favoured by a high fictive temperature of the glass [22], but no systematic experimental data exist to test this hypothesis. In addition, thermodynamic arguments may not apply to glasses fabricated by low-temperature processes such as sol–gel or PECVD. In fact, for Er-doped PECVD glass it is an advantageous strategy to keep the processing temperatures as low as possible in order to limit Er diffusion and thereby cluster formation [19].

An important effect of the local environment around RE dopants is to modify the level spacings and optical matrix elements within the 4f manifold due to ligand-field effects. The site-dependent Stark shifts are an advantage for device fabrication, since they facilitate the manufacturing of amplifiers with wide and flat gain curves suitable for operation at multiple wavelengths. It has been found that the addition of Al leads to an increase of the inhomogeneous broadening by more than a factor of two compared to pure or P-doped silica [23]. The ligand fields also lead to a slight mixing of the f-orbitals with states of even parity, in effect making f–f transitions dipole allowed. As it turns out, this mechanism controls the oscillator strengths of the f-shell transitions. The optical intensities of the f-shell transitions are usually rationalized through the so-called Judd–Ofelt theory [24, 25], which expresses all oscillator strengths in terms of three phenomenological parameters which are related to the matrix elements of the local electrostatic field, but which are most often used as fitting parameters. The Judd–Ofelt theory is approximate, and the underlying assumptions were only partially justified in a recent theoretical analysis of the local fields and electronic structure around an Er impurity [22]. However, in most practical cases the theory is able to describe all oscillator strengths of RE impurities to an accuracy of 10–30% with suitable parameter choices [26–28]. Most systematic investigations of the dependence of Judd–Ofelt parameters on chemical composition of silicate glasses have focused on glass containing significant amounts (>10 mol %) of dopants such as Na, Al, B, Mg or Ca [26, 27, 29, 30]. Even for such mixed glasses the Judd–Ofelt parameters show only slow and moderate (within a factor of 2–3) variation with composition, suggesting that the possibilities for engineering these quantities by varying impurity concentrations is limited in the lightly doped, so-called high-silica, glasses commonly used for fibre amplifiers. Interestingly, the Judd–Ofelt parameters found in Al-codoped fibre preforms [28] differ substantially from those found in heavily doped silicates, possibly due to a more covalent character of the Er–O bonding in the weakly Al-doped silica glass.

B5.8 Summary

EDFAs have revolutionized optical communication systems and are widely deployed. They have removed the loss limit and thereby extended the optical reach to over 10 000 km. They have also enabled mass deployment of WDM systems, and transmission of several terabits per second has been demonstrated in laboratories. The use of lossy components, including optical switches for all-optical networks, is made possible by EDFAs. The only limitation of EDFAs is their limited bandwidth, but they have the potential to cover over 140 nm (~18 THz) in split band configurations and even the more standard 30 nm bandwidth is fully sufficient for systems considered today.

Distributed Raman amplification can provide the best system performance, but deployment is so far very limited. Several amplifier technologies (semiconductor, Raman, OPAs) can operate at any wavelength that is considered for telecoms. Bandwidths of 20 THz or more have been realized in a continuous band. The rapid progress in this field continues towards better optical amplifiers that will find even more uses in the telecom systems of tomorrow. In particular metro applications benefit from the ongoing cost reduction and the development of simple amplifiers [16].

Acknowledgments

We would like to acknowledge the significant help provided by Dr Thomas Feuchter from NKT Integration A/S for his assistance in writing section B5.6, and providing the most recent results on planar erbium-doped optical amplifiers.

B6
Ultrafast optoelectronics

Günter Steinmeyer

B6.1 Introduction

Optoelectronics is based on electronic devices, which are used for emitting, modulating, transmitting, or sensing light. At a very fundamental stage, these devices require interaction of light with an electronic current, effectively converting photons into electrons or vice versa. The temporal response of an optoelectronic emitter, for example, is therefore always limited by the fastest available rise time of a current-pulse generator. Similarly, detection of light in a photo-detector can only be accomplished directly with a few picosecond temporal resolution [75]. On the electronics side, additional constraints can be imposed by parasitic inductances or capacitances in the electronic circuitry and high-frequency attenuation mechanisms in microwave cables. Streak cameras [71], which merge the generation of photoelectrons and their temporal resolution into one device, overcome some limitations. Nevertheless, even these fastest direct optoelectronic detection devices are typically limited to a response time of the order of 1 ps. The examples discussed so far rely on a direct interaction of light with an electronic current. In the following, we will describe ways to circumvent the electronic bandwidth problem. The fundamental idea behind ultrafast optoelectronics becomes clear from the latest developments for optical communication networks. In early fibre optic data links, light was converted back into an electronic current prior to any processing. This has been replaced by all-optical means of processing photonic data streams. A major improvement in terms of data capacity has been achieved by the method of wavelength-division multiplexing, which allows for terabit/second rates by simultaneously transmitting many channels at different wavelengths through one and the same fibre. In this chapter, we will introduce methods to provide the fundamental optoelectronic functions of emitting, modulating, transmitting, and sensing light, all with a temporal response or resolution of a few femtoseconds. These methods are ultimately limited only by the duration of the optical cycle itself. We will refer to these schemes as *ultrafast optoelectronic devices*, even though the individual optoelectronic components, mediating between photons and electrons, can be inherently slow. The methods described split the optoelectronic process into two steps, an ultrafast all-optical step, which ensures sufficient bandwidth, and a second slow electronic step to allow for efficient conversion between photons and electrons at a strongly reduced bandwidth.

Before continuing our technical discussion in detail, it is appropriate here to indicate how this chapter is organized: first we review methods for the *generation of femtosecond pulses*. Short light pulses can experience strong reshaping effects, which may modify their pulse shape. Compared to electronic pulses, however, these effects start to become significant on terahertz rather than gigahertz bandwidth scales, and they also mainly affect the spectral phase rather than the amplitude. Therefore, particular attention will be paid to methods that allow compensation of *dispersive pulse broadening*. This discussion will be followed by an overview of *femtosecond pulse characterization methods*. Finally, in section B6.5, we will address *methods to modulate phase and amplitude* of femtosecond pulses. Together with the characterization methods, ultrafast optoelectronics nowadays allows for synthesis of desired pulse shapes and control of optical waveforms, very similar to the generation of arbitrary electronic waveforms.

B6.2 Ultrafast laser pulse generation

Compared to electronics, the available bandwidth in optical systems is enormous. This is a clear driving force behind all-optical telecommunications. Fiber-optic systems can provide terabit/second of transmission capacitance over transatlantic distances [2, 76]. From elementary Fourier theorems, it is also clear that the widest bandwidth can be used to support extremely short pulses. The laser material with the widest known gain bandwidth is titanium-doped sapphire [23]. The 650–1100 nm gain bandwidth allows us to generate directly pulses of about 5 fs pulse duration, corresponding to less than two optical cycles of the electric field.

Laser operation is generally sustained by an optical cavity to provide optical feedback into the gain material. The photons circulating in the cavity experience laser gain and losses due to output coupling [84]. Laser gain saturation favours equal filling of the cavity with photons, i.e. cw operation of the laser [57]. In order to generate a short pulse, the energy content of the optical cavity has to be temporally confined into an interval as short as possible. This requires us to introduce a condition which provides an advantage for the laser to operate in short pulses. One means of doing so is to insert an intracavity amplitude modulator, which opens and closes in synchronism with the light travelling through the cavity [85] (figure B6.1). This generates an advantage for those photons which travel during the fully open state of the modulator. If conventional electro-optic or acousto-optic modulators are used, this whole scheme is always limited to some extent by the electronic pulse width of the modulator driver, even though optical pulses shorter than the electronic driving pulses can be generated. Following the philosophy mentioned in our introduction, it is therefore desirable to eliminate electronic bandwidth limitations by switching to an all-optical modulator.

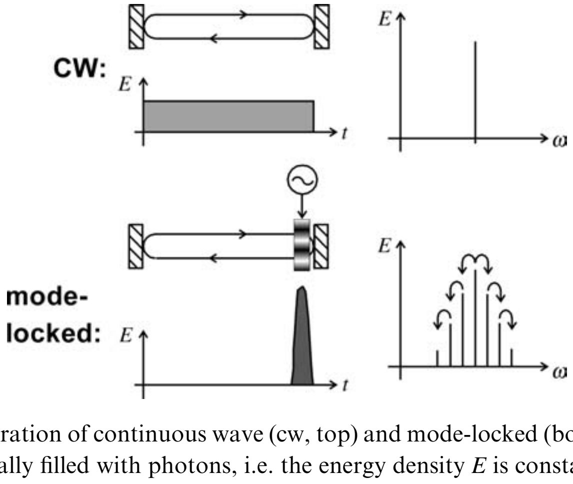

Figure B6.1. Schematic illustration of continuous wave (cw, top) and mode-locked (bottom) operation of a laser. In the cw case, the cavity is equally filled with photons, i.e. the energy density E is constant. Insertion of a modulator synchronously driven at the cavity roundtrip frequency focuses light into a small time slot centred at the fully open position of the modulator (bottom). The two situations are also depicted in the frequency domain on the right side. Continuous operation results in single-longitudinal-mode operation of the laser. The modulator creates sidebands at the neighbouring modes, effectively transferring energy to the spectral wings. This is called mode-locking.

B6.2.1 Saturable absorber mode-locking

The simplest all-optical modulator schemes rely directly on saturable absorption of an optical material [39, 49, 68]. Typically, either organic dyes or semiconductor materials can be used. At high intensities, the absorption of these materials bleaches out, because the majority of electrons or holes has been excited from the ground state to higher energy states. Such *an all-optical modulator* is automatically self-synchronous with the light in the cavity. A small initial power spike inside the cavity will experience less loss than the rest of the cavity's energy content. This positive feedback will self-amplify until all the energy is concentrated in a small time slot. Unfortunately, the relaxation of the bleaching process is not arbitrarily fast, but again, pulses shorter than the modulation time constants can be produced. It is not even necessary for the relaxation time of the absorber to be faster than the cavity round trip. Nevertheless, the all-optical method still experiences a limitation from response-bandwidth effects. Typically, this forbids the generation of pulses much shorter than a picosecond. There are, however, some ingenious schemes that overcome some of the limitations of a slow absorber and extend the operation of saturable absorber mode-locking well into the femtosecond range [28, 38, 52].

Some of these approaches are fairly specialized and rely on the interplay of several optical mechanisms inside the cavity. An alternative approach came from the use of the so-called *reactive nonlinearities* (e.g. the Kerr nonlinearity, see figure B6.2). Other than amplitude changes due to saturable absorption, these effects influence the phase of the light only. This self-phase modulation delays high light intensities in respect to low intensities [1]. As no carrier dynamics are involved in the process, this mechanism can be very fast with a typical response time of less than 1 fs. The 'reactive' character of the nonlinearity calls for a conversion mechanism to transfer the nonlinear phase modulation into an effective amplitude modulation.

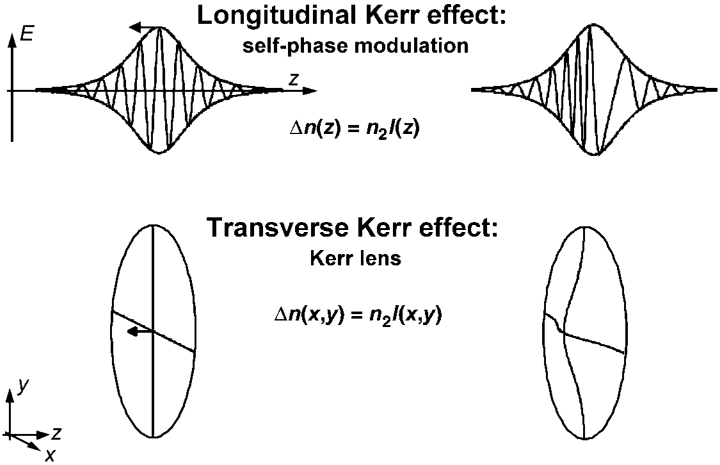

Figure B6.2. The nonlinear optical Kerr effect is caused by a dependence of the index of refraction on intensity. Along the axis of propagation z, this causes a phase retardation of the most intense part of the temporal pulse profile due to self-phase modulation. In the plane perpendicular to z, the retardation causes a deformation of the phase fronts. In the central part of the spatial beam profile, the phase fronts experience an additional curvature, i.e. the Kerr effect causes an effect similar to a lens. Therefore, the transverse Kerr effect is also referred to as a Kerr lens.

B6.2.2 Passive mode-locking based on reactive nonlinearities

We shall now consider the concept of an *effective saturable absorber*. Such a device is actually a combination of a phase-to-amplitude converter and a reactive nonlinearity. Several types of effective saturable absorber have been proposed. One method is to place the self-phase modulator in a second cavity, which is coupled to the gain cavity. The coupled cavity acts as a nonlinear mirror, providing high reflectivity for the more intense centre part of the pulse and low reflectivity everywhere else. This method is called additive-pulse mode-locking [47]. Another method is Kerr-lens mode-locking (KLM) [55, 79, 90]. Here the transverse effect of the Kerr nonlinearity is used instead (see figure B6.2). As the most intense axial region of an optical beam is also phase retarded compared to the outer region, this corresponds to the focusing action of a lens. A suitable arrangement of intracavity apertures (field stops) can then be used as spatial filters to translate the Kerr nonlinearity into an effective absorber. The focused high-intensity light experiences fewer losses at these apertures due to its smaller diameter. Alternatively, one can also arrange the cavity for a better spatial overlap with the pump light when the additional nonlinear lens is in place. Pulses as short as approximately 5 fs have been produced with this method [24, 96].

B6.2.3 Amplification

Typical Kerr-lensed mode-locked lasers can deliver pulse energies of a few nanojoules at a repetition rate of 100 MHz. Pulse energies can be increased either by using a longer cavity [16], by additional extracavity amplification [64], or by cavity dumping [9]. All these methods allow for a few 10 nJ pulse energy at megahertz repetition rates. Further increase of the pulse energy into the microjoule range, whilst still maintaining femtosecond time duration, would increase the peak power of the pulse into a regime where most optical materials are likely to encounter damage. For achieving greater amplification, the pulse therefore needs to be 'stretched' before amplification and then be recompressed to its original duration after the amplifier. The design of the stretcher and compressor will be treated in the following section. The method is called *chirped pulse amplification* (CPA) [6, 94] and has been demonstrated with 15 fs pulses of millijoule energy at a 10 kHz repetition rate [5, 115]. Even stronger amplification and reduction of repetition rate can lead to hundreds of joules pulse energy at 450 fs pulse duration [74]. The latter system reaches a peak power of 1.5 PW (1.5×10^{15} W). The focused intensity reaches $6 \times 10^{20}\,\mathrm{W\,cm^{-2}}$. The electric field strength in the focus of such a laser pulse exceeds typical interatomic binding forces by about three orders of magnitude [12].

B6.2.4 Wavelength conversion—from terahertz to x-rays

So far we have concentrated on direct oscillator and amplifier schemes. Laser materials with wide bandwidth as needed for short-pulse generation are only available in the near-infrared and part of the visible spectral range [17, 27, 28, 118]. Another approach for the generation of short pulses is conversion of femtosecond radiation by nonlinear optical mechanisms. One mechanism is *frequency-doubling* in nonlinear optical crystals. For frequency-doubling of extremely short pulses, typically very thin crystals with a thickness in the few-micrometre range have to be employed [31]. Another method is *optical parametric amplification*, which can be used both in the near-infrared and visible spectral range. The parametric process splits an input photon into two of lower energy, with wavelengths depending on the phase matching conditions in the nonlinear optical material. Beta-barium borate (BBO) has been shown to provide extremely wideband phase-matching, which has been used to generate pulses well below 5 fs [82, 116]. There is a wealth of other methods leading deeper into the UV, including Raman side-band generation [111], high-harmonic generation [12, 58, 61], and Thomson scattering [80]. Wavelength conversion is also a very important mechanism to generate radiation of longer wavelengths than directly available from oscillators. Again, parametric processes can be used here [56]. Another important case is *terahertz radiation* [89]. All these mechanisms allow access to wavelength regions that are not readily covered by wideband laser materials.

B6.3 Femtosecond pulse propagation effects and dispersion compensation

In microwave electronic systems, a severe limitation is imposed by high-frequency damping mechanisms. In optics, limitations due to spectral absorption are typically not a concern or can be easily avoided. Many dielectric media, like glasses and crystals, are transparent in the range of 150–1000 THz [103]. Limitations typically only arise in optical amplification or nonlinear optical conversion. In a 10 THz window in the near infrared (1.55 μm wavelength), exceptionally low losses of 0.3 dB km^{-1} have been demonstrated in silica fibres [70]. In this exact wavelength region, Er-doped glass amplifiers [11, 18] can easily be embedded into optical telecommunication systems. Compared to electronic systems, optical bandwidth is therefore abundant and a much lesser concern.

B6.3.1 Group delay dispersion as leading-order propagation effect

If one tries to launch a 100 fs pulse train into an optical fibre, one finds that the extremely short pulses already broaden to picoseconds after only a few metres of propagation because of dispersion. Dispersion causes different spectral components of the pulse to propagate at different group velocities, which induces broadening of short pulses during propagation. Compensation of dispersive effects therefore poses a ubiquitous problem not only in telecommunication systems [2], but also with ultrashort pulse generation systems [107]. A pulse with angular carrier frequency $\omega = 2\pi c/\lambda$ experiences a *group delay*

$$\mathrm{GD}(\omega) = l\frac{\mathrm{d}}{\mathrm{d}\omega}\frac{\omega}{c}n(\omega) \tag{B6.1}$$

when propagating through a dispersive medium with index n and length l. The group delay determines the propagation time of a pulse and must not be confused with the phase delay $l\,n/c$. To first order, pulse broadening is governed by the *group delay dispersion*

$$\mathrm{GDD}(\omega) = l\frac{\mathrm{d}^2}{\mathrm{d}\omega^2}\frac{\omega}{c}n(\omega). \tag{B6.2}$$

Gaussian pulses of duration τ_0 are stretched to a duration τ, where

$$\tau = \tau_0\sqrt{1+\left[\frac{|\mathrm{GDD}|^2}{\tau_0}\right]^2} \tag{B6.3}$$

when propagating through a material with dispersion GDD. Equation (B6.3) is a useful relation to estimate the severity of pulse broadening in optical systems [1]. Optical materials can exhibit either negative or positive dispersion, and this can change sign as the wavelength varies (see figure B6.3). Fused silica, for example, shows zero dispersion at 1.3 μm with positive dispersion below and negative dispersion above this wavelength. At the *zero-dispersion wavelength* of a material, broadening effects due to GDD are eliminated; but similar effects are caused by higher-order derivatives of the refractive index, e.g. *third-order dispersion*

$$\mathrm{TOD}(\omega) = l\frac{\mathrm{d}^3}{\mathrm{d}\omega^3}\frac{\omega}{c}n(\omega). \tag{B6.4}$$

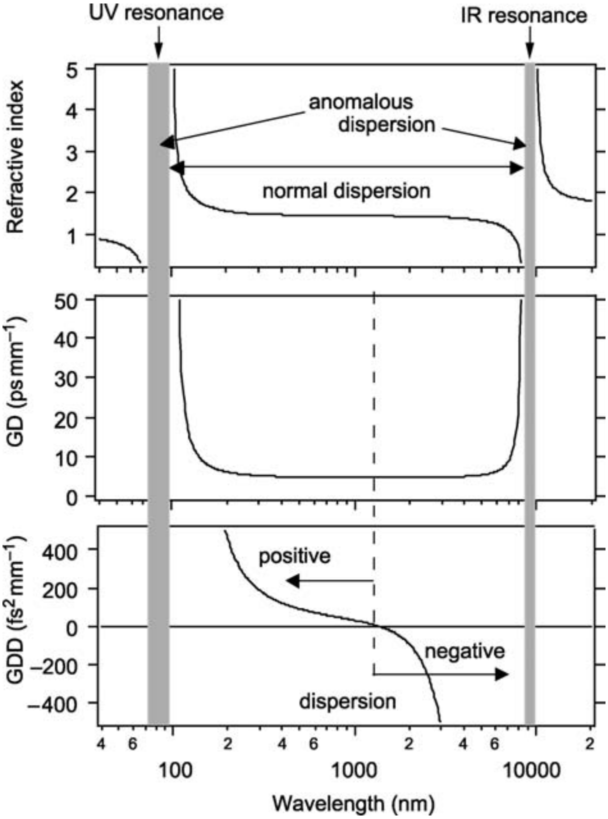

Figure B6.3. Material dispersion. The dispersion of a dielectric material (simplified model of fused silica) with a UV resonance at 80 nm and a vibronic IR resonance at 10 μm is schematically shown. The top figure shows the refractive index itself. For the entire range between the resonances, $\mathrm{d}n/\mathrm{d}\lambda \leq 0$ holds, which is referred to as normal dispersion. Only on resonance, we find anomalous dispersion $\mathrm{d}n/\mathrm{d}\lambda > 0$. The resulting group delay (GD) and group delay dispersion (GDD) are also shown. The GDD is the leading term responsible for pulse reshaping during propagation. Note that regions of positive and negative GDD do not coincide with those of normal and anomalous dispersion.

Positive and negative GDD must not be confused with normal or anomalous first-order dispersion, which refers to the sign of $\mathrm{d}n/\mathrm{d}\omega$. In a system with positive dispersion, blue spectral components will be retarded relative to red components. This causes a variation of the pulse carrier frequency with time, which is usually referred to as a chirp. Depending on the sign of the dispersion, one talks about positive or negative chirp. If no other mechanism is present, both signs of dispersion are totally equivalent in terms of pulse broadening. However, self-phase modulation will typically generate a positive chirp. As self-phase modulation also introduces spectral broadening, its combination with negative dispersion can be used for pulse compression schemes. Balancing of a positive chirp, generated by the nonlinear optical process of self-phase modulation, and negative material dispersion can lead to self-stabilizing optical pulses called *solitons*. These solitons can propagate over great distance through dispersive systems without changing their pulse shape [1, 37].

The discussion so far makes it clear that control and engineering of dispersion is of paramount importance for ultrafast optical systems and for telecommunications. Dispersion management is particularly important for long-distance fibre links [87, 88]. With ever-wider bandwidth becoming accessible, compensation of higher-order dispersion becomes a consideration [73]. Pulse compression is a major mechanism in ultrashort pulse generation [1, 35]. Passively mode-locked lasers (described above in its basic function) make extensive use of recompression of pulses, employing self-phase modulation in the laser crystal together with negative dispersion in the cavity [13, 40]. Only by fully exploiting this mechanism can the shortest pulses be generated. In general, an ultrafast pulse compressor can only be built with negative dispersion, which unfortunately is not a characteristic available for optical materials below 1 μm wavelength. This calls for alternative concepts to compensate for material dispersion and chirps caused by nonlinear optical mechanisms.

One can classify sources of dispersion into bulk or *material dispersion* (i.e. from homogeneous materials like glasses and crystals), *geometrical dispersion* (prism and grating arrangements), *dispersion from interferometric effects*, and *microstructured dispersion* (fibre Bragg gratings, chirped mirrors, chirped quasi-phase matched crystals, arrayed-waveguide gratings). Bulk dispersion has already been treated earlier. Reference data for many materials can be found in [103].

B6.3.2 Geometrical dispersion—prism and grating compressors

In the following, we will firstly address geometrical dispersion, as can be produced by prism [29, 81] and grating sequences [100]. When a short pulse is sent into a prism or on to a grating, its spectral components are angularly dispersed and sent into different directions (see figure B6.4). A second prism of opposite alignment can then be used to make the spectrally dispersed beams parallel again. On their propagation between both prisms, the outer rays have experienced a delay relative to the centre ones. It is important to note that this 'parabolic' spectral delay is equivalent to negative GDD. It can therefore be used to compensate positive material dispersion. Pairs of Brewster-cut prisms can compensate dispersion without introducing losses and have been very successfully used inside laser cavities [29].

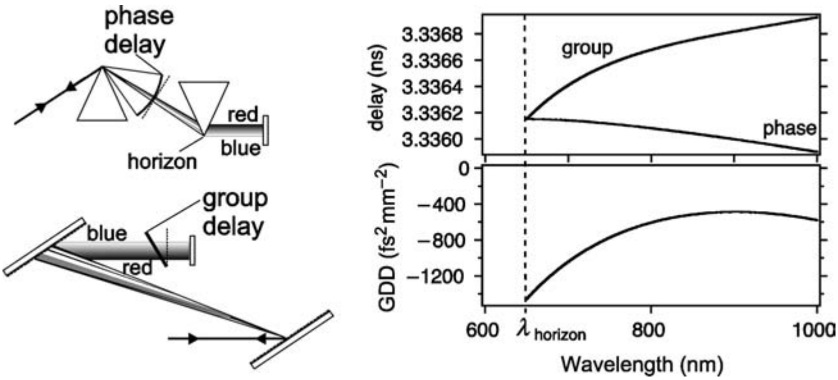

Figure B6.4. Geometric dispersion as caused by prism and grating sequences. Both prisms and gratings exhibit angular dispersion. A beam with broad input spectrum is dispersed into different direction of propagations, with all beams originating at one and the same location at the tip of the first prism. Positions with equal phase delay therefore describe a circle centred at the prism tip. To leading order, the phase delay relative to the centre beam is parabolic. The second prism only serves to render all beams parallel again. Typically, such an arrangement is used in double pass with a retroreflecting mirror as shown. The beam propagating exactly from tip to tip marks the short-wavelength horizon of the prism compressor. A parabolic phase delay front corresponds to a linear group delay (as shown in the grating compressor). An exact calculation for the group and phase delay of a prism compressor (fused silica Brewster prisms with 1 m apex distance) based on [81] is also shown. The resulting GDD is depicted below. Note the strong higher-order dispersion of this approach.

The major shortcoming of the geometrical approach, however, is that it introduces higher-order dispersion terms. For prism compressors, a careful choice of the prism material can give vanishing third-order dispersion in the wavelength range above 800 nm [59]. In particular, fused silica prism pairs introduce vanishing third-order aberrations in the Ti:sapphire wavelength range, which was used for the first demonstration of sub-10 fs pulse generation with this laser [119].

Grating sequences may be used instead for the same purpose (see figure B6.4). They are of extreme importance for CPA [65, 94], which allows for the amplification of pulses from the oscillator up to the millijoule or, at a reduced repetition rate, even to the joule level. To prevent optical damage in the amplifier chains, the oscillator pulse is stretched into the picosecond range before amplification. This reduces its peak power by the stretching ratio and also prevents significant nonlinear optical effects. After amplification, the pulse can then be recompressed into the femtosecond range, using a grating sequence with exactly the opposite dispersion of the stretcher plus any amplifier material dispersion. This restores a short pulse duration and allows for the generation of extremely high peak powers. The *stretcher* [120] employed in CPA is typically a grating sequence, which incorporates a telescope with -1 magnification. The telescope exactly inverts the dispersion of a compressor in all orders. The trick is now to slightly unbalance a stretcher and a matched compressor and to accommodate for material dispersion using the difference between stretcher and compressor dispersion. Second-order dispersion (equation (B6.2)) is adjusted by a difference in grating distances; third-order dispersion (equation (B6.3)) can be zeroed out by adjusting grating angles [60]. Finally, fourth-order aberrations can be compensated by the use of gratings having different line spacings [91]. Typically, aberrations of the telescope have to be compensated by using suitably corrected optics [14]. This approach has been used for the demonstration of 15 fs amplified pulse duration [5, 115]. Other approaches exist, which introduce a controlled amount of imaging aberration in the stretcher's telescope to achieve compensation up to fourth order [95].

B6.3.3 Microstructured dispersion—chirped mirrors and similar devices

One of the major shortcomings of the geometrical dispersion compensation approach is that, with the few exceptions already noted, they typically allow only for the compensation of second-order dispersion. Geometrical dispersion compensation schemes are therefore limited to approximately 100 THz bandwidth. However, the idea of the prism compressor can be readily extended to compensation of arbitrary dispersion: rather than using free-space propagation of laser beams, one could imagine coupling each and every spectral component into an individual fibre of precisely engineered length. A discrete approach would certainly be cumbersome, but integrated optical devices similar in function have been demonstrated and are referred to as *arrayed-waveguide gratings* (AWGs) [22, 86, 98]. The main use of these devices is channel multiplexing in telecom systems; nevertheless their use for dispersion compensation has recently been pointed out [73]. This type of device is shown in figure B6.5, and it is probably the most pictorial example for microstructured dispersion compensation, even though its application is not very widespread yet.

Rather than directly introducing a wavelength dependent propagation length, several other methods for arbitrary dispersion compensation are possible. These are also shown in figure B6.5. One of these approaches is *chirped mirrors* [53, 67, 92, 97]. These dielectric mirrors consist of alternating pairs of transparent high-index and low-index layers. The same effect can be achieved in optical fibres by modifying the refractive index with exposure to UV light through a periodic mask [43, 54]. The portions of the fibre that have been exposed to the short-wavelength radiation show a modified index of refraction. Even though the index differences are much smaller in the fibre grating approach, they provide the same functionality as a distributed Bragg reflector if the period of the index modulation is chirped along the fibre [25, 72]. A Bragg mirror reflects light when all Fresnel reflections at

Figure B6.5. Microstructured dispersion compensation. Shown are four different concepts that can compensate for arbitrarily shaped dispersion. Top: arrayed wave guides (AWGs). The coupling sections provide wavelength-dependent coupling into wave guides of different lengths. This makes the path length a designable function of wavelength. Second: chirped mirrors. Here the Bragg wavelength is varied over the mirror stack, making the penetration depth a function of wavelength. Impedance matching sections are required to reduce detrimental interferometric effects. Third: fibre Bragg gratings. They work similarly to chirped mirrors, but achieve impedance matching by a different apodization method, as shown on the right. Bottom: chirped grating quasi-phase matching. Here the input light is converted into the second harmonic in a quasi-phase-matched crystal. The pooling period of the crystal determines the conversion wavelength, which again allows control of the total group delay as a function of wavelength.

the high/low-index interfaces constructively interfere. This is the case when the optical thickness of all layers is chosen to be equal to a quarter of the light wavelength. Varying the optical layer thickness along the mirror structure then results in a dependence of the wavelength of peak reflectivity, the so-called Bragg wavelength λ_B, on the penetration depth z into the mirror structure. Chirping the mirror structure therefore allows the generation of a desired group delay GD(ω). It is obvious that the Bragg wavelength does not have to be varied linearly with penetration depth; in fact, any single-valued function can be tailored into the Bragg-wavelength chirp function.

It needs to be mentioned that this simple picture is often distorted by other contributions to the dispersion. In chirped mirrors, the top reflection at the interface to air gives rise to undesired interferences, which spoil the dispersion characteristics of the mirror and give rise to strong spectral fluctuations of the dispersion. A solution to this problem is impedance matching from the ambient medium to the mirror stack. In deposited mirror structures, a partial solution can be provided by *double-chirping* [53, 67]. Other methods have been proposed to overcome these dispersion fluctuations [66, 99]. In fibre optics, the UV exposure level can be slowly reduced to give a slow increase of the index modulation in the initial part of the fibre Bragg grating. This is referred to as *apodization* [3].

A novel approach to compensation of arbitrary dispersion is also offered by the method of *quasi-phase matching* (see figure B6.5). Here, the wavelength of conversion of a broadband nonlinear optical conversion process is varied with propagation distance. This means that short wavelengths are converted, e.g. into the second harmonic, at a different propagation distance compared to longer wavelengths. This offers a means to tailor processes like second-harmonic generation in order to support extremely broad bandwidths [32, 46].

B6.3.4 Interferometric effects—Gires–Tournois interferometers

The dispersion of chirped mirrors arises from change in Bragg wavelength of alternating high- and low-index layers. An alternative approach to achieve dispersion compensation is the use of a *Gires–Tournois interferometer* (GTI) [35]. Such an interferometer consists of a partial reflector and a high reflector. This combination reflects all incoming light and has a spectrally flat reflection amplitude response. Its phase response, however, exhibits resonances spaced by $\Delta\nu = c/2L$, similar to a Fabry–Perot interferometer. The spectral phase is a periodic function with regions of negative and positive dispersion. The GTI can be implemented from two air-spaced discrete components, but also using a monolithic mirror structure with a relatively thick spacer layer between quarter wave sections for the partial and high reflector. These structures have been successfully used in femtosecond oscillators [36, 42]. Compared to chirped mirrors, they typically exhibit a lower bandwidth, but they can provide larger values of negative GDD. Their manufacture is not quite so demanding as for chirped mirrors and they can also exhibit very high values of reflectivity [36]. This concept is therefore interesting for lasers having much greater intracavity dispersion and working at longer pulse durations than cavities with chirped mirrors.

B6.4 Measurement of optical waveforms with femtosecond resolution

B6.4.1 Autocorrelation

The major problem in monitoring or characterizing optical waveforms lies in the fact that optical pulses are among the shortest man-made events and there is no shorter controllable event that could be used to sample the waveform. Because of this fundamental limitation, all early characterization methods employed *autocorrelation* [19], a method which characterizes a laser pulse using one and the same pulse, firstly as the sample pulse and secondly as the pulse to be sampled. Using one replica of the input pulse as the reference sample, a second replica is delayed relative to the reference and then optically mixed (i.e. multiplied) with the reference pulse (figure B6.6). Technically, the multiplication of the two optical signals is done using a nonlinear optical effect such as *second-harmonic generation* (SHG) or *two-photon absorption* [78]. As a result, the autocorrelation trace

$$\mathrm{AC}(\delta t) = \int_{-\infty}^{\infty} I(t) I(t - \delta t)\,\mathrm{d}t \tag{B6.5}$$

is measured as a function of time, where $I(t) = E(t)E^{*}(t)$ is the optical intensity [41, 48]. This type of autocorrelation is called *background free*, as it will measure zero signal for large delays $\delta t \to \pm\infty$. A background-free autocorrelator uses a *noncollinear beam geometry*, in such a way that SHG requires one photon from each of the two beams while SHG from each individual beam is not phase matched. This background-free set-up allows for large dynamic ranges, but is typically not the preferred set-up in

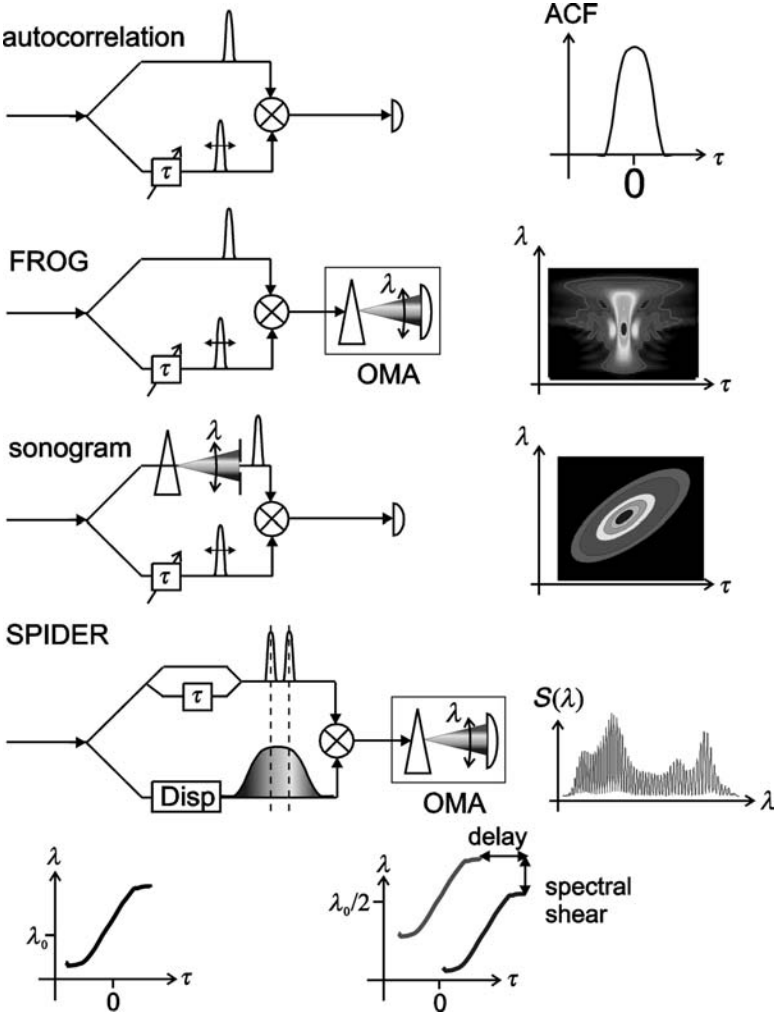

Figure B6.6. Pulse characterization methods. From top to bottom: autocorrelation. The input pulse is split into two identical replicas. One of them serves as the reference sample and is temporarily delayed relative to the other. Multiplication of both replicas in a process such as second-harmonic generation or two-photon absorption delivers the autocorrelation function versus delay time shown on the right. This allows a coarse estimation of the pulse duration. Frequency-resolved optical gating (FROG) additionally spectrally disperses the autocorrelation function and delivers a wavelength-resolved autocorrelation function called a FROG trace. Other than simple autocorrelation, FROG allows complete reconstruction of the input pulse profile. Related is the sonogram technique, which spectrally resolves one of the input replicas instead. Spectral phase interferometry for direct electric-field reconstruction (SPIDER) also creates two replicas of the input pulse at a fixed delay and mixes these two with a chirped copy of the input pulse. The resulting two upconverted replicas are spectrally sheared with respect to each other. The resulting spectral interference pattern $S(\lambda)$ allows reconstruction of the spectral phase of the input pulse.

the sub-10 fs regime. In a *noncollinear set-up*, an additional problem occurs due to '*beam smearing*' caused by the finite crossing angle of the two beams [8]. Therefore a *collinear set-up* is preferred. This then yields the *interferometric autocorrelation* trace [20]:

$$\mathrm{IAC}(\delta t) = \int_{-\infty}^{\infty} \left|\left[E(t) + E(t - \delta t)\right]^2\right|^2 \mathrm{d}t. \tag{B6.6}$$

Unfortunately, no way exists to retrieve the original pulse profile from any measured autocorrelation traces without additional knowledge. Being inspired by an expected theoretical description of the mode-locking process, one can sometimes assume an expected pulse shape, and then retrieval is simple. This is, unfortunately, not a valid assumption in the sub-10 fs regime with its complex pulse shapes. In this regime, simple analytical functions can no longer be assumed for *decorrelation* of the measured autocorrelation function. Additionally, the sub-10 fs regime is very demanding, and pulse shaping by spectral filtering or dispersion in the beam splitters and nonlinear crystal have to be kept to a minimum. Wherever possible, this regime calls for the use of metal-coated reflective optics.

Methods have been discussed to solve the problem of decorrelation [9, 69]. Decorrelation methods require additional experimental information, which, in the simplest form, can be provided by a simultaneous measurement of the power spectrum of the laser. Decorrelation methods employ a computer optimization strategy to find a simultaneous fit to the measured spectrum and autocorrelation. This removes the arbitrariness of assuming a particular pulse shape for pulse retrieval, but, for reliable operation, requires data with excellent signal-to-noise ratio. A practical example based on decorrelation of the IAC trace (equation (B6.6)) and the spectrum is shown in figure B6.7.

B6.4.2 Frequency-resolved optical gating and sonogram

We shall now describe advanced methods called *frequency-resolved optical gating* (FROG) and sonogram to determine the pulse shape. One can conceptually understand the FROG method [101, 102] and the *sonogram technique* [15, 77] as a further extension of the decorrelation methods. For FROG, the autocorrelation of equation (B6.5) is spectrally resolved for each and every delay step (see figure B6.6). The autocorrelation is then sampled on a $\{\delta t, \omega\}$ grid. The autocorrelation spectrogram of the electric field E of the pulse

$$I_{\mathrm{FROG}}^{\mathrm{SHG}}(\delta t, \omega) = \left|\int_{-\infty}^{+\infty} E(t)E(t - \delta t)\exp(-\mathrm{i}\omega t)\mathrm{d}t\right|^2 \tag{B6.7}$$

is called a *FROG trace*. The sonogram technique is very similar in principle, but cuts out a spectral slice of one of the two replica pulses using a narrowband filter function $F(\Omega - \omega)$ centred at a frequency offset Ω from the pulse centre frequency. This filtered replica is then crosscorrelated with the other unfiltered replica yielding the *sonogram trace*

$$I_{\mathrm{sonogram}}(\delta t, \omega) = \left|\int_{-\infty}^{+\infty} E(\Omega)F(\Omega - \omega)\exp(-\mathrm{i}\Omega t)\mathrm{d}\Omega\right|^2. \tag{B6.8}$$

Both these techniques, FROG and sonogram, record data on a two-dimensional array, rather than recording two one-dimensional data traces as in the decorrelation. Examples of such measurements are shown in figure B6.7. The excess data give rise to an increased robustness of the two-dimensional methods, which result in an improved immunity towards noise. Moreover, FROG and sonogram provide built-in consistency checks (marginals), which allow one to detect experimental flaws, e.g. due to limited phase-matching bandwidth or spectral filtering in the set-up. Beyond SHG-FROG, which can be

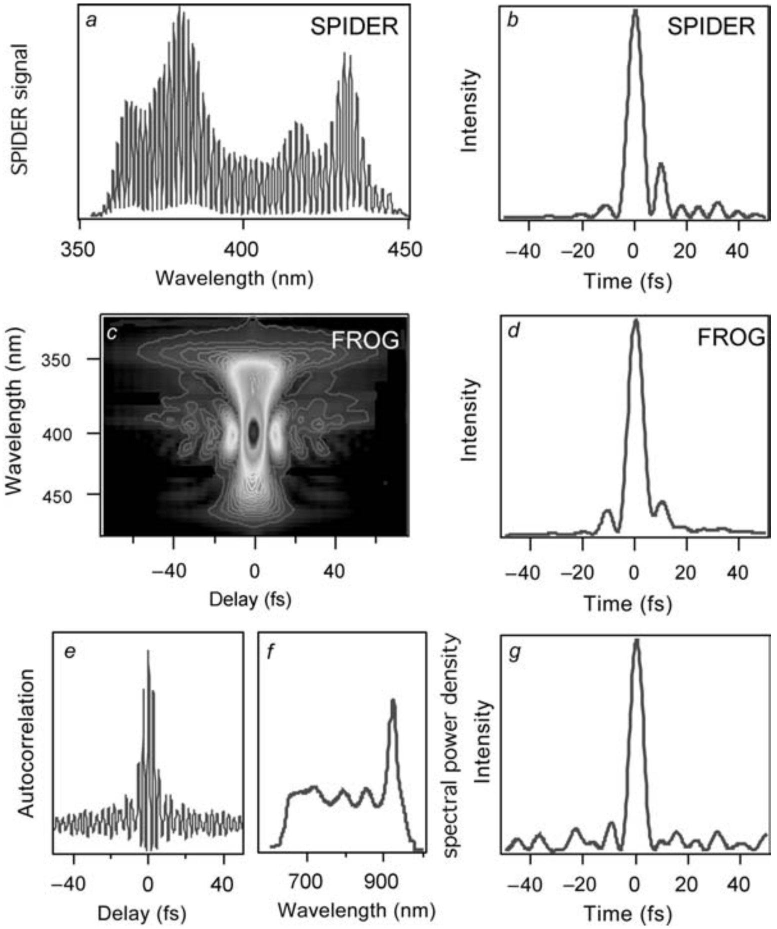

Figure B6.7. Examples of measurements of pulses from a Ti:sapphire laser. Top left: SPIDER measurement and reconstructed pulse [34]. Below: FROG trace and reconstructed pulse measured under nearly identical conditions at the same laser [33]. Bottom part: iteratively reconstructed pulse shape from interferometric autocorrelation and power spectrum of the laser [96]. Note that all three measurements gave compatible pulse durations of about 6 fs or slightly below.

simply understood as an extension of autocorrelation methods, a wide variety of FROG methods have been described. Most notable is *self-diffraction FROG (SD FROG)*, which is very important for measurements on amplifier systems [51]. Here the FROG trace is given by

$$I_{\mathrm{FROG}}^{\mathrm{SD}}(\delta t, \omega) = \left| \int_{-\infty}^{+\infty} E(t)^2 E(t - \delta t)^* \exp(-\mathrm{i}\omega t)\mathrm{d}t \right|^2. \tag{B6.9}$$

The main advantage of SD FROG is that it cannot suffer from limited phase-matching bandwidths as the SHG variant does and can be used in the deep UV. SD FROG generates a sinusoidal intensity pattern in a dielectric medium by crossing two beams under a small angle. This pattern creates an index grating via the Kerr effect and causes self-diffraction of both beams. One of the self-diffracted beams is then spectrally resolved and detected, similar to the SHG variant. This FROG variant, however, requires significantly higher pulse energies and cannot be used for the oscillator-level pulse energies. FROG can also be used in a cross-correlation variant to characterize one unknown pulse with the aid of another known one. This method is called XFROG and is of particular interest for the characterization of pulses in the UV and infrared spectral range [62, 63]. This variant of FROG has been demonstrated with the extremely complex pulse shapes of white-light continua generated in microstructure fibres [112].

Similar to the one-dimensional methods, FROG and the sonogram technique use an optimization strategy for pulse retrieval. Mathematically, it can be strictly shown that knowledge of the FROG trace of a pulse unambiguously defines the pulse's amplitude and phase except for *time reversal*, i.e. one does not know what is the front and what is the back of the pulse. This ambiguity can be removed with an additional measurement. In contrast to the one-dimensional case, a solution always exists, even though it can be a time-consuming computation to find this solution. Recent improvements of the FROG technique have led to very sophisticated retrieval procedures, which can rapidly retrieve the pulse from the FROG trace and allow update rates up to several hertz [50].

B6.4.3 Spectral phase interferometry for direct electric field reconstruction

All techniques described so far involve auto- or crosscorrelation, together with spectral resolution to remove any ambiguity in the pulse reconstruction. Recently, a completely different technique based on *spectral interferometry* [30] emerged for the characterization of femtosecond pulses. This technique is called *spectral phase interferometry for direct electric-field reconstruction* (SPIDER) [45]. The spectrum $S(\omega)$ of two identical pulses $I(t)$ with respective temporal delay ΔT is the spectrum of the single pulse $\tilde{I}(\omega)$, multiplied by a spectrally oscillating term. Measuring the spectral fringe spacing $\Delta\omega = 2\pi/\Delta T$ of $S(\omega)$ allows determination of the temporal spacing ΔT of the two pulses. If these two pulses are identical, the fringe spacing of $S(\omega)$ is also strictly constant over the entire spectrum. A spectral interferogram between a chirped and an unchirped pulse, however, allows not only determination of the delay between the pulses, but also the difference in chirp between the two pulses (figure B6.6). This is the fundamental idea of spectral interferometry. SPIDER generates two delayed replicas of the pulse to be measured. It also generates a third pulse from the input pulse. The third is strongly chirped by sending it through a grating sequence, or through a highly dispersive glass block. The dispersion creates a group delay between the red and blue Fourier components of the third pulse (equation (B6.1)). This chirped pulse is then used to frequency-shift the two replicas of the input pulse using sum-frequency generation. Because of their temporal delay and the strong chirp on the upconverter pulse, both replicas are shifted in frequency by different amounts. Measuring the spectral interferogram of the upconverted replicas allows sampling their relative phase delay as a function of frequency. This is now exactly the information needed to reconstruct the spectral phase. Together with an independent measurement of the amplitude spectrum, this yields a complete description of the pulse. Again, this technique has been demonstrated using pulses from a Ti:sapphire laser (see figure B6.7).

The SPIDER method has been demonstrated with sub-6 fs pulses from Ti:sapphire lasers, with compressed pulses from an amplifier system [21] and with optical parametric amplifiers [116]. One of the major advantages of SPIDER is that it offers a direct reconstruction of the pulse profile, rather than requiring computationally intensive optimization strategies. Typically, the acquisition speed is only limited by the read-out speed of the CCD array used in the spectrograph. Acquisition and reconstruction rates of up to 20 Hz have been demonstrated [83], which makes SPIDER an ideal online tool for aligning complex femtosecond laser systems. SPIDER can also be used in combination with pulse shapers [10]. Other than evolutionary strategies, which try to compensate phase distortions of a pulse by optimizing, e.g. its second-harmonic efficiency, SPIDER provides enough information to set directly the spectral phase to generate a bandwidth-limited pulse.

Given the much more concise data of the SPIDER method, this should allow for a direct and much more rapid phase adaption than lengthy evolutionary optimization strategies. The rapid data acquisition capabilities of the SPIDER method can also be exploited in another way to measure spatially resolved temporal pulse profiles. SPIDER can be adapted to spatially resolve measurements using an imaging spectrograph together with a two-dimensional array. This set-up spatially resolves temporal pulse profiles along the axis defined by the entrance slit of the spectrograph. Rather than the methods discussed so far which integrate over the spatial beam profile, the spatial resolution enables building of an ultrafast camera. Such an ultrafast camera can detect differences in pulse width between beam centre and off-centre regions.

Several methods have been introduced to carry the functionality of a simple photo-diode well into the femtosecond range. The most concise diagnosis is offered by FROG and SPIDER, which set a new standard for the determination of pulse parameters. It needs to be emphasized that the additional information provided by either FROG or SPIDER can directly help to improve pulse generation schemes. Baltuska *et al* designed the mirrors, which were used in the generation of some of the shortest pulses generated to date, according to earlier measurements of the uncompressed pulse [7]. Generally, it depends on the experimental constraints whether to prefer FROG, sonogram, or SPIDER for pulse characterization. All these methods are very well adapted to the particular challenges of femtosecond pulse characterization.

B6.5 Phase and amplitude modulation of short optical pulses

Grating or prism sequences, such as those introduced in section B6.3.2, can also be employed to adjust dispersion in an adaptive way. A very common set-up is the so-called *4f zero dispersion delay line* shown in figure B6.8 [108, 109]. This set-up is very similar to the previously described stretcher, but operates at exactly −1 magnification equivalent to an effective grating distance of zero. A first grating disperses the input pulse, then a lens at distance *f* from the grating creates a spectrally dispersed picture of the input. A second identical lens–grating system reimages the spectrally dispersed picture back onto one point at a distance *f* from the second grating. Provided proper alignment, this set-up is totally neutral in terms of dispersion, i.e. the shape of a pulse propagating through a 4*f* assembly is not modified. However, as the pulse is spectrally dispersed in the Fourier plane in the centre of the set-up, a phase or amplitude modulator array at this location allows manipulation of the waveform.

B6.5.1 Liquid crystal arrays

Several approaches exist for the technical implementation of the modulator array. These can be categorized into phase, amplitude and combined amplitude/phase modulators. Another important aspect is pixelation and the number of pixels or degrees of freedom of such a device. Historically, *liquid crystal arrays* were first used in a 4*f* shaper [109]. Liquid crystals can be used for *phase modulators*, and in combination with polarizers they may also serve as *amplitude modulators*. Combined devices consist of two liquid crystal arrays and polarizers and allow the control of both amplitude and phase. Most devices are pixelated with pixel numbers between 128 [110] and 640 [93]. The pixels typically consist of stripes of a few 10 μm width and can be individually electronically addressed. Liquid crystal phase masks have been used for a variety of applications. Used in a phase shaper, they can compensate for arbitrary dispersion. In this regard, the shaper can be understood as a programmable, microstructured dispersive device. It is particularly useful when dispersion is not very well known or where it may change over time. Recently, as an example, an adaptive pulse compressor was used to compress pulses to sub-6 fs pulse duration [113, 114]. Despite the capability to impose an arbitrary spectral modulation on the pulse, one has to emphasize that a phase modulator can never compress pulses beyond the limit imposed by a Fourier transform of the spectral amplitude profile.

B6.5.2 Acousto-optic pulse shaping

The same functionality can be achieved with an *acousto-optic approach*. The acousto-optic device replaces the liquid crystal array and serves both as amplitude and phase modulator. The acoustic wave transmitted into the acousto-optic modulator is generated by an arbitrary waveform generator, synchronized with the kilohertz repetition rate of the laser source. This acoustic wave generates an index pattern in the acousto-optic crystal. This pattern determines the amplitude and phase of spectral components which are diffracted into the first order of the acousto-optic deflector [26, 44, 104]; see figure B6.8. The main application of this technique is with amplified *kilohertz-repetition-rate* pulses for amplitude shaping. A very similar device, the so-called '*dazzler*', was recently introduced [106]. Here, the interaction of acoustic wave and optical wave is collinear rather than perpendicular. The acoustic wave transfers the input pulse entering in one axis of an acousto-optic crystal into the perpendicular axis. Again, an arbitrary waveform allows one to control the location and efficiency for each and every spectral component of the pulse. This allows compensation for the dispersion and spectral narrowing effects in amplifiers [106]. Note that both acousto-optic approaches are suited only for kilohertz repetition rates.

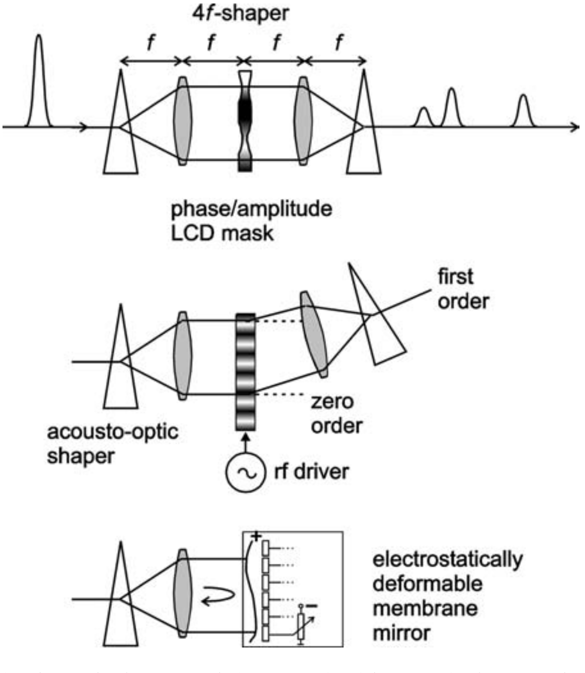

Figure B6.8. Ultrafast amplitude and phase modulators. Liquid crystal phase and amplitude shaper. The input pulse is spectrally dispersed and imaged onto the array with an adjustable retardation/absorption profile. This allows the generation of controllable pulse sequences from an input pulse. The same function can also be achieved by an acousto-optic device. An ultrasonic wave is written into an acousto-optic deflector, where control of the acoustic waveform allows control of the deflection of the optical Fourier components into the first order of the device. Phase control can also be achieved with micro-machined mirror membranes, which can be electrostatically controlled.

B6.5.3 Flexible membrane mirrors

A further approach to phase shaping is to place a mirror with adjustable shape in the Fourier plane of the 4*f* set-up. Such *flexible membrane mirrors* [105] consist of a thin metal-coated silicon nitride membrane. The membrane is suspended over a number of planar electrodes, which act as *electrostatic actuators* (figure B6.8). The membrane is electrically grounded, and a voltage is applied to the actuators, which locally deforms the membrane shape. Typically, these devices have around 10–20 electrodes, and deformations of a few microns can be achieved. For applications in dispersion compensation this complexity is normally more than sufficient. Pulses as short as 7 fs have been generated with this approach [4, 10, 117].

B6.6 Summary

In this chapter, we have highlighted methods to generate and measure ultrafast optical pulses, thereby circumventing the fundamental electronic bandwidth limitations in conventional optoelectronics. The methods described allow for the generation and the characterization of optical pulses much shorter than a picosecond. We have examined propagation effects in optical media and their compensation. Finally, we also addressed set-ups that allow for a manipulation of amplitude and phase of an optical pulse with femtosecond temporal resolution. It is important to note that all these methods are based on rather conventional and relatively slow optoelectronic building blocks, such as cw laser pump diodes for light generation, photodiodes, photomultipliers, or CCD cameras for photodetection, and liquid crystal arrays for the modulation of optical short pulses. The trick lies in exploiting physical optics either by using an ultrafast nonlinear optical effect or by wavelength-division multiplexing. This allows for ultrafast control, without having to control or measure electronic currents on a femtosecond time scale. Telecommunications is a paradigm for the possibilities enabled by optical multiplexing. Transferring more and more of the functionality of a communication network into photonic rather than electronic components has the potential for greatly increased capacities in the near future. Elementary ultrafast optoelectronic building blocks have been introduced in this chapter. These sub-systems open up an avenue for many more applications of photonics in the ultrafast realm.

B7
Integrated optics

Nikolaus Boos and Christian Lerminiaux

B7.1 Introduction

Integrated optics, which has been a research topic for about 20 years, deals with compact single function devices and the integration of multiple optical functionalities on a single chip or into a single package. Ultimately, this is seen as a way to reduce footprint and cost with respect to conventional bulk and micro-optic components, and also to obtain components with increased performance or even new functionalities.

The fabrication technologies have benefited from the experience in the semiconductor industry. However, there are a few main differences between integrated electronics and integrated optics: routing of photons on a chip needs structures with sizes of the order of millimetres, which results in a lower circuit density with respect to electronics. Also, for a given optical function there may be one preferred material, which currently puts a limitation on the development and deployment of monolithic integrated optical circuits. Hybrid integration combines the best materials on a common platform and represents an intermediate solution to this problem. Both monolithic and hybrid integration approaches will probably coexist depending on application, performance and cost.

At present, integrated optics is the technology of choice for a few functions in the optical network. With the increasing maturity of the fabrication technology and the growth in bandwidth and ongoing standardization of optical networks, integrated optic devices will become more cost effective than discrete components.

This chapter is organized as follows: we will start with a description of waveguides and basic elements for phase and polarization control, waveguide couplers and interferometers.

Fabrication processes and properties of common opto-electronic materials will be sketched in section B7.3, followed by device packaging and the techniques for function and material integration.

Section B7.5 gives a brief overview of optical networks and the functions therein, followed by a selection of recent publications on integrated devices to realize these network elements. We will conclude with all-optical components, which will slowly replace electronics in future generation networks.

B7.2 The integrated optics toolbox—waveguides and basic devices

B7.2.1 Waveguides and requirements

Planar optical waveguides are the keys for the construction of integrated optical circuits. In chapters A1.5 and A2.4 a detailed formalism for the propagation of an electromagnetic wave in dielectric media based on Maxwell's equations and the boundary conditions for the electrical and magnetic fields has been developed for:

- Slab waveguides, in which light is confined in only one direction.
- Rectangular waveguides, in which light is confined in two directions. As an exact analytical solution for the electric and magnetic fields cannot be given in this case, a variety of approximation and numerical methods [1, 2] exist. For example, tightly confined modes are needed for low threshold III–V lasers or merely guiding light efficiently from one point to another point, and they represent the foundation of planar integrated optics. Cross-sections for commonly used rectangular waveguides are shown in figure B7.1.

One basic requirement for large-scale integration is that the overall device losses should be low, which in turn translates into an upper limit for the propagation losses through straight and curved waveguides. Exact values depend on the functionality and final device size, but typically $< 0.1\,\mathrm{dB\,cm^{-1}}$ is needed for silica waveguides. There are essentially four loss contributions:

- Absorption in the material through atomic/molecular transitions in amorphous materials, and through excitation of electrons from the valence to the conduction band (interband absorption), or electrons within the conduction band (free carrier absorption) in semiconductor materials.
- Scattering occurs at defects or material inhomogeneities within the guide, or through scattering at the surfaces through roughness induced in the waveguide fabrication process.
- Radiation losses arise in waveguide bends with constant bend radius and in waveguides with discontinuities in the bend radius (transition losses). Bending losses can be minimized by increasing the bend radius R and confining the mode well by increasing the relative index contrast Δ

  $$\Delta = (n_{\mathrm{core}} - n_{\mathrm{clad}})/n_{\mathrm{core}}$$

  Transition losses can be minimized through a lateral offset between waveguide sections or by varying the bend radius adiabatically.
- Substrate leakage—as will be mentioned in section B7.3.1, silica waveguides are commonly fabricated on a silicon substrate, from which they are optically separated via a buffer layer. If this buffer layer is not thick enough, the high index of silicon gives rise to leakage of light from the core into the substrate. As a rule of thumb, the buffer layer should be at least twice as thick as the core layer.

Other losses that play a role in interconnecting optical building blocks arise from a mismatch of the respective mode fields as well as angular or lateral misalignments (see section B7.4.1).

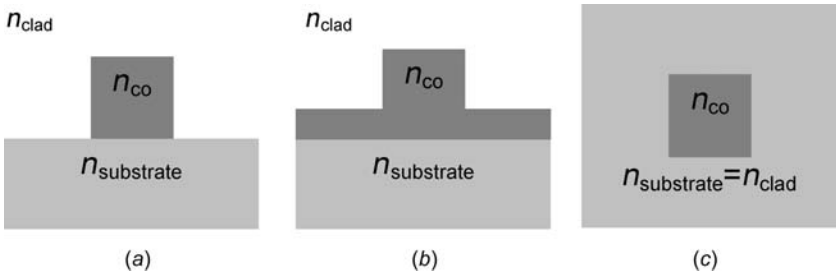

Figure B7.1. Cross-sections through common waveguides. (*a*) The raised strip guide is formed by an etching process removing the higher index material n_{co} on both sides of the guide. (*b*) The rib or ridge waveguide is similar to (*a*), except that the higher index material n_{co} is not completely removed. (*c*) The channel waveguide can be formed by ion implantation, ion exchange/diffusion processes or over-cladding a waveguide as depicted in (*a*).

In the remainder of this section we will give an overview on

- Dynamic index control in waveguides.
- Waveguide couplers and power splitters.
- Interferometric devices—*Mach–Zehnder interferometers*, the *arrayed waveguide grating* (AWG) and *ring resonators*.
- Modelling of integrated functions.

B7.2.2 Dynamic phase and polarization control in optical waveguides

Functional devices often need a dynamic control of the properties of the guided mode (effective index, polarization state), and depending on the application different physical phenomena are used.

The *thermo-optic effect* uses the temperature dependence of the waveguide index $\mathrm{d}n/\mathrm{d}T$ to obtain a phase shift

$$\Delta\phi = \frac{2\pi}{\lambda}\frac{\mathrm{d}n}{\mathrm{d}T}\Delta T \cdot L$$

where L is the length over which the waveguide temperature is changed by ΔT.

In practice, this effect is used in silica ($\mathrm{d}n/\mathrm{d}T = 1\times10^{-5}\,\mathrm{K}^{-1}$ [3]), polymer ($\mathrm{d}n/\mathrm{d}T = -2\cdots-3\times10^{-4}\,\mathrm{K}^{-1}$ [4]), Si ($1.8\times10^{-4}\,\mathrm{K}^{-1}$ [5]) or lithium niobate ($\mathrm{LiNbO_3}$, $\mathrm{d}n/\mathrm{d}T = 5\times10^{-5}\,\mathrm{K}^{-1}$) waveguides for switching or modulating devices with tuning speeds of the order of milliseconds (polymer, silica) to microseconds (silicon).

Electro-optic effects

- Current injection into a semiconductor junction or application of a reverse voltage changes the electron/hole density in the valence and conduction bands of a semiconductor. As a consequence, the absorption for photons with a wavelength close to the band gap energy will change, which in turn results in an index variation, since both parameters are linked through the Kramers–Kronig relations [6, 7].
- Application of an electric field to a dielectric medium leads to an instantaneous induced polarization P [8]

$$\boldsymbol{P} = \varepsilon_0{}^*(\chi(1)\boldsymbol{E} + \chi(2)\boldsymbol{EE} + \chi(3)\boldsymbol{EEE} + \cdots) \equiv P_{\mathrm{Linear}} + P_{\mathrm{Nonlinear}}$$

where $\chi(i)$ are the tensors of the linear ($i = 1$), quadratic ($i = 2$) and higher order susceptibilities. $\chi(1)$ accounts for linear phenomena like absorption and reflection.

The second order susceptibility $\chi(2)$ in materials without inversion symmetry leads to the linear electro-optic (Pockels) effect, and the associated index change is usually expressed as

$$\Delta\left(\frac{1}{n^2}\right)_i = \sum_{j=1\cdots3} r_{ij}E_j$$

with $j = 1\cdots3$ denoting x-, y- and z-axes and r_{ij} being the electro-optic tensor.

Lithium niobate ($\mathrm{LiNbO_3}$, $r_{33} = 30.9\,\mathrm{pm\,V^{-1}}$ [9]) is widely used for high speed modulation and switching. Induced $\chi(2)$ is possible through poling, which has been reported in silica glasses ($r = 1\,\mathrm{pm\,V^{-1}}$ [10]) and polymer ($r_{33} = 13\,\mathrm{pm\,V^{-1}}$ [11]).

Third order susceptibility $\chi(3)$ allows the control of the refractive index through the electrical field of a second optical signal (all-optical processing). The index change can be parametrized as

$$\Delta n = n_2 I$$

with I being the power density of the optical control signal. In silica, n_2 is of the order of $10^{-16}\,\mathrm{cm}^2\,\mathrm{W}^{-1}$ [10, 8], and therefore is too small for integrated devices. On the other hand, semiconductors exhibit a very large nonlinearity (n_2 of the order of 10^5–$10^6\,\mathrm{cm}^2\,\mathrm{W}^{-1}$) used for switching (section B7.5.4) and all-optical signal processing (section B7.5.6).

We also refer to chapters B1.2, B4 and B6 for a more detailed treatment of electro-optic control.

The *acousto-optic* effect: mechanical strain from a surface or volume acoustic wave induces index changes, which in turn alter the phase of light. Depending on the interaction length between the acoustic wave and the optical mode, one distinguishes between Raman–Nath (short interaction length) and Bragg type modulators.

Magneto-optic control uses the Faraday effect, i.e. linearly polarized light is rotated in the presence of a magnetic field. The Faraday effect can be used for polarization-splitting and nonreciprocal devices such as optical isolators and circulators.

B7.2.3 Waveguide couplers and power splitters

Waveguide couplers and power splitters are needed for the construction of interferometric devices, which will be described in section B7.2.4.

Directional couplers: when waveguides are brought into proximity in such a way that their mode fields partially overlap, power is transferred from one waveguide to another (figure B7.2). For identical lossless waveguides and co-propagating modes, the power coupling ratio is given by (I_0 is the incoming

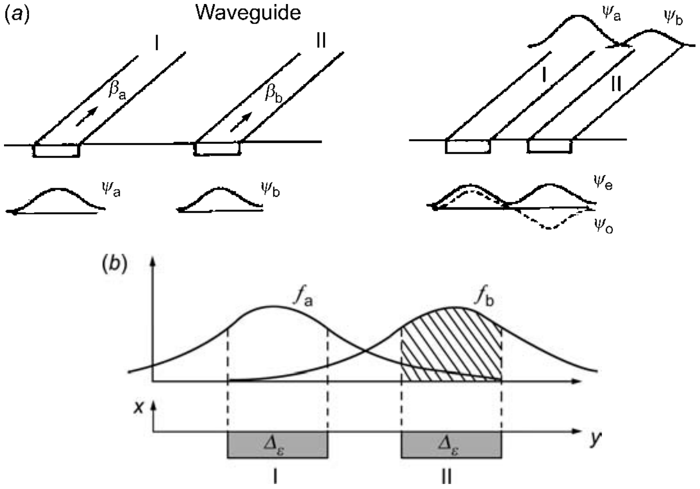

Figure B7.2. Directional coupler [13]. (*a*) Propagating modes in two uncoupled (left) and coupled (right) waveguides. In analogy to a coupled pendulum, the coupled system has both symmetric ψ_e and asymmetric ψ_o fundamental modes (having different propagation constants) which are excited and lead to a periodic energy exchange between modes ψ_a and ψ_b. (*b*) Cross section through a directional coupler. The coupling coefficient κ is proportional to the overlap integral of the shaded areas. Reproduced by permission of The McGraw-Hill Companies.

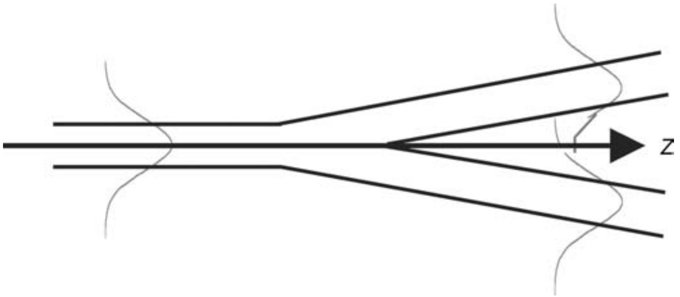

Figure B7.3. Y-splitter—the fundamental mode propagating in the left input waveguide will be equally split between the two output guides. For a symmetric device, the splitting ratio is 50%/50% (3 dB). 2^n splitter trees can be obtained through cascading of Y-splitters.

power, I_1 and I_2 are the powers at the end of the coupler)

$$I_1/I_0 = \sin^2(\kappa z) \equiv \sin^2\left(\frac{\pi}{2L_c}z\right) \quad I_2/I_0 = \cos^2(\kappa z) \equiv \cos^2\left(\frac{\pi}{2L_c}z\right)$$

The coupling coefficient κ (figure B7.2(*b*)) increases with the decreasing gap between the coupled waveguides, and by adjusting the ratio of propagation length z to coupling length L_c (defined as the length needed for complete power transfer), any splitting ratio can be designed. However, the wavelength dependent mode field diameter makes the coupling ratio also wavelength dependent; this can be avoided in more sophisticated designs with tapered asymmetric coupling regions [12]. For a treatment of counter-propagating modes, see reference [13].

On the other hand, the operation of Y-splitters (figure B7.3) depends only on their symmetry and thus the splitting ratio is wavelength independent. Power splitters (1×2^n) can be built by concatenation of Y-splitters.

A simpler way to obtain a large number of input or output ports is the star coupler [14], in which a multimode slab waveguide is placed between a fan of input and output waveguides (figure B7.4).

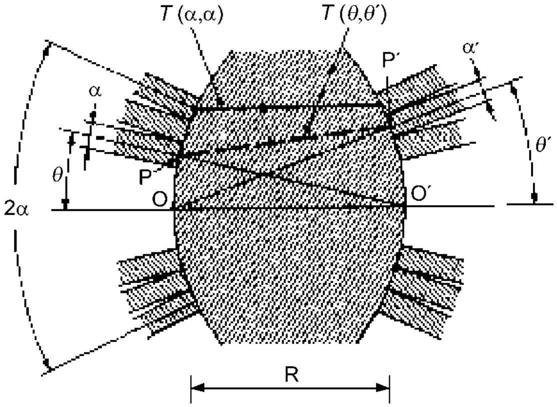

Figure B7.4. Star coupler [14], consisting of an array of input and output waveguides interconnected by a multimode slab guide. Light entering the multimode slab waveguide will diffract and excite fundamental and higher order modes, resulting in mixing and excitation of the guided modes of the output waveguide array. Reproduced by permission of IEEE.

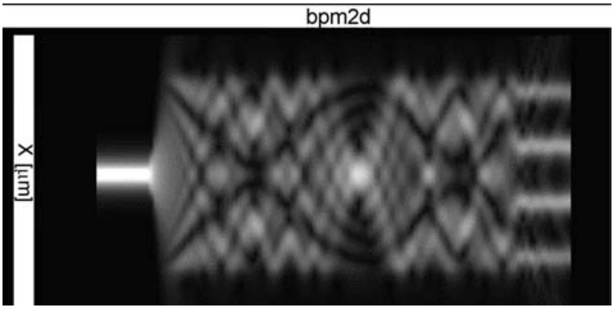

Figure B7.5. Multimode interference MMI coupler [16]. The diagram shows the amplitude distribution in a 1 × 4 splitter as obtained from beam propagation modelling (BPM) [196]. Light entering from the left will excite multiple modes in the middle section, which interfere and create local minima and maxima. Finally, constructive interference is obtained in multiple focal points, and the fundamental mode in the output waveguides is excited.

A uniform splitting ratio is achieved by adequate mutual coupling between input waveguides, and couplers with up to 144 × 144 ports have been published [15].

Multimode interference couplers [16] are based on self-imaging, i.e. the fact that single or multiple images are produced when higher order modes are excited within a wide multimode waveguide, and these modes interfere (constructively or destructively) along the propagation direction of the light. An example of a 1 × 4 splitter is depicted in figure B7.5.

B7.2.4 Interferometric devices—Mach–Zehnder interferometers, the arrayed waveguide grating, ring resonators

The Mach–Zehnder interferometer is a key element for filters, switches and modulators, which will be discussed later in section B7.5. A schematic is shown in figure B7.6—light is split in a first directional

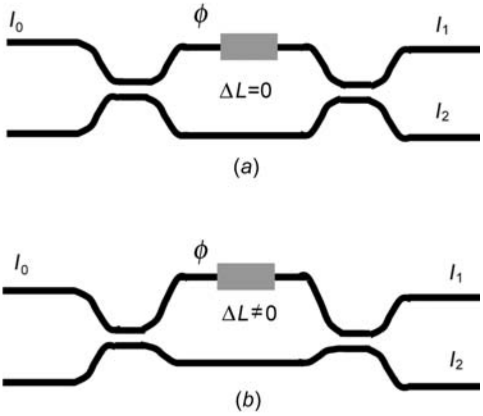

Figure B7.6. Symmetric (*a*) and asymmetric (*b*) Mach–Zehnder interferometer consisting of two directional couplers, two interferometer arms and a dynamic phase shifter. The path from input 0 to output 1 is called 'bar', the path 0 → 2 'cross'.

coupler, passes through the delay lines and then recombines. The transmitted optical power is a function of the phase difference, and is given by

$$I_1/I_0 = \sin^2(\phi/2) \ \text{‘bar’ path}$$

$$I_2/I_0 = \cos^2(\phi/2) \ \text{‘cross’ path}$$

in the case of perfect 50%/50% (3 dB) directional couplers.

For the ‘cross’ path, there will be a constructive interference for $\phi = m{\cdot}2\pi$ and destructive interference for $\phi = (2m+1)\pi$. Tunable devices can be made by dynamic control of ϕ via the effects as described in section B7.2.2.

For broadband devices (i.e. devices having a flat spectral response over a wide passband), such as switches, the phase difference will be within $[0, \pi]$ (‘symmetric MZI’). If spectral features within the passband are desired (as in the case of the equalizing filters described in B7.5.2), the phase difference will rather be chosen to be within $[m{\cdot}2\pi, (m+1)2\pi]$. The fixed part $\phi = m{\cdot}2\pi$ will be generated by a fixed delay of geometrical length in one arm (‘asymmetric MZI’)

$$\Delta L = \frac{m\lambda}{n}$$

and the additional 2π will be kept tunable. The device has a periodic response, which will be repeated for every free spectral range (FSR)

$$\text{FSR} \equiv \Delta\lambda = \frac{n\Delta L}{m(m+1)}$$

The arrayed waveguide grating (AWG) is the analogue to a bulk diffraction grating and can be used in optical networks as a multiplexer/demultiplexer (figure B7.7(*a*)) in wavelength division multiplexed (WDM) transmission systems, or as a wavelength selective building block for add–drop devices or optical crossconnects (OXCs) (sections B7.5 and C1).

The AWG [17, 18] (figure B7.7(*b*)) consists of input/output waveguides, two star couplers and an array of waveguides with a constant path length difference ΔL between adjacent guides. Light coming into the first ‘free propagating region’ (FPR) radiates and excites all waveguides in the grating. After propagation through the array, the light will constructively interfere in one focal point of the second star coupler if the grating condition

$$m\lambda = n\Delta L$$

is fulfilled. n is the effective index of the mode guided in the waveguide array, λ is the wavelength, m is the grating order. The location of the focal point depends on the wavelength as the phase delay between adjacent guides is given by $\Delta L/\lambda$, and the passbands have a Gaussian shape as shown in figure B7.7(*c*).

A ring resonator consists of couplers and a feedback loop of geometrical length L and is the analogue to the free-space Fabry–Perot interferometer.

The two-port resonator shown in figure B7.8(*a*) is the simplest case: it has a unity power transmission and a phase response, making it useful in the synthesis of phase compensating devices [100].

Open ring resonators (figure B7.8(*c*)) have resonances in both amplitude and phase response and may be used in $N \times N$ switch matrices [19] or for bistable devices having a nonlinear medium in the feedback loop [2].

(*b*) Schematic configuration of an AWG [17]: light enters the input star coupler (free propagating region FPR), will then diffract and then excites guided modes in each of the waveguides in the array. In the arrayed waveguide section there is a constant delay ΔL between adjacent arms, and finally constructive interference is obtained in the image plane (second star coupler). (*c*) Spectrum of a 1×16 demultiplexer with Gaussian passband and $<5\,\text{dB}$ fibre–fibre losses [197]. Reproduced by permission of IEEE.

(*b*) The phase response calculated from the transfer function given in table B7.1 has a resonance peak which is repeated every free spectral range FSR. (*c*) Open ring resonator.

In analogy to the Mach–Zehnder interferometer, the FSR of a ring resonator is given by

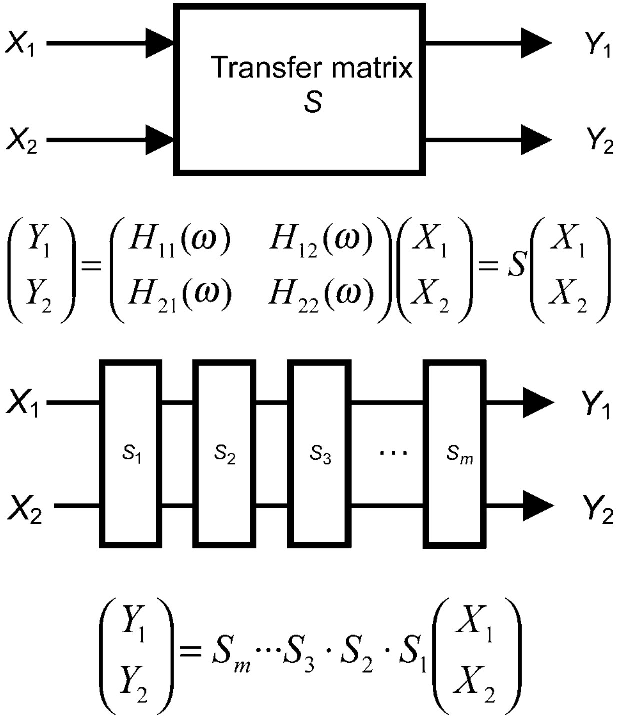
$$\mathrm{FSR} = \frac{\lambda^2}{nL}$$

B7.2.5 Optical modelling—beam propagation methods and the transfer matrix formalism

For the modelling of simple components or optical integrated circuit building blocks, the beam propagation method (BPM) and mode solvers are used:

- In BPM, the field is propagated stepwise through slices of the known waveguide structure, and in each step a phase correction is applied if the propagation constant of the guided mode changes through variations of the refractive index or the waveguide geometry. BPM is extensively treated in [20], [7] and [2].
- Mode solvers calculate the field distributions and propagation constants for the electrical and magnetical eigenmodes, and are often used as starting conditions for a subsequent beam propagation modelling. Methods solving the full Maxwell vector equations or semivectorial approximations are employed. The accuracy of different methods is compared in [7].

The applicability of the BPM is limited by the computation time needed for the simulation, so that alternative tools are needed for circuits with a higher degree of complexity. One way to achieve this is to use a transfer matrix formalism relating the amplitudes at the inputs and outputs of a device (figure B7.9), and the unitarity of the matrix assumes that filters are lossless. $H_{11}(\omega)$ is the complex transfer function giving access to the filter's power transmission $|H_{11}(\omega)|^2$ and phase $\phi(\omega) = \arctan[\mathrm{Im}(H_{11}(\omega))/\mathrm{Re}(H_{11}(\omega))]$.



$$\begin{pmatrix} Y_1 \\ Y_2 \end{pmatrix} = \begin{pmatrix} H_{11}(\omega) & H_{12}(\omega) \\ H_{21}(\omega) & H_{22}(\omega) \end{pmatrix} \begin{pmatrix} X_1 \\ X_2 \end{pmatrix} = S \begin{pmatrix} X_1 \\ X_2 \end{pmatrix}$$

$$\begin{pmatrix} Y_1 \\ Y_2 \end{pmatrix} = S_m \cdots S_3 \cdot S_2 \cdot S_1 \begin{pmatrix} X_1 \\ X_2 \end{pmatrix}$$

Figure B7.9. Device with two input and output ports and unitary transfer matrix S (top); serial filter through concatenated two port devices (bottom).

Table B7.1. Transfer matrices and transfer functions for waveguide devices described in sections B7.2.3 and B7.24.

Sketch	Matrix/transfer function	Interpretation
Directional coupler	$\begin{pmatrix} \cos(\theta) & -\mathrm{j}\sin(\theta) \\ -\mathrm{j}\sin(\theta) & \cos(\theta) \end{pmatrix} \equiv \begin{pmatrix} \cos(\kappa z) & -\mathrm{j}\sin(\kappa z) \\ -\mathrm{j}\sin(\kappa z) & \cos(\kappa z) \end{pmatrix}$	$\theta =$ coupling angle ($\pi/4$ for 3 dB coupler)
Phase shifter/delay line	$\begin{pmatrix} \mathrm{e}^{-\mathrm{j}\phi} & 0 \\ 0 & 1 \end{pmatrix}, \begin{pmatrix} \mathrm{e}^{-\mathrm{j}2\pi nL/\lambda} & 0 \\ 0 & 1 \end{pmatrix}$	Propagation of a mode with effective index n, wavelength λ through a section of length L
Mach–Zehnder	$1/\sqrt{2}\begin{pmatrix} 1 & -\mathrm{j} \\ -\mathrm{j} & 1 \end{pmatrix} \times \begin{pmatrix} \mathrm{e}^{-\mathrm{j}\phi} & 0 \\ 0 & 1 \end{pmatrix} 1/\sqrt{2}\begin{pmatrix} 1 & -\mathrm{j} \\ -\mathrm{j} & 1 \end{pmatrix}$	For 3 dB couplers, $\theta = \pi/4$
Phasar/AWG	$H(\omega) = \sum_{l=1}^{N} A(l)\exp\left(-\mathrm{j}\omega \frac{n_{\mathrm{eff}} l \Delta L}{c}\right)$	$N =$ number of waveguides in the arrayed waveguide grating. $A(l)$ is the amplitude in guide l, following a Gaussian distribution
Open ring resonator	$H(\omega) = \frac{\rho - \exp[-\mathrm{j}(\omega T + \phi)]}{1 - \rho\exp[-\mathrm{j}(\omega T + \phi)]} = \frac{\cos(\theta) - \exp[-\mathrm{j}(\omega T + \phi)]}{1 - \cos(\theta)\exp[-\mathrm{j}(\omega T + \phi)]}$	ρ is the through path amplitude transmission of the coupler. T is the roundtrip time through the feedback loop
Parallel lattice filter/tapped delay line filter (MA)	$H(\omega) = \sum_{k=0}^{N-1} h_k \mathrm{e}^{-\mathrm{j}kT_k\omega}$	$N =$ number of delay lines. T_k is the time delay through arm k.

Transfer matrices and transfer functions of some devices described in this section are listed in table B7.1. The amplitude and phase characteristics of a more complex filter are then obtained from the multiplication of the elementary matrices, and examples are the serial and parallel lattice filters to be described in section B7.5.

Finally, the transfer function can be expressed as

$$H_{11}(\omega) = \frac{A(\omega)}{B(\omega)}$$

where the polynomials $A(\omega)$ and $B(\omega)$ have only zeros. Depending on the numbers of zeros or poles of $H_{11}(\omega)$, filters are classified as [21, 22]:

- Moving average (MA), also called finite impulse response (FIR), filters have only zeros and consist only of forward paths. Examples are the AWG and the Mach–Zehnder interferometer.
- Autoregressive filters (AR) have only poles, and the two-port ring resonator (figure B7.8(*a*)) is one example.
- Autoregressive moving average filters (ARMA) have both zeros and poles. Infinite impulse response filters (IIR) represent a sub-category with at least one pole.

For a detailed treatment of the transfer matrix formalism, see references [20] (chapter 6.5) and [22] (chapter 3.3), with application to the synthesis of optical filters in [23], [24] and [25].

B7.3 Integrated optics materials and fabrication technology

A major challenge facing integrated optical circuit developers is the fact that devices can be fabricated in different materials, and the ultimate technology choice will be based on the performance, manufacturability and cost.

Hybrid integration (section B7.4) allows combining the best suitable materials on one platform, but for monolithic circuits a compromise may be needed.

This section will give an overview of the commonest materials, their properties and the fabrication processes currently deployed in integrated optics; we refer to chapter A1.2 for further reading.

B7.3.1 Silica

Most of the commercially available passive opto-electronic circuits use doped silica waveguides, as propagation losses below $0.1\,\mathrm{dB\,cm^{-1}}$ are easily achieved in the 1.3 and $1.5\,\mu\mathrm{m}$ telecom windows. Pioneering work in this field has been done in the early 1970s–1980s by NTT, and today devices are commercialized by many vendors (NEL, SDL/PIRI, IONAS/NKT Integration, Agere, Hitachi etc).

A typical fabrication process based on deposited thin films is shown in figure B7.10: a thin layer of silica is deposited on a planar silica or silicon substrate via chemical vapour deposition (CVD) processes such as flame hydrolysis (FHD) [26, 3] or plasma enhanced deposition (PECVD) [27] of gaseous precursors. In the case of the silicon substrate, a pure SiO_2 buffer layer with $10–20\,\mu\mathrm{m}$ thickness optically isolates the waveguide layer. The index of the waveguide layer is raised from the initial silica index ($n = 1.444$ at 1550 nm) above the index of the cladding by adding dopants such as germanium, phosphorus or titanium during thin film deposition, and index contrasts between $0.34\%\Delta$ (matched to standard single mode fibre) and $2\%\Delta$ are obtained with losses as low as $0.017\,\mathrm{dB\,cm^{-1}}$ for $0.75\%\Delta$ [26]. Mechanical stresses built up during waveguide deposition can be released by annealing at high temperature [28], and stress due to the mismatch of the thermal expansion coefficients of the substrate and waveguide materials can be avoided by a proper choice of dopant levels and waveguide geometries [29, 30]. Waveguide patterning is done by photolithography and etching [31, 32 chapter V-2], and finally a cladding covers the waveguides. Additional metallization layers can be deposited for the powering of thermo-optic phase shifters ($\mathrm{d}n/\mathrm{d}T = 1\times10^{-5}\,\mathrm{K^{-1}}$ [3]).

An alternative to thin film deposition is to fabricate the waveguides through ion exchange [33]: alkali ions, such as Na^+ or K^+, present in the glass are replaced by another cation such as Ag^+ or Tl^+, which locally increase the index proportional to their concentration. The process for fabricating buried channel waveguides usually consists of two steps: first, a glass substrate with an appropriate lithographic mask is immersed in a molten salt containing the silver or thallium ions, but no sodium or potassium ions. There will be an inter-diffusion of the species, resulting in a channel waveguide at the surface of the substrate. In the second step, an electric field is applied leading to the migration of the exchanged ions

deeper into the substrate. The resulting waveguides have an index profile, which is determined by the diffusion characteristics of the Ag^+ or Tl^+ ions. Passive directional couplers with $<0.15\,\mathrm{dB\,cm^{-1}}$ propagation loss have been reported in [34].

At present, ion exchange is primarily used for fabricating waveguides in lithium niobate (B7.3.4) and rare-earth doped glasses (section B7.3.6).

The availability of strong laser sources has allowed us to study the photo-refractivity in glasses: in GeO_2 doped films, permanent index changes can be induced by irradiating with 240 nm [35] or 157 nm laser light [36], and the sensitivity is usually enhanced by deuterium loading [37]. Index changes Δn between -6×10^{-3} [38, 39] and $+3\times10^{-3}$ [37] have been reported, allowing direct laser writing of waveguides [35], Bragg gratings [40] and waveguide couplers [41].

B7.3.2 Silicon oxynitride

Higher index contrasts and thus integration densities are available from silicon oxynitride (SiO_xN_y or SiON) films, which cover the index range between SiO_2 ($n = 1.45$) and Si_3N_4 ($n = 2.0$) and are deposited by PECVD or LPCVD (low pressure CVD) [27]. Although not yet commercialized in volume, there is an industry pull mainly from IBM and Kymata/Alcatel.

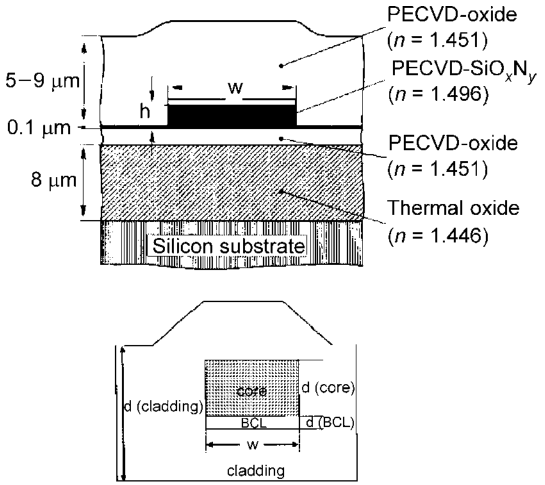

Figure B7.11. PECVD waveguides with compensated birefringence: rectangular waveguide cross section [42] (top, indices are at 1300 nm); guide with Si_3N_4 birefringence compensating layer BCL underneath the channel waveguide [43] (bottom). Reproduced by permission of IEEE.

Reduction of the stress-related birefringence after waveguide fabrication has been reported by having waveguides with a rectangular cross-section [42], or by an extra Si_3N_4 birefringence compensating layer underneath the channel waveguide [43] as shown in figure B7.11.

Propagation losses of $<0.1\,\mathrm{dB\,cm^{-1}}$ are achievable for lower index oxy-nitride materials, and thermo-optic devices (the coefficient $\mathrm{d}n/\mathrm{d}T = 1.2\times10^{-5}\,\mathrm{K^{-1}}$ being close to that of silica) have been made out of SiON waveguides with $3.3\%\Delta$ index contrast [44]. In this particular case, coupling losses due to the mismatch of the mode field diameter have been reduced by attaching a fibre with smaller core diameter.

Silicon-rich nitride (SRN) [45] deposited by LPCVD allows us to obtain index contrasts of $\Delta n = 0.6$, and thus a bending radii of 40 μm. Although the reported propagation losses are still of the order of $0.6\,\mathrm{dB\,cm^{-1}}$ (measured in a one-dimensional slab waveguide), SRN will be a promising candidate for high density integrated optics.

B7.3.3 Silicon-on-insulator

Silicon-on-insulator (SOI) integrated photonic circuits may have a potential for true monolithic integration with electronics due to their compatibility with the micro-electronics CMOS process, which can provide gigabits/second electronic circuitry with a low noise. As we will see in section B7.4, silicon is also the preferred substrate material for hybrid integrated circuits. The main commercial source for SOI devices is Bookham (transceivers, multi-channel monitors).

SOI layers can be fabricated by the bonding of thermal oxide layers (BESOI [46]), oxygen ion implantation [47, 48] and sputtering, CVD or evaporation [49].

Single mode rib waveguides [50] with dimensions comparable to single mode fibre are fabricated via etching techniques, and propagation losses of $<0.2\,\mathrm{dB\,cm^{-1}}$ [51] at 1550 nm and $<0.1\,\mathrm{dB\,cm^{-1}}$ at 1300 nm [52] are obtained. The cross-section of a SOI rib waveguide is shown in figure B7.12.

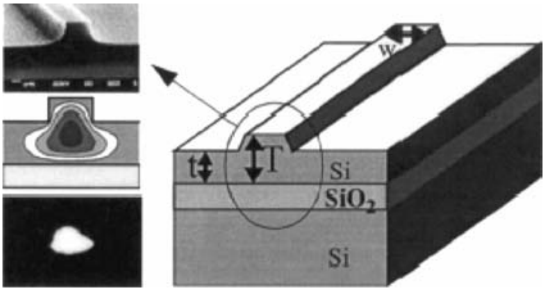

Figure B7.12. Silicon-on-insulator (SOI) single mode rib waveguide [46] fabricated by wafer bonding and etching. Schematic (right), scanning electron micrograph (left top), modelled (left middle) and experimental guided mode (left bottom). Reproduced by permission of IEEE.

The high index of $n = 3.45$ allows high confinement of the optical mode. This makes Si a suitable material for photonic bandgap structures [53], for which an index contrast of >2 is required for guiding [54].

Modulators have used the thermo-optic coefficient ($\mathrm{d}n/\mathrm{d}T = 1.8 \times 10^{-4}\,\mathrm{K}^{-1}$ [5]). Carrier injection is the most important electro-optic effect in Si [55, 56], and index changes of the order of $\Delta n = 1.5 \times 10^{-3}$ have been demonstrated [57, 48].

B7.3.4 Lithium niobate

Lithium niobate ($\mathrm{LiNbO_3}$, often abbreviated as LN) is a uniaxial crystal with large birefringence ($n_{\mathrm{extraordinary}} = 2.2$, $n_{\mathrm{ordinary}} = 2.286$) and a large linear electro-optic (Pockels) effect of $r_{33} = 30.9\,\mathrm{pm\,V^{-1}}$ [9]. Wafers with 100 mm diameter are commercially available [58]; common techniques for fabricating waveguides are thermal in-diffusion of titanium or proton exchange [59] and both processes do not seriously disrupt the lattice structure of the host material.

Ti-diffused channel waveguides typically have index contrasts of $\Delta n = 0.5$–1% [60] and $<0.1\,\mathrm{dB\,cm^{-1}}$ propagation losses [61], but index contrasts of up to 7% are possible with proton exchange [59].

The large EO effect of LN is used for external modulation of laser sources, and bandwidths of up to 100 GHz are reported on probed devices [62]. For achieving these high modulation bandwidths, special designs for the electrodes are required to match the velocities of the electrical and optical mode [58]. Modulators are treated in detail in chapter B4. Main industry players in the modulator segment are JDS Uniphase and Corning OTI.

Polarization converters and tunable wavelength filters via acousto-optic effects are reported in [63 chapter B7.8].

B7.3.5 Polymer

While not traditionally a high performance optical material, polymer has a number of attributes that make it an interesting material for optical circuits [64] and structural devices [65].

For optical waveguides, photosensitive optical polymers based on various monomers (including acrylates, polyimides, cyclobutenes) have been developed and are commercially available. Upon exposure, these monomers form crosslinked networks and materials with indices between 1.3 and 1.6 are available [4]. Mixing of two polymers which can be co-polymerized allows tailoring of the refractive index with an accuracy of 10^{-4}.

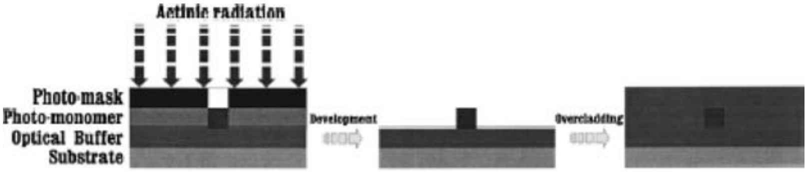

Figure B7.13. Schematic of the photolithography process for patterning of polymer waveguides [64]. Reproduced by permission of SPIE.

Adding photoinitiators to the material allows fabrication of waveguides by conventional mask photolithography (figure B7.13) or direct waveguide writing, although etching or moulding processes are also possible [4].

Standard materials offer waveguide propagation losses of 0.2 dB cm^{-1}, and the large temperature dependence of the refractive index $\mathrm{d}n/\mathrm{d}T = -2 \cdots - 3 \times 10^{-4}\,\mathrm{K}^{-1}$ [4] makes polymers particularly attractive for thermally tunable devices with low power consumption such as photoinscribed Bragg gratings and Mach–Zehnder switches, but also passive AWGs [66]. Main commercial products are thermo-optic switches (Akzo Nobel/JDS Uniphase).

The wide index range allows us to use polymers in hybrid silica/polymer devices [67], and the negative $\mathrm{d}n/\mathrm{d}T$ can compensate the positive $\mathrm{d}n/\mathrm{d}T$ of silica for athermalizing temperature sensitive silica waveguide components [68, 69, 70].

Electro-optic coefficients of $r_{33} = 10–15\,\mathrm{pm\,V^{-1}}$ have been achieved in polymer waveguides containing chromophores aligned in an electric field. Although photochemical stability and loss (typically 1 dB cm^{-1}) still remain to be addressed, modulating devices with >110 GHz bandwidth have been reported [71].

Waveguides with integrated structures to grip optical fibres with $< 1\,\mu$m alignment tolerance can be fabricated by etching [64], but also LIGA moulding processes [65], and optical backplanes have been reported in [72].

B7.3.6 Active waveguides

Active waveguides have been obtained from the implantation of rare-earth ions into a host material [73], ion exchange in Er/Yb co-doped glasses [74] and through PECVD thin film deposition [75].

Er^{3+} has a transition in the 1.54 μm telecom window, and optical pumping from the ground to the excited states is possible by 980 or 1480 nm pump lasers (figure B7.14) [73]. Net gains of 20 dB can be obtained with 120 mW pump power [63 chapter 6] (see this reference for a state-of-the-art on this subject). TEEM Photonics and NKT Integration commercialize Er^{3+}-doped planar amplifiers.

In a similar way, Nd^{3+} doping in silica waveguides provides a gain at 1.05 nm wavelength [76].

Active Er-doped devices have also been fabricated in $\mathrm{LiNbO_3}$ [77, 7 chapter 6], and other oxide materials, ceramics and Si [78].

B7.3.7 Indium phosphide gallium arsenide

Among the III-V semiconductors, InP plays a major role, as it is the current material of choice for the fabrication of lasers and detectors, which in turn can be monolithically integrated with passive InP waveguides. The possibility of matching the lattice constant of the quarternary alloy $\mathrm{In}_x\mathrm{Ga}_{1-x}\mathrm{As}_{1-y}\mathrm{P}_y$ to InP over a large window of compositions results in a wide range of bandgaps, thus operating wavelengths between 1000–1700 nm are obtained. However, the fabrication process is quite expensive and wafer sizes are limited to 2–3 inches. Although we will illustrate a few monolithic InP circuits

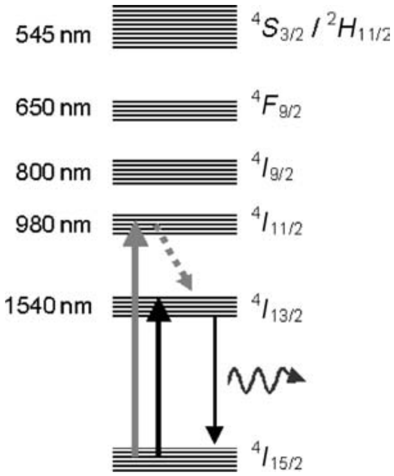

Figure B7.14. Simplified representation of the Er^{3+} energy levels. Optical pumping into the excited $^4I_{11/2}$ and $^4I_{13/2}$ states requires semiconductor lasers operating at 980 or 1480 nm [73]. Reproduced by permission of the Materials Research Society.

integrating passive and active device functionalities in section B7.5, most of the InP-based components today are combined with other passive components through hybrid integration (section B7.4.).

GaAs has a major role in the development of high speed electronics, thus up to 6 inch wafers are available. The bandgap of GaAlAs/GaAs and InGaAs/GaAs can be engineered for obtaining laser operation in the 780 and 980 nm wavelength regions, respectively, the latter being used for optical pumping of Er^{3+}-doped glasses.

We refer to chapters B1.1, B1.2 and B2 for further reading.

B7.3.8 Conclusion

Table B7.2 summarizes the key properties and primary phase tuning mechanism of the materials presented in this section. Each of the materials has its advantages and disadvantages, so that there is no clear winner. The choice of the material depends primarily on the specific needs for a given functionality.

B7.4 Device packaging and function integration

The first part of this section is about packaging of opto-electronic circuits, which fulfil a single or multiple functions in the network. The second part will discuss briefly the different technologies for the integration of multiple functions on one chip, and we will focus more specifically on hybrid integration, as this is the main integration technique today.

B7.4.1 Device packaging

There are different levels of opto-electronic integration in a communication system [79] (figure B7.15):

- A system consists of several racks or cabinets of equipment.
- A rack or cabinet contains frames, which in turn have units combining a multitude of optical and electronic functions.
- A single or a few optical functions together with control electronics are packaged on a board.

Table B7.2. Key properties of the materials described in section B7.3. For the coupling loss to a standard single mode fibre SMF28 [82] we indicate only a range (high >3 dB/interface, medium 1–3 dB/interface, low <1 dB/interface), as exact coupling loss values (see section B7.4.1 and table B7. 3) depend on mode field diameters which in turn can be adapted.

	Propagation loss	Coupling loss	Refractive index n	Primary phase tuning mechanism	Primary application
Silica	<0.05 dB cm^{-1}	Low–medium	1.444	Thermo-optic	Passive components, thermo-optic tunable devices
Silicon oxynitride	<0.1–0.2 dB cm^{-1} for n around 1.45 0.6 dB cm^{-1} for n around 2.0	Low–medium	1.444–2.0	Thermo-optic	Passive components, thermo-optic tunable devices
Silicon-on-insulator SOI	<0.2 dB cm at 1550 nm	High	3.45	Thermo-optic, electro-optic	Passive components, photonic bandgap devices
Lithium niobate LN	<0.1 dB cm^{-1}	Medium	2.0	Primarily electro-optic, but also thermo-optic and acousto-optic	High speed gigabit/second modulators and switches
Polymer	<0.2 dB cm^{-1}	Low–medium	1.3–1.6	Thermo-optic, electro-optic (chromophores)	Passive components, Thermo-optic tunable devices/switches with low power consumption
Er^{3+} doped glasses	<0.1 dB cm^{-1}	Low	1.49–1.50		Pre- and post-amplifiers
InP	ca. 3 dB cm^{-1}	High	3.1	Electro-optic, $\chi(3)$ nonlinearity	Lasers, detectors, semiconductor optical amplifiers, gigabit/second optical gates and switches
GaAs	ca. 0.5 dB cm^{-1}	Medium	3.3737		Pump lasers (980 nm)

Figure B7.15. Packaging levels in a generic communication system [79]. Reproduced by permission of John Wiley & Sons, Inc.

The purpose of packaging is (as an example, see figure B7.16)

1. (1) To connect a fibre to the monolithic or hybrid integrated optic *chip* without adding loss.
2. (2) The monolithic or hybrid integrated optical circuit can in turn contain dynamic elements (phase shifters, active opto-electronic devices) which need to have an *electrical interconnection to control electronics*.
3. (3) The fibre-optical circuit ensemble needs to be fixed into a *housing* or *package* without degradation of the mechanical stability or optical performance.
4. (4) The housing or package ensures *reliability* under different operating or environmental conditions.

Coupling from a fibre to an optical integrated circuit can be accomplished [80]

- From the waveguide surface via prisms or surface gratings.
- Through edge coupling into the waveguide cross-section via focusing lenses, or through direct attachment of the fibre to the chip. For the latter, fibres can be placed into V-grooves fabricated into Si substrates [81], or actively aligned to the chip which is the standard method used today.

Edge coupling losses arise from the mismatch of the fibre and waveguide mode fields, as well as from angular or lateral misalignments and are given by the overlap integral

$$\text{Loss} = -10\,\text{dB} \times \log_{10}\left[\frac{\left(\int_{\text{area}} \phi_1 \phi_2 \mathrm{d}A\right)^2}{\left(\int_{\text{area}} \phi_1^2 \mathrm{d}A\right)\left(\int_{\text{area}} \phi_2^2 \mathrm{d}A\right)}\right]$$

with ϕ_1, ϕ_2 being the mode fields and A the waveguide cross-section. Approximations for the various contributions are given in table B7.3.

As an example, the mode-field mismatch of a standard single mode fibre (mean field radius $w_0 = 4.6\,\mu\text{m}$ [82]) to a planar waveguide ($w_0 = 3.3\,\mu\text{m}$) results in losses of the order of 0.5 dB. To keep

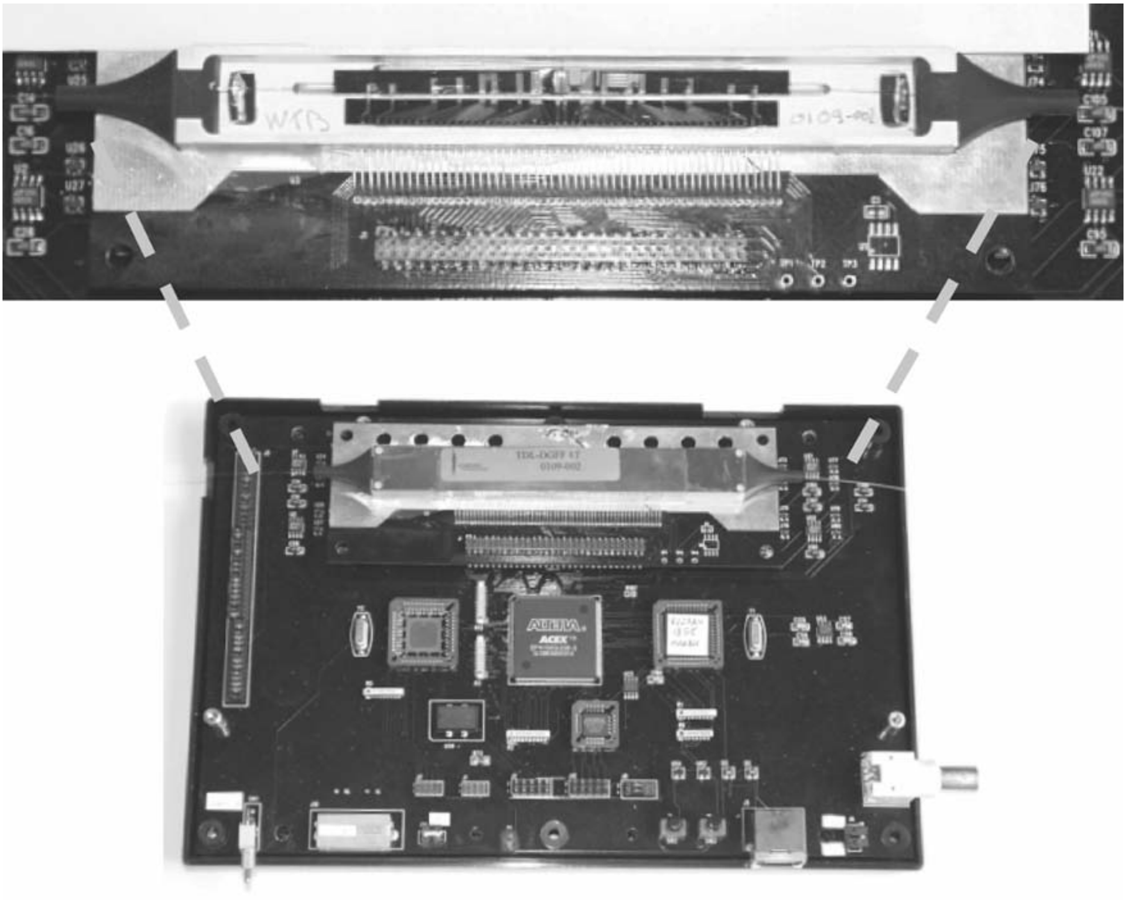

Figure B7.16. Example design for a opto-electronic component consisting of a silica waveguide chip in its housing (top) and electronics control board [135]. Reproduced by permission of IEEE.

the excess loss from lateral misalignment to below 0.3 dB, the fibre needs to be positioned with $<1.0\,\mu\text{m}$ accuracy. The fibres are usually attached by optical adhesives or directly fused to the chip using a CO_2 laser [83, 84].

Edge coupling of III–V components such as lasers, detectors or semiconductor optical amplifiers (SOAs) to fibres is more difficult, because their small modefield diameter of 1–2 μm would immediately lead to increased mode-field mismatch losses and also slightly reduced alignment tolerances.

In this case, loss reduction is possible by using fibres with anamorphic lenses [85] or enlarging the mode field of the active component with a taper [86] (figure B7.17) [87]. These relaxed alignment tolerances are the keys to high yield low cost passive alignment techniques as used in hybrid integration.

For electrical interconnection of active semiconductor and dynamic elements mainly two technologies are used in opto-electronics [88, 89, 90]:

- Bonding of a thin (typically 10–250 μm diameter) gold or aluminium wire onto metallic pads near the OE circuit chip edge. Wire bonding is a sequential process, and the wire length of a few millimetres leads to parasitic impedances limiting the electrical bandwidth to about 15 GHz.

Table B7.3. Coupling loss mechanisms and formulas.

Loss mechanism	Loss (dB)	Schematic
Mode mismatch	$-20\log_{10}\left[\frac{2w_1\cdot w_2}{w_1^2+w_2^2}\right]$ w = mean field radius (1/e amplitude)	Transverse offset	$-10\log_{10}\left[\frac{x^2}{w^2}\right]$ $\approx 4.343\left(\frac{x}{w}\right)^2$ where $w=\sqrt{(w_1^2+w_2^2)/2}$ and x is the offset	Angular misalignment	$-10\log_{10}\left[\exp\left[-\frac{1}{2}\left(\frac{2\pi n_{\mathrm{eff}}w\theta}{\lambda}\right)^2\right]\right]$ $\approx 8.69\left(\frac{\pi n_{\mathrm{eff}}w\theta}{\lambda}\right)^2$ where $w=\sqrt{(w_1^2+w_2^2)/2}$ and θ is the angular misalignment (rad)	
- Shorter interconnection (typically 100 μm), and thus higher electrical bandwidth, is possible with the flip chip process, which is moreover a parallel process. The electrical interconnection can be made with higher density anywhere on the device surface, and the flip chip (or solder bump self-alignment technique) is also one of the passive assembly techniques used in hybrid integration.

The package or housing of the device needs to enclose and protect the optical circuit without performance degradation through

- Thermal effects—heat is generated by the active components, so that a good dissipation is essential for maintaining the circuit at stable temperature. This is achieved by

Figure B7.17. Mode-field converting waveguides [86]. The principle is to have the high index waveguide (with small mode-field diameter) connected through an intermediate taper to a low index waveguide (with larger mode-field diameter), which is then coupled to a single mode fibre. Reproduced by permission of John Wiley & Sons, Inc.

  - * Having laser submounts with high conductivities (diamond, silicon carbide (SiC), alumina (Al_2O_3), aluminium nitrite (AlN), silicon (Si)) or Si substrates for thermo-optic and hybrid components.
  - * Thermo-electric coolers or passive heat dissipation.
- Stress related effects, as they induce birefringence and change the response of an optical circuit based on phase control. Potential issues are addressed by using substrates and packaging materials with adapted thermal expansion coefficients and filled adhesives with low Young's modulus.

At present, commonly used housing materials are aluminium, Kovar, Invar and organic/inorganic composites with near zero expansion coefficient [79]. Bending losses or breakage of the fibre attached to the optical circuit can be avoided by keeping the fibre bend radii above 2–3 cm.

Opto-electronic components are required to have failure-free performance over a range of operating temperatures (typically −5 to +70°C) over their lifetime (miminum 25 years). For assuring a reliable operation, testing procedures are defined [91], the purpose of which is to

- Verify reliability against thermal shocks, thermal cycles (−40 to 70°C), damp heat (85°C/85% relative humidity) and moisture.
- Screen devices through thermal cycling and short term storage at high temperature.
- Estimate life expectancy through accelerated ageing (70 or 85°C, 2000–5000 h). The principle is to test several identical components at different temperatures and to estimate the mean time to failure (MTTF) from an Arrhenius relation.

Depending on the application, operating environment and chip materials, the OE components can be packaged hermetically or nonhermetically.

B7.4.2 Function integration and hybrid technology

The integration of optical functions can be accomplished mainly in three different ways:

(1) Precision placement of the various elements into one package and interconnection via free-space optical links. This method has limitations for the complexity of the OE circuit, and the cost reduction potential through mass production is questionable.

(2) In monolithic integration, the optical and electrical functions are fabricated—in analogy to electronic LSI—on the same semiconductor substrate such as InP or GaAs. The main drawback is that currently best performances for different optical functions may be obtained with different materials (see section B7.3), for example modulators with $LiNbO_3$, passive wavelength multiplexers with silica waveguides and so on. Also, the achievable integration density is limited by optical constraints (waveguide bend radii and the size of the fibre/chip interconnection) rather than the size of the electronic circuitry.

(3) In hybrid integration, active devices and electronics are assembled together with passive lightwave optical circuits on a common platform, which allows combining the best available circuits. Furthermore, the yield for this technology may be higher than for monolithic integration, since the components can be selected for performance prior to the assembly. The remainder of the section reviews the critical technologies needed for surface-hybrid integration (for the various types of hybrid integration, see reference [86]).

A generic hybrid integrated circuit is shown in figure B7.18, and the main technical ingredients for functional integration are:

(1) A platform onto which the active and passive optical circuits are integrated. Among the materials used in packaging (diamond, SiC, Al_2O_3, AlN, Si), Si is considered to be the best material for a number of reasons: low cost, good thermal conductivity ($1.57\,\mathrm{W\,cm^{-1}\,K^{-1}}$) for evacuation of thermal load from active components, a thermal expansion coefficient ($\mathrm{CTE} = 2.33 \times 10^{-6}\,\mathrm{K^{-1}}$) almost matched to that of InP components ($\mathrm{CTE} = 4.5 \times 10^{-6}\,\mathrm{K^{-1}}$), availability of processes for fabrication of electrical circuits and Si alignment features. Moreover, passive silica waveguide components are usually fabricated on Si substrates.

Reproduced by permission of IEEE.

There are mainly two different types of platform:

(i) The Si optical bench has fibre V-grooves fabricated by anisotropic etching as well as other alignment features for active components, but has no passive waveguides.

(ii) NTT has developed a planar lightwave circuit (PLC) platform [92, 93], which also integrates passive silica waveguide components. A cross-section of the structure is depicted in figure B7.19.

(2) In the integration step, the optical building blocks need to be interconnected with low optical loss due to physical misalignment, i.e. within the roughly 1 μm accuracies mentioned in section B7.4.1. Both active and passive alignment methods [63 chapter 10] are used today:

In an active alignment process—for example coupling of a fibre to a laser diode—the optimum position is found through a measurement of the transmitted laser power, and sub-micrometre accuracy can be achieved with commercial precision alignment stages.

In a passive alignment process, the accuracy is defined through alignment features fabricated on both the OE building blocks and the integration platform:

(i) The index method uses microscopes and precision manipulators for accurate alignment in the horizontal (platform) plane; an example is shown in [94].

(ii) Mechanical contact alignment uses topographic features such as stops, standoffs, notches, pedestals (figure B7.20) for alignment in both horizontal and vertical directions. The major difficulty is the precise definition of the vertical plane during the waveguide fabrication process. Accuracies of 0.8 μm are reported for lasers coupled to fibres [95], passive alignment of single mode fibres to both facets of a semiconductor optical amplifier is shown in [96], and integration of both diode laser and photodiode with <3 μm precision has been demonstrated in [97].

(iii) The flip chip or solder bump technique uses precisely known volumes of solder confined between wettable metal pads on either side of the bond. Raising the temperature above the solder melting point will simultaneously align the structures through surface tension and provide an electrical interconnection [98, 90] (figure B7.21). Solder bumps can be fabricated by vapour or liquid phase deposition [99], and a variety of active/passive circuits have been published with alignment accuracies of up to ± 1 μm [98].

(iv) A combination of mechanical and solder bump alignment has been reported for transceiver modules [100, 101].

(3) A reliable mechanical and electrical interconnection between the opto-electronic circuits and the platform. Materials and processes commonly used are [102, 103, 98]:

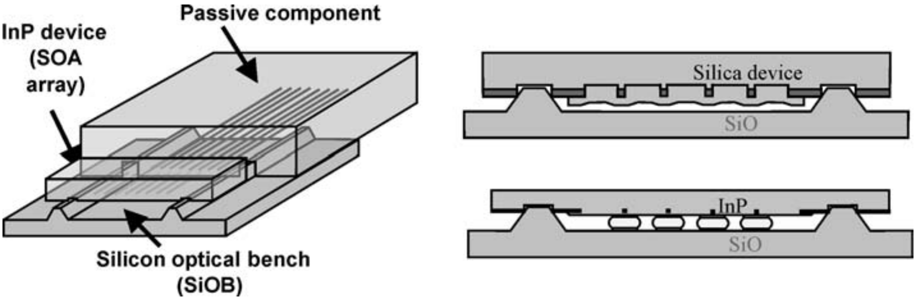

Figure B7.20. Mechanical contact alignment: notches fabricated into the active InP and passive silica waveguide components allow sub-micron alignment on a common silicon optical bench [199].

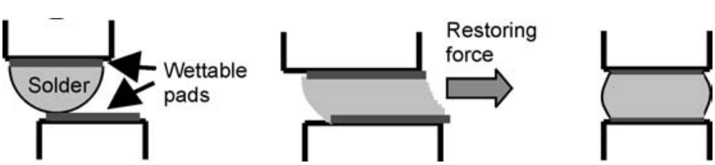

Figure B7.21. Flip chip solder bond—solder bumps with precise volumes (typically AuSn or PbSn) are fabricated on wettable pads, then brought into contact and heated above the melting point. The surface tension acts as a restoring force, resulting in alignment.

(i) In the flip chip process, eutectic 63%Sn/37%Pb (melting point 183°C) or 80%Au/20%Sn (melting point 281°C) solder bumps are fabricated on Ti or Cr adhesion layers.

(ii) Bonds can also be formed through a thermo-compression process at lower temperatures using Au/Sn or Au/In alloys.

(iii) Metal-filled epoxies with good thermal and electrical conductivity are suitable for curing at 150–200°C.

B7.5 Optical networks and integrated optical functions

With the increasing demand for communications bandwidth, digital optical transmission has become more and more important over the last few years. Currently, systems with capacities of hundreds of gigabits/second are commercially available, and transmission of 10.2 Tbit s^{-1} over 100 km of single fibre has been demonstrated in laboratory experiments [104]. In practice, this is done by simultaneously carrying optical signals with slightly different wavelengths over a single fibre (wavelength division multiplexing, WDM). In parallel, the bit rates for single channels have steadily increased to 40 Gbit s^{-1}, and in future systems of higher capacities will be achieved through time domain multiplexing (TDM) of several signals with identical wavelength into one high speed data stream.

The ultimate system figure of merit in digital transmission is the bit error rate (BER), which is defined as the probability of detecting a ‘1’ although a ‘0’ was received and vice versa. Typical goals are $\mathrm{BER} < 10^{-9}$ for voice traffic and $\mathrm{BER} < 10^{-12}$ for data transmission. For a fixed bit rate, the BER mainly depends on the received power and one speaks about power penalty (PP) when imperfect components are introduced into a network resulting in a BER degradation.

For optical networks, we refer to section C1, but for simplicity and for illustrating the use of integrated optical devices we will consider a generic WDM system as shown in figure B7.22:

- Light from a semiconductor *transmitter laser Tx* is *modulated*. In a WDM system, several signals are combined into the transmission fibre by an *optical multiplexer* MUX.
- The propagating signals are amplified every 70–100 km; mainly *Er^{3+} doped fibre amplifiers* are deployed [105], and distributed *Raman amplification* [106, chapter 8] in the transmission fibre is used to increase the system reach. Er^{3+} doped amplifiers need semiconductor pump lasers operating at 980 and 1480 nm; Raman amplified systems are pumped at 14xx nm wavelength.
- The gain of an EDFA is wavelength dependent, which leads to significant variations in signal-to-noise ratio (OSNR) of the received channels. The OSNR in turn depends on the power per channel and the number of amplifiers in the system. Nowadays, the channel power is periodically flattened with (static) thin film filters, but upcoming reconfigurable systems will require *dynamic gain equalization*.
- The finite spectral width of the source laser together with the positive fibre chromatic dispersion (i.e. the variation of the group velocity with wavelength) and nonlinear effects (self-phase modulation (SPM), cross-phase modulation (XPM), four-wave mixing) in the transmission fibre lead to a spreading of the optical pulse, which can be reshaped in *chromatic dispersion compensating devices*.

  In addition to that, the transmission fibre may not have perfect circular symmetry, giving rise to different propagation velocities as a function of the incoming polarization state (*polarization mode dispersion (PMD)*).
- More complex optical networks contain *add–drop multiplexers* (ADMs) and/or *optical crossconnect* (OXC) switches for interconnecting fibre links and for provisioning a path through the network:

Figure B7.22. Schematic of a wavelength division multiplexed system. (*a*) Schematic of an optical add–drop multiplexer. As an example, there are four signals $\lambda_1 \cdots \lambda_4$ on the fibre. The signal λ_3 is dropped and replaced by λ'_3. (*b*) Optical cross connect with two input and two output fibres, each carrying four signals. In this example, signals 2 and 3 are exchanged between fibres 1 and 2.

  - ADMs (figure B7.22(*a*)) have $M = 2$ fibre ports. Their function is to locally drop and add a few wavelengths out of a stream of N signals carried on a fibre while directly passing on the other data streams. ADMs can be static or reconfigurable.
  - OXCs (figure B7.22(*b*)) have $M > 2$ aggregate ports and allow routing of any of the N signals from any input fibre to any output fibre.

  The hearts of reconfigurable ADMs and OXCs are *space switches*: for the ADM, an array of N 1×2 or 2×2 switches is required, and the OXC needs a matrix of dimension $N \times M$.

- At the end of the optical link, the signals are demultiplexed, and the *receiver Rx* converts the signals back into the electrical domain. The signal can be either terminated or regenerated; in the latter case, a fresh copy of the signal is produced through optical–electrical–optical (O–E–O) conversion and fed into the next link.

As a single fibre carries several gigabits/second of information, the system operators have to guarantee the reliability of the transmission system against failures such as a fibre break. *Network protection* techniques ensure reliability by providing redundant capacity in the network, and by using protection switches for re-routing the traffic in case of failures (figure B7.23).

Transmitter laser wavelength drifts and power variations are likely to cause an increase in BER, and it is therefore important for network operators to *monitor the performance* of the communication channels in order to guarantee quality of service (QoS) to their users.

Wavelength conversion of an optical signal is needed, for example, in OXCs if a signal gets switched onto a fibre in which a certain wavelength is already occupied.

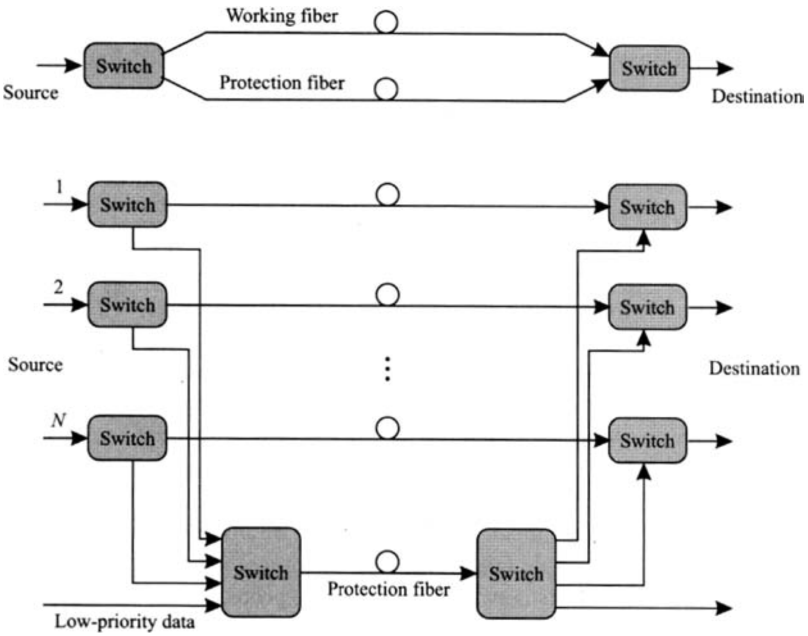

Figure B7.23. Protection in optical point–point networks by switching traffic from a working fibre on a protection fibre: 1:1 (top) and 1:N (bottom) protection [142]. The 1:N scheme is more bandwidth efficient as N working fibres share only one protection fibre.

Imperfect filters, dispersion, nonlinear effects and accumulated noise from Er^{3+} amplifiers limit the transparent length, over which a signal can be transmitted with a reasonable OSNR of about 1500–2000 km, and regeneration of the signal is required. As mentioned before, nowadays this is usually done at the receiver end in the electrical domain, but *regeneration in the optical domain* [107] has been demonstrated [108], resulting in extended reach [109]. Optical regeneration may eliminate a part of the cost of the current O–E–O conversion.

In current systems, a light path is set up for the duration of the communication (circuit switching). Future systems may evolve—in analogy to ATM or SONET packet switching in the electrical domain—to *optical packet switching* in which data packets are optically routed through the network based on information (such as the destination address) carried within the packet.

After the basic toolbox and technology overview in sections B7.2–B7.4, this last part will allude to examples of integrated devices. We will concentrate on some of the optical network functions mentioned above, and for avoiding duplication, we will not treat lasers, modulators, receivers and amplifiers for which we refer to chapters B1.2, B2, B4 and B6.

For most of the examples, several technologies are available and integrated waveguide devices represent one option, and the user will make his final choice based on performance, cost and maturity of the technology. Some of the functions are commercially available today, but most are still in research and will emerge over the next few years with the deployment of future generation systems.

B7.5.1 Optical multiplexers

Optical filters for WDM systems should have low insertion loss, low polarization and temperature dependence of both transmission wavelength and transmission loss, and they should not distort the incoming signals due to their average chromatic dispersion (nonlinear group delay of the filter) or dispersion variation within the filter bandwidth (dispersion slope) [110]. Technologies available today are mainly dielectric thin film filters, fibre Bragg gratings and planar devices.

Early wideband filters for separation of signals in the 1.3 μm/1.5 μm telecommunication windows have used single stage asymmetric Mach–Zehnder interferometers as described in chapter B7.2.4 [3], and wider passbands have been obtained by concatenation of three Mach–Zehnder filters [111]. Similar architectures are used for separating odd from even channels (interleaver) [112, 113].

Planar narrowband filters use the AWG (section B7.2.4) with typical channel spacings of 100 or 200 GHz (see also as an example, the 16 channel device in figure B7.7(*c*)). Commercial AWGs with Gaussian passband have fibre–fibre losses of the order of 4–5 dB, and in research devices with <1.2 dB insertion loss [114] and up to 1010 channels on a 10 GHz grid [115] (concatenated devices) have been demonstrated.

A wide transmission passband rather than a Gaussian passband is preferred for accommodating fluctuations in the transmitter laser Tx frequency and minimizing distortions due to filter concatenation [116]. Usual techniques modify the mode profile at the first AWG star coupler by MMI couplers [117] or Y-splitters [119], or interleave two gratings resulting in two separate focal points [120, 121]. Dynamic shaping of the passband is also possible [122].

The silica $\mathrm{d}n/\mathrm{d}T$ leads to a temperature dependence of the transmission spectrum, and for silica waveguide devices compensation methods [123, 124, 70] have been published. Polarization dependence has been eliminated by converting a TE mode into a TM mode in the middle of the device [125] and minimizing stress birefringence in the fabrication process [29, 30].

Both chromatic dispersion and dispersion slopes across filters also lead to signal degradation; however, the dispersion of the AWG filter is negligible and strictly zero if the component is symmetric and the loss can be neglected [118] (note that the transfer function in table B7.1 corresponds to that of an AR/FIR fitter without poles).

Other applications use very high resolution AWGs for converting a single data pulse from the frequency domain into the spatial domain. Examples are

- Shaping of ps pulses, which was reported first using dispersive bulk gratings and phase masks in the grating's focal plane [126] and later on using fully integrated AWGs with phase shifter arrays [2].
- Dispersion compensation [127] (section B7.5.3) and optical code division multiplexing [128].

B7.5.2 Dynamic gain equalization

Dynamic gain equalization is starting to be implemented in current systems, and a variety of technologies are being investigated today:

- Diffractive micro-electro-mechanical systems (MEMS) [129, 130].
- Bulk optic diffraction gratings in combination with liquid crystal spatial light modulators (LC-SLMs) [131, 132].
- Bulk and fibre acousto-optic gratings [133].
- Waveguides with surface electro-optic switchable Bragg gratings [134].

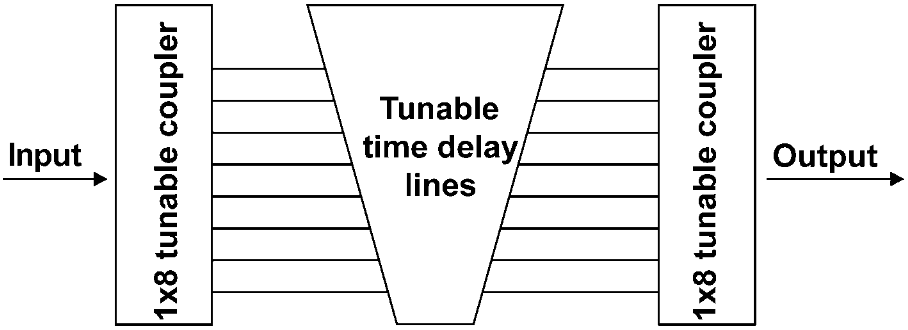
We will describe integrated optic solutions in more detail, and there are basically two types:

- Fourier filters—multiple sinusoidal transmission functions are generated by a multitude of asymmetric Mach–Zehnder interferometers (chapter B7.2.4) having path length differences ΔL. The ΔL results in different free spectral ranges, and superposition of the terms leads to the desired spectrum.

  The Mach–Zehnder devices can be arranged in parallel ('tapped delay line filter') or by concatenation ('serial lattice filter') [22, chapters 4.3 and 4.5].

  As an example, a schematic tapped delay line gain flattening filter [135] with eight arms (resulting in seven interference terms) is shown in figure B7.24 (top), and its transfer function is listed in table B7.1. Tailoring the delay T_k between adjacent arms and the amplitudes h_k allows synthesis of targets as in figure B7.24 (bottom). The typical insertion loss of such a device is 4 dB.

  Other applications of tapped delay lines are narrowband filters with small free spectral range [136] and multi-channel selectors [137]. Serial lattice gain flattening filters have been published using SiON waveguide technology [138], and silica waveguides [139].
- Channelized devices, which equalize individual wavelengths or groups of channels. An example is shown in figure B7.25 (top) [140]: a portion $\sqrt{R}$ of the light propagates through the upper unfiltered arm, and $\sqrt{(1-R)}$ will go through the lower arm. This lower arm contains a demultiplexer for selecting a single wavelength or a band of wavelengths and an array of phase shifters. Depending on the setting of the phase shifters, constructive or destructive interference between upper and lower arms results for each spectral band. Devices have been fabricated in both InP [140] and silica waveguides [141], and for the latter device a typical spectrum is shown in figure B7.25 (bottom). The insertion loss through the device is around 6.5 dB.



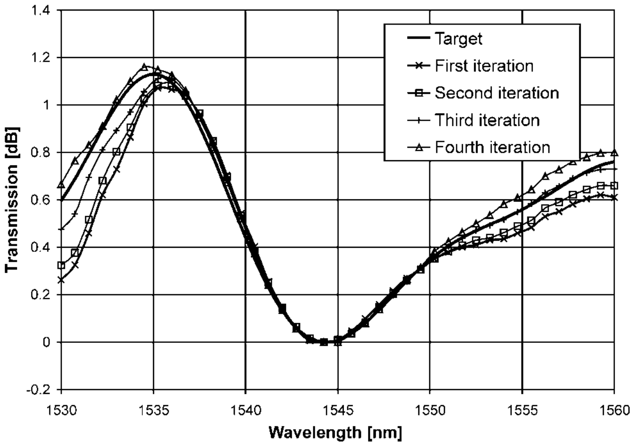


Figure B7.24. Tapped delay line filter for dynamic gain flattening. The device consists of a tunable 1 × 8 splitter made from cascaded MZIs, the tunable delay lines and an 8 × 1 combiner (top) architecture. Feedback is given to an electronic control circuit, and the measured transmission after four iterations (triangles) is closer than 0.1 dB to the target (thick solid line) [135]. The transmission is normalized to 0 dB. Reproduced by permission of IEEE.

B7.5.3 Chromatic and polarization mode dispersion compensation

Spreading of the light pulses propagating through a fibre arises from chromatic dispersion of the fibre itself, from nonlinear effects leading to a modulation of the phase, and from the chromatic dispersion of filters present in the link. As a consequence, the pulses in adjacent bit periods will start to overlap (intersymbol interference (ISI)) leading to an increased BER.

For a signal with bit rate B and a fibre of length L (km) with dispersion D ($\text{ps}\,\text{nm}^{-1}\,\text{km}^{-1}$), the condition

$$B^2LD < 11\,000\,\text{ps nm}^{-1}(\text{Gbit/s})^{-2}$$

has to be fulfilled for a PP of <1 dB [142]. In other words, a 10 Gbit s^{-1} signal tolerates an accumulated dispersion LD of 1100 ps nm^{-1}, but for a 40 Gbit s^{-1} signal, the limit is only 69 ps nm^{-1}.

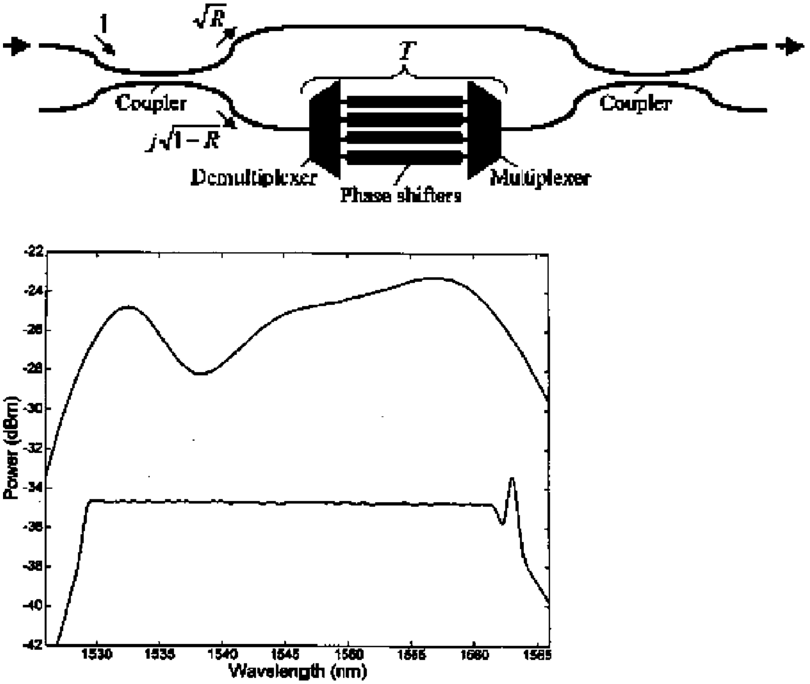

Figure B7.25. Channelized dynamic gain flattening filter [140, 141]—device architecture (top) and result of automatic flattening of the emission from an erbium doped amplifier (bottom), the upper and lower curves corresponding to before and after flattening. Reproduced by permission of IEEE.

In practice, the chromatic dispersion of standard single mode fibre [82] $D = +17\,\mathrm{ps\,(nm\,km)^{-1}}$ is compensated by periodically adding a section of dispersion compensating fibre (DCF) having negative dispersion, thus bringing the cumulated dispersion back to tolerable values. However, the tight limits for $40\,\mathrm{Gbit\,s^{-1}}$ signals and variations in the fibre dispersion (through fabrication tolerances and daily temperature changes) may necessitate tunable dispersion compensation devices operating on single channels or groups of channels.

In addition to the dispersion D, the dispersion slope $\mathrm{d}D/\mathrm{d}\lambda$ across a single WDM channel needs to be compensated for ultra-high speed systems ($>100\,\mathrm{Gbit\,s^{-1}}$) as well.

Technologies for dispersion compensation are chirped fibre Bragg gratings [143], micro-optic Gires–Tournois interferometers [144] and virtual phased arrays [145], and in the following we will describe the integrated optic devices, which offer an opportunity for integration with the multiplexers at the end of the transmission link.

Planar dispersion compensators have been studied based on both Mach–Zehnder filters and ring resonators, corresponding to the FIR and IIR categories (section B7.2.5).

An FIR dispersion slope compensator is shown in figure B7.26 (top) [146], and in this case integration with an AWG multiplexer allows us to compensate 16 WDM channels simultaneously.

For each channel, the dispersion equalizer consists of five asymmetric Mach–Zehnder filters and six tunable couplers. The asymmetric MZIs provide a wavelength sensitive splitting and a delay between the signals propagating through the upper and lower arms, resulting in a wavelength dependent delay. The device itself is fabricated in $1.5\%\Delta$ silica waveguides, and the thermo-optic phase shifters allow tuning of

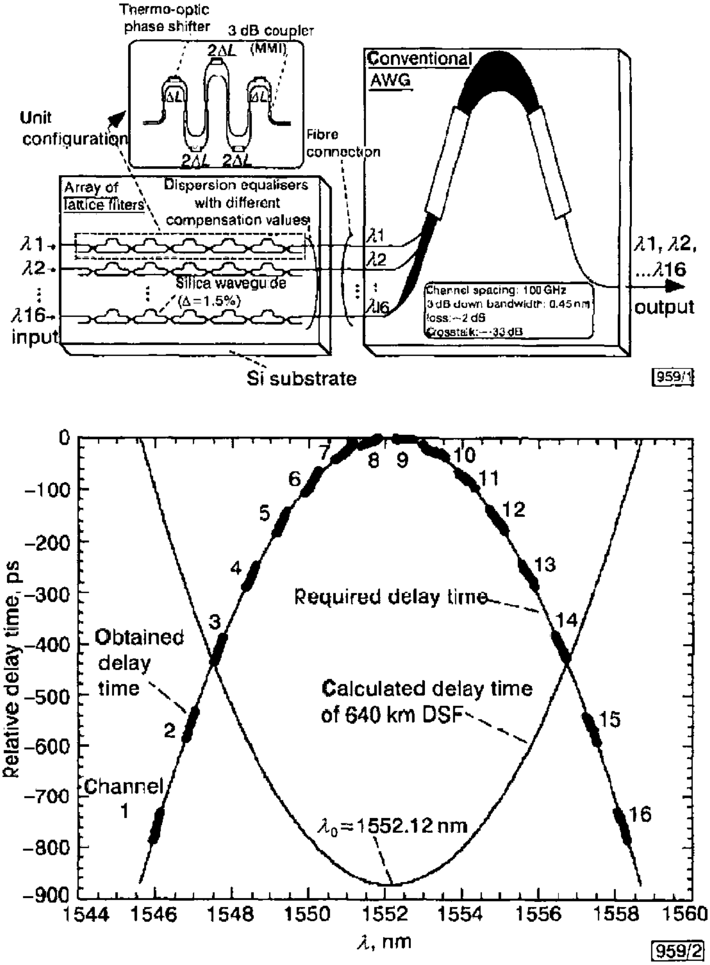

Figure B7.26. Sixteen channel dispersion slope compensating lattice filter (top). The dispersion slope is compensated separately for each wavelength through a five stage lattice filter. The bottom figure shows the delay of the transmission fibre, the required delay and the experimental delay (full symbols) [146]. Reproduced by permission of IEEE.

the dispersion characteristics. The measured versus required delay for transmission over 640 km dispersion shifted fibre (DSF) is shown in figure B7.26 (bottom).

An alternative architecture for compensation of both dispersion and dispersion slope is based on a pair of AWGs and a filter (figure B7.27)[127]: the AWG separates the incoming signal into its frequency components, and the spatial phase filter will apply the appropriate delay. Designs for compensation of up to 260 ps nm^{-1} are proposed, but losses are expected to be of the order of 15 dB due to the specific design of the AWG and coupling losses from the AWG to the spatial phase filter.

IIR filters are particularly interesting, since the poles in their transfer function lead to a nonlinear phase response and thus naturally provide dispersion.

In particular, the example shown in figure B7.28 (top, see also the transfer function in table B7.1) [147] represents a two stage all-pass filter which is theoretically lossless, and the dispersion can be

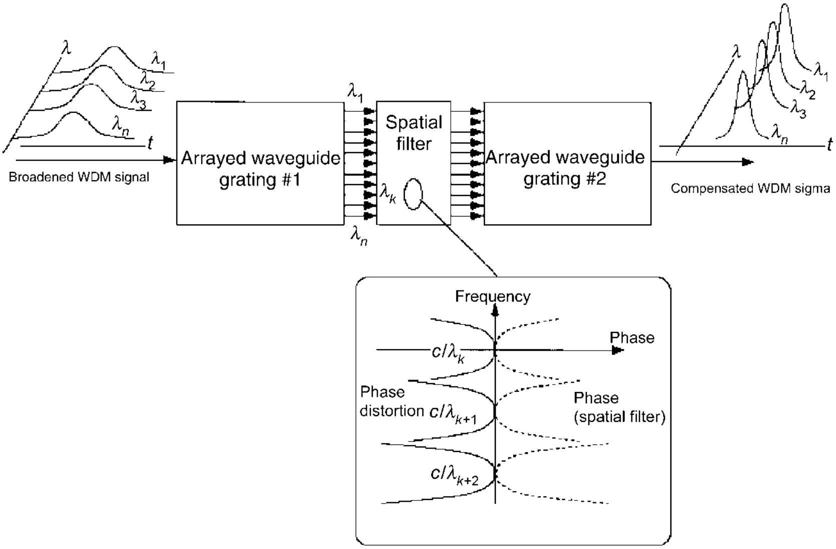

Figure B7.27. Dispersion compensator using arrayed waveguide gratings [127]. AWG 1 will spread the spectrum, and for each WDM channel there is a spatial filter (shown as an inset) which will correct for the phase distortion/ chromatic dispersion. AWG 2 then recombines the compensated signals. Reproduced by permission of IEEE.

tailored by adjusting the power coupling ratios κ_1, κ_2 and the phase shifts ϕ_1, ϕ_2. A dispersion of $\pm 4000\,\mathrm{ps\,nm^{-1}}$ has been demonstrated over a bandwidth of 4.5 GHz (figure B7.28, bottom), and more recently [148] the bandwidth has been increased to 13.8 GHz (dispersion $\pm$ 2000 $\mathrm{ps\,nm^{-1}}$) by using a silica waveguide fabrication process with a $2\%\Delta$ index contrast and thus shorter feedback path.

PMD arises from ellipticity of the transmission fibre as well as from polarization dependent performance of the components within the transmission link, and as a result TE and TM modes experience a differential delay. PMD is a time dependent statistical phenomenon and needs to be compensated adaptively.

Early PMD compensators [149] were based on a series of three squeezed polarization maintaining fibres, and a planar solution is described in [150] (figure B7.29, top). The compensator splits the incoming signal into TE and TM components at the first polarization beam splitter (using stress birefringence) [151], then TM is converted into TE allowing interference between TE and TM modes in the subsequent serial MZI. In this particular case, the group delay difference for the two polarization states is compensated in a fixed 7.5 ps delay line, and then the polarization modes are recombined. The systems benefit is demonstrated in figure B7.29 (bottom), showing the BER for a transmission link with (□) and without compensator (Δ).

B7.5.4 *Space switches and all-optical switching*

In the beginning of this section we mentioned multiple applications for switches in an optical network:

- Space switches in OXCs and add–drop multiplexers enable dynamic provisioning or reconfiguration of an optical WDM lightpath (circuit switching), thus replacing manual fibre patch panels. For OXCs, the number of input/output ports needed is difficult to estimate, but the many

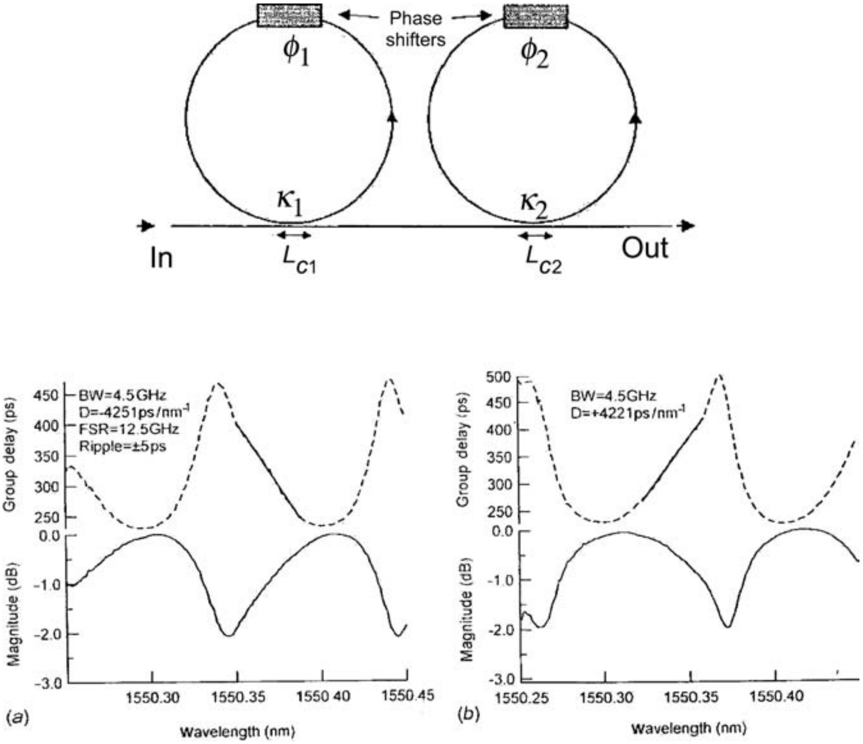

Figure B7.28. Two stage optical AR filter based on ring resonators (top) [147] for compensation of both positive and negative chromatic dispersion. Each stage has a feedback path with radius $R = 2.2$ mm, resulting in a free spectral range of about 0.12 nm (15 GHz). Measured group delay and normalized insertion loss are shown for negative (bottom, left) and positive (bottom, right) dispersion. Reproduced by permission of the Optical Society of America.

wavelengths carried on one fibre (at present usually $N = 40-80$) and the large number of fibres M will drive the demand for a high port count (256×256 and larger) devices. The switching speed required for this application is of the order of 1–10 ms.

- Fibre optic networks can encounter two types of failure: problems with the transmission equipment or path interruptions due to fibre break. Both issues can be addressed by switching the traffic onto a second unused fibre which is dedicated (1:1 protection) or shared with other traffic streams (figure B7.23). Protection switches are required to have a commutation time of <10 ms.
- Future systems will use high speed switches for switching and routing of data packets rather than provisioning a dedicated lightpath. The required switching speed is inversely proportional to the bit rate, i.e. it is of the order of a few nanoseconds.

Electronic data processing seems to be currently limited to around 40 Gbit s^{-1}, and there is an interest performing switching (and more generally signal processing such as multiplexing, routing, wavelength conversion, optical logic) in the all-optical domain [152]. As an example, we will briefly mention all-optical switches at the end of this section, and we refer to chapter C1.3 and reference [63, chapter 9] for all-optical time > 1 Tbit s^{-1} systems.

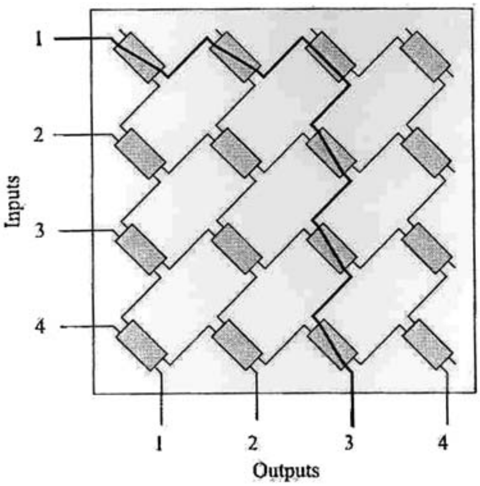
In addition to the commutation time, other important switch characteristics are extinction (or ON–OFF) ratio, insertion loss, crosstalk (i.e. leaking of light from one path into another), polarization dependent loss and power consumption.

The basic elements are 1×2 or 2×2 switches, and larger size devices can be realized by appropriate cascading of these devices. As an example out of many possible arrangements, the crossbar and the Beneš architectures [142] are shown in figure B7.30, and the choice between architectures will depend on criteria such as

- The number of 1×2s or 2×2s. An $n \times n$ crossbar switch consists of n^2 elementary switches, and Beneš switches need only $n/2{*}(2{*}\log_2(n) - 1)$.
- Loss and loss uniformity—in the Beneš switches, each signal crosses the same number of 2×2s, but in the crossbar switches there is a shortest path (going through one switch only) and a longest path (through $2n - 1$ elements).



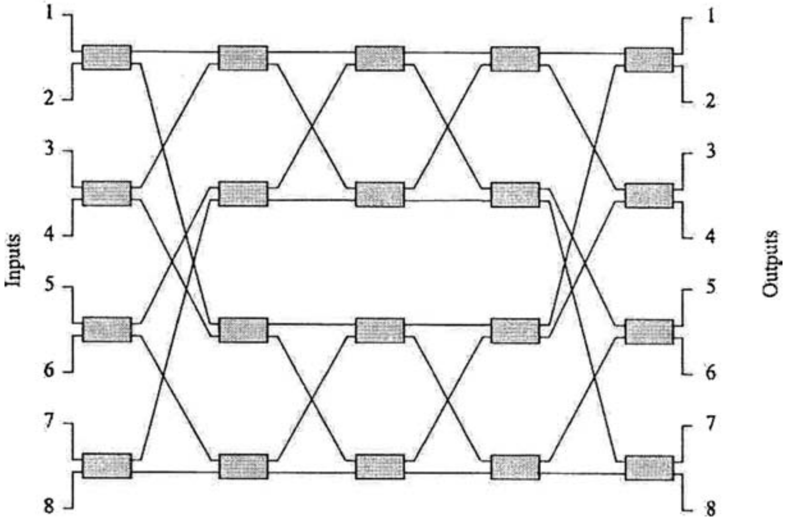


Figure B7.30. 4 × 4 switch: crossbar (top) and Beneš architectures (bottom) [142].

- The number of waveguide crossovers—this will lead to crosstalk between the lightpaths. Crossbar switches have no crossovers, in contrast to Beneš switches.
- Switches can be blocking or nonblocking. In the latter, a connection can be made between any unused input port and any unused output port. If this new connection can be made without interrupting the traffic on the other channels, the switch is called 'wide sense nonblocking' (the crossbar switch belongs to that category); otherwise it is called 'rearrangeably nonblocking' (e.g. Beneš switches).

Other architectures are described in [153, 142 chapter 3.7].

The elementary 1 × 2 or 2 × 2 optical switches themselves use a wide range of operating principles, which can be roughly classified into:

		Operating principle	
		Interferometric	Noninterferometric
Switching mechanism	Mechanical		Mechanical micro-optic systems, MEMS
	Nonmechanical	Mach–Zehnder interferometer: thermo-optic effect in doped silica and polymer waveguides, electro-optic LN switches	Y-branch devices with polymer thermo-optic, LN and InP electro-optic effects
		Hybrid silica/polymer tunable vertical coupler switch	Total internal reflection: silica–air interfaces, InP electro-optic
		All-optical $\chi(3)$ switches in GaAs, InP	Polarization switching in liquid crystals
			Semiconductor optical amplifier (SOA) ON–OFF gate

Mechanical switches route light through a physical displacement of the light path: the fundamental switching elements are movable mirrors or prisms, which are mechanically actuated. Another approach is to steer beams from N input fibres on N output fibres, the difficulty being that an analogue control of the beam position is required.

Main advantages of mechanical switches are low insertion losses and high crosstalk between channels. However, their commutation speed is of the order of tens of milliseconds to seconds, and their size is limited to about 32 × 32.

An emerging technology is MEMS, which combine the optical performance of mechanical switches with the benefits of integrated optics (compactness, low cost volume production, optical prealignment) [154, 155, 156]. Schematic drawings and SEM pictures of the two-dimensional (2D) matrix and the movable mirrors are shown in figure B7.31. The mirrors are fabricated via Si surface micro-machining; the translation movement of a scratch drive is translated into a rotation, and as a result the mirror flips between the two states. For 8 × 8 2D devices insertion losses of 3.1–3.5 dB with <1 ms switching speed have been reported, and large scale cross connects with <6 dB losses and 512 × 512 ports or higher are expected to be constructed out of 32 × 32 modules [155].

Higher port count monolithic devices are accessible through MEMS mirrors with two rotational degrees of freedom. The continuous rotation is used for steering the beam in all three dimensions, and the MEMS panel is placed between an array of input/output fibres and a fixed reflecting mirror. Switches with 112 × 112 ports have been demonstrated [157].

In general, mechanical switches use expanded beam optics to minimize coupling losses.

Nonmechanical noninterferometric switches depend on the control of waveguide index or polarization state.

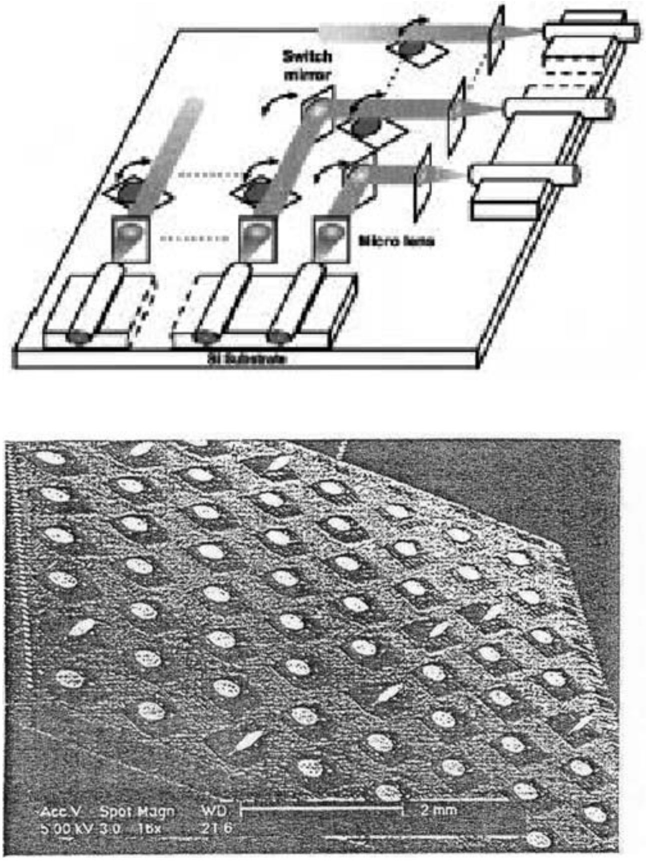

Figure B7.31. Free space MEMS switch: schematic [200] and scanning electron microscope picture [155] of a switch matrix (above). Schematic drawing of a single mirror and SEM close-up (next page). Reproduced by permission of IEEE and the Optical Society of America.

In a fixed symmetric Y-branch (section B7.2.3), light is equally divided between the output waveguides, but dynamic control of the refractive indices allows us to ‘push’ or ‘pull’ light into one or the other output.

Layout and switching characteristics for a 1 × 2 digital optical polymer waveguide switch are shown in figure B7.32 [7]: increasing the temperature of the upper arm will decrease the waveguide index, thus coupling more light into the lower arm. Typical power consumption is around 50–80 mW with about 1 ms commutation time.

Electro-optic switches can use the same principle, but provide higher speeds. Hundreds of megahertz have been reached using Ti:$LiNbO_3$ waveguides [158], and crosstalk has been enhanced to 30–50 dB by concatening 1 × 2 switches (‘dilated switch’). Although power consumption is low, the main inconvenience is the applied voltage of about 25 V. Monolithic 4 × 8 and 6 × 6 LN switches are reported in [159].

Crossconnects based on EO-InP switches combined with SOAs are particularly promising for nanosecond packet switching applications, as they provide high extinction ratio and can be lossless. Figure B7.33(*a*) shows an elementary switching element [160]: in the Y-junction the switching is done by

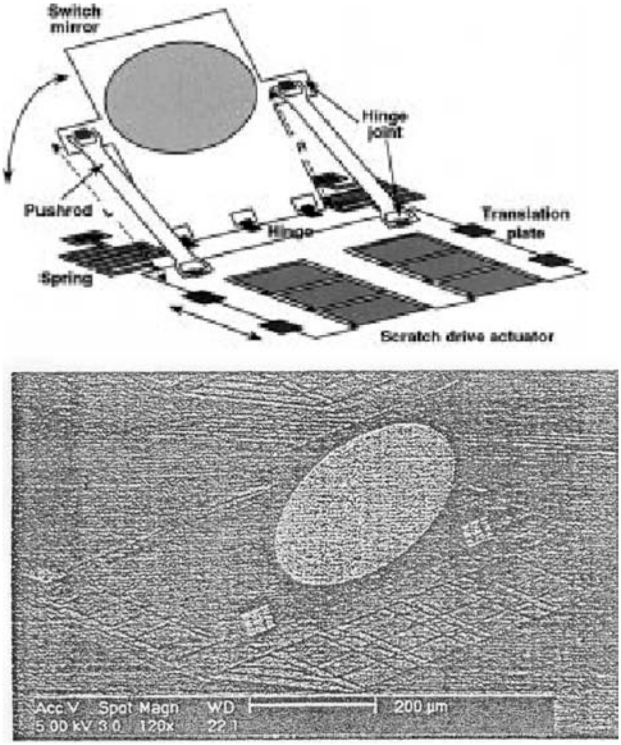

Figure B7.31. (Continued)

current injection and the associated index change (section B7.2.2). The travelling wave amplifier TWA compensates for loss when the switch is in the ‘ON’ state and suppresses crosstalk from other channels when the switch is ‘OFF’. Fibre-to-fibre performance of a 4 × 4 crossbar switch operating at 1.31 µm wavelength is depicted in figure B7.33(*b*)—the device is lossless for an injected current of >200 mA, and the extinction ratio is in excess of 40 dB. Polarization sensitivity is an issue but can be reduced to <1 dB by using square shaped waveguide cross-sections [161].

Switches using total internal reflection (TIR) at silica waveguide–air interfaces are reported in [162], [163] and [164]. The principle is shown in figure B7.34 (top): a drop of index matching fluid can be moved within a narrow trench, leading to transmission or TIR.

An example of asymmetric Y-couplers and electro-optic induced TIR is shown in figure B7.34 (bottom) [165].

Polarization rotation in liquid crystal (LC) spatial light modulators in conjunction with birefringent crystals results in space switching. The first birefringent polarization beam splitter in figure B7.35 (bottom) [166] will separate the beam into ordinary and extraordinary beams having orthogonal polarizations, and the arrayed $\lambda/2$ plate symbolizes a matrix of liquid crystal modulators. Depending on the orientation of the LC molecules (which in turn can be changed by application of an electric field) the polarization of incoming light is rotated by 90° or remains unchanged. The subsequent birefringent crystals will recombine ordinary and extraordinary rays.

SOAs can be used as a gate (ON/OFF switch) by the variation of the applied bias voltage: a low voltage results in low population inversion, and an incoming signal gets absorbed. Application of the bias voltage leads to an increase in population inversion, resulting in the transmission and gain of

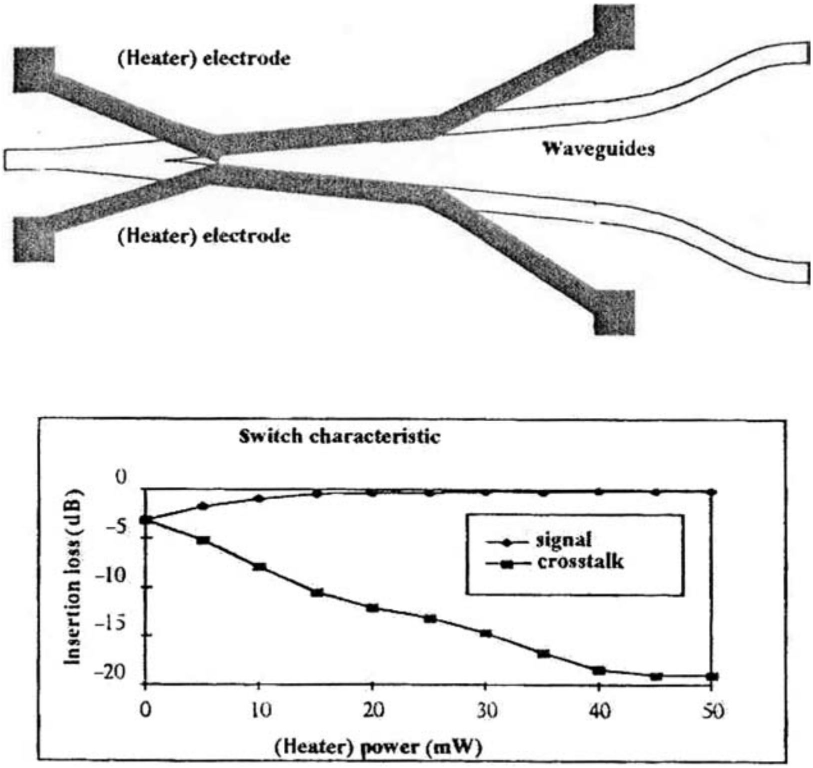

Figure B7.32. 1 × 2 digital optical Y-branch switch: layout with waveguides and heating electrodes for TO effect, extinction as a function of the applied power [7]. Reproduced by permission of Marcel Dekker Inc.

the signal. The commutation speed is of the order of 1 ns [142]. 1 × 4 [167], 4 × 4 [168] and 8 × 8 space switches [169] operating at 10 Gbit s^{-1} have been demonstrated based on a broadcast-and-select (the incoming signal is split, then the SOA ON/OFF gates pass through or block the signals) architecture. Devices have been fabricated through hybrid integration of the SOA gates on SiO_2 motherboards.

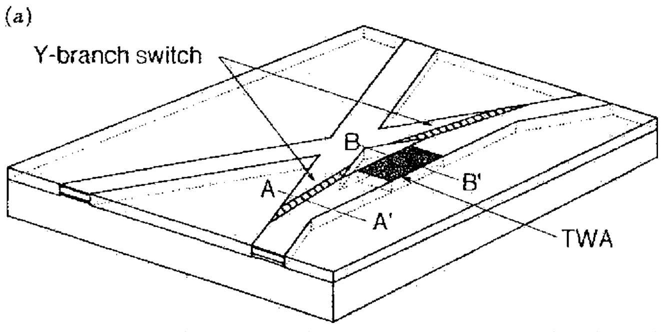

Figure B7.33. (*a*) Elementary semiconductor switch element consisting of Y-branches and a semiconductor travelling wave amplifier for loss compensation. Figure B7.33. (Continued)

Another application for SOA gates is to select a set of wavelengths from a WDM signal, and both hybrid [170] and monolithic integrated InP [171] devices have been demonstrated (figure B7.36): the incoming WDM signal is wavelength demultiplexed in a first arrayed waveguide grating, passed through or blocked in the SOAs and then recombined in a second arrayed waveguide grating.

Nonmechanical interferometric switches are based on tunable directional couplers or Mach–Zehnder interferometers (sections B7.2.3 and B7.2.4) and used in thermo-optic, linear (Pockels) or nonlinear (Kerr) electro-optic effects for achieving the required phase shift.

Monolithic 16 × 16 crossbar switch matrices using silica waveguide MZIs and the thermo-optic effect fabricated on a 6 inch substrate are described in [172] (figure B7.37). The high extinction ratio of 55 dB is achieved by concatenation of two MZIs ('dilated switch'), and the average insertion loss is 6.6 dB. The electrical power consumption per switch point is 450 mW resulting in a total of 17 W. However, in recent 2 × 2 and 8 × 8 switches a reduction to 45 mW per stage has been demonstrated by micro-machining grooves on either side of the waveguide and insertion of a thick silica buffer layer for enhanced thermal isolation between the waveguide and the Si substrate [173, 174].

Polymer waveguides and their large dn/dT further reduce the power consumption, and for a 2 × 2 device, 5 mW [175] have been reported in the 1.3 μm telecom window.

The vertical coupler 1 × 2 switch shown in figure B7.38 [67] combines the low propagation loss in silica with the low switching power of polymer devices: the structure consists of a vertically

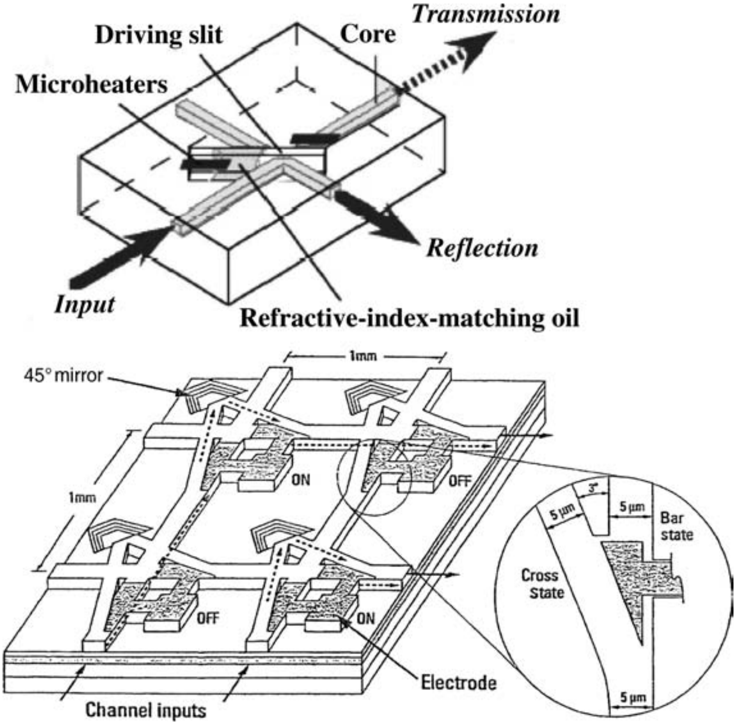

Figure B7.34. Total internal reflection switch with silica waveguides (top, [163]). The left part of the driving slit is filled with index matching oil. stacked lower doped silica waveguide layer, a thin silica cladding and the polymer waveguides. When the electrodes are not powered (OFF), input light coupled to the lower silica waveguide will propagate through this silica waveguide (bar state). When the electrodes are sufficiently powered (ON), the input light is coupled to the polymer waveguide in the first element and coupled back to another parallel silica waveguide in the second element (cross state). The reported switching power was <80 mW and crosstalk <20 dB.

For electro-optic MZI $LiNbO_3$ waveguide switches see reference [176].

Forward current injection into InGaAsP/In structures leads to a negative index change of $-0.4\,\mathrm{rad\,mA^{-1}}$ [177], and application of a reverse voltage [178] increases the refractive index, leading to a positive phase change of $0.25\,\mathrm{rad\,V^{-1}}$.

All-optical switching is a very attractive concept for ultra-high speed systems ($>100\,\mathrm{Gbit\,s^{-1}}$) as bandwidth-limited electronic processing is replaced by the manipulation of an optical data signal via a second optical control pulse [7, chapter 11.3] (see chapters A2.4 and B6).

Third order nonlinearity $\chi(3)$ (section B7.2.2) in GaAs has been used in the monolithic device shown in figure B7.39 (top) [179]: when the first control pulse is absorbed in the upper nonlinear waveguide the Mach–Zehnder interferometer becomes asymmetric and the incoming signal is switched from one output to the other. The second control pulse then cancels the index change from the first

pulse, thus switching the signal back. The control pulses with an energy of <7 pJ and a length of 1.3 ps came from a Ti:sapphire laser, and switching speeds were 8 ps (figure B7.39, bottom).

B7.5.5 Integrated add–drop multiplexers and optical crossconnects

Add–drop multiplexers are wavelength selective switches allowing dropping of one or more signals from an incoming data stream and adding signals to the outgoing data stream. Different monolithic arrangements based on AWGs (chapter B7.2.4) and switches are shown in figure B7.40 (top) [17], and configurations (*a*) and (*b*) use the same AWG for demultiplexing and multiplexing the incoming traffic into individual wavelength channels. The loop back configuration (*a*) has been chosen for the monolithic InP component in figure B7.40 (bottom) [180], which is designed for four channels on a 200 GHz grid. The component is extremely compact ($3 \times 6\,\mathrm{mm}^2$) and uses electro-optic MZI 2 × 2 switches for passing through or adding/dropping traffic on each of the four channels.

Another device architecture for ADM is the serial lattice filter (chapter B7.5.3) made of SiON waveguides (figure B7.41, top) [144]: there are 12 asymmetric Mach–Zehnder stages resulting in a chip size of $6 \times 65\,\mathrm{mm}^2$. The device operates on a 200 GHz grid and can dynamically add/drop one

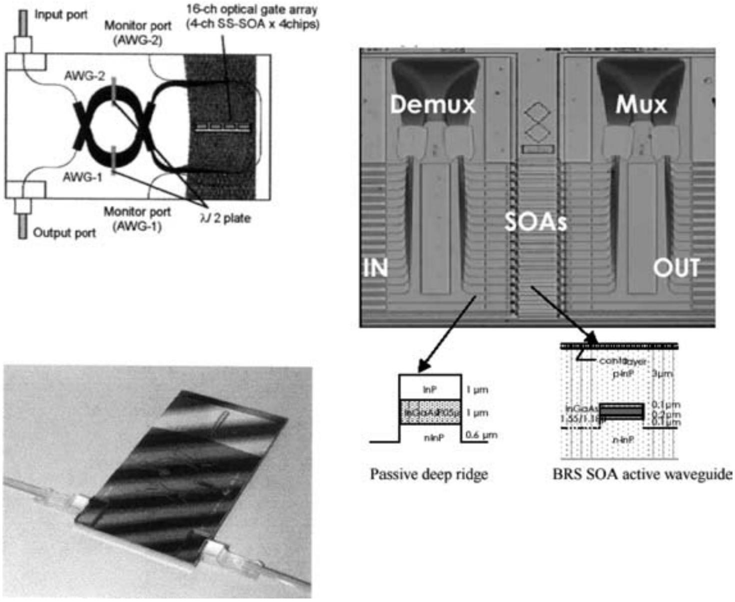

Figure B7.36. Hybrid (left, [173]) and monolithic InP (right, [171]) channel selector. In both cases, a DEMUX will separate the wavelengths, which are gated through InP SOAs. The second MUX then re-combines the channels. Reproduced by permission of IEEE.

out of the incoming eight channels. The 12 MZI stages give sufficient finesse for suppressing crosstalk from adjacent channels as shown in the theoretical filter response (figure B7.41, bottom). Experimental on-chip losses at 1550 nm were about 2 dB, isolation of the through channels from the dropped wavelengths was around 20 dB and tuning was accomplished with thermo-optic phase shifters.

Polymer waveguides with their 10 × higher thermo-optic coefficient $\mathrm{d}n/\mathrm{d}T$ and the possibility of writing Bragg gratings (see chapter B7.3.5) provide another possible architecture when combined with four-port circulators (figure B7.42) [64]. The function of the Bragg grating is to separate the drop wavelength by reflecting it back to the left circulator and to pass all other wavelengths through. The main challenge is the fabrication of the Bragg grating with uniform and strong reflection within a narrow wavelength band, no out-of-band spectral features, low insertion loss and polarization dependence.

Other material systems for AD filters are Si waveguide ring resonators [181] and acousto-optic $\mathrm{LiNbO_3}$ Mach–Zehnder switches [182, 63 chapter 7.8].

The integrated 2 × 2 optical cross connect shown in figure B7.43 [183] consists of AWGs giving simultaneous access to all 16 wavelengths and an array of thermo-optic 2 × 2 switches: light entering AWG1 is demultiplexed and enters the left hand side of the switches. When the switches are ‘OFF’, the signals will be recombined in AWG3; otherwise they are routed to AWG4. The second data stream coming into the OXC/AWG2 will arrive at the right hand side of the TO switches and go through to AWG4 (‘OFF’) or is exchanged to AWG3 (‘ON’). The switches consist of two stage MZIs for reaching an extinction ratio of <-28 dB. A transmission spectrum is shown in figure B7.43 (bottom). The size of the device was $87 \times 74\,\mathrm{mm}^2$ and insertion losses between 7.8 and 10.3 dB.

Figure B7.39. Monolithic all-optical symmetric Mach–Zehnder switch using nonlinearity in GaAs [179]. Device layout with inputs for the signal and the two control pulses defining a gate (top); switching characteristics (bottom). Reproduced by permission of the American Institute of Physics.

A simpler arrangement (figure B7.44, top) [184] uses only two AWGs. The AWGs have an interleaved chirped grating, thus producing two separate images for each wavelength in different grating orders (denoted by ω_0, ω_{-1}, ω_{+1}). Per channel, there are three connecting waveguides with InP phase shifters between the two AWGs, allowing the dynamic re-routing of wavelength channels to either line 1 or line 2 of the second AWG. The footprint of the device is $4.2 \times 9.8\,\mathrm{mm}^2$ [177], and experimental on-chip spectra for a 2×2 crossconnect with six channels are shown in figure B7.44 (bottom). Reported on-chip losses were about 10 and 19 dB including fibre/chip coupling.

B7.5.6 Integrated monitoring devices

Among the different network management functions [142 chapter 10.1], performance monitoring deals with providing a guaranteed QoS to the network users. As an example, a drift of the transmitter laser Tx wavelength due to temperature variations or ageing can lead to a decrease in received signal power (and thus increased BER), when the laser wavelength is not centred any longer on the passbands of the MUX/DEMUX filters. The silica waveguide component in figure B7.45 [185] simultaneously monitors 16 WDM channels present in a system. The operation principle is to feed a WDM signal (the wavelength is marked by the circle in figure B7.45, bottom) into an arrayed waveguide grating with large passbands and to compare the received power on adjacent outputs. Misalignment of the laser frequency will result

in a positive or negative differential signal. A molecular absorption line serves as a wavelength reference, and a resolution of 10 MHz with sub-gigahertz accuracy was reported.

B7.5.7 All-optical signal processing—wavelength conversion and TDM switching

Like the all-optical switches described in section B7.5.4, all-optical signal processing [152] devices rely on third order nonlinearity $\chi(3)$. For practical all-optical devices, the nonlinearity has to be large enough to achieve a π phase shift with control pulses having picosecond length and picojoule energy, but at the same time the losses need to be sufficiently low. The semiconductor optical amplifier can overcome this trade-off, thus playing an important role in wavelength conversion, all-optical time division multiplexing and regeneration [186, 171].

For an SOA in the gain regime (i.e. with inverted population densities between valence and conduction bands), the following nonlinear phenomena occur.

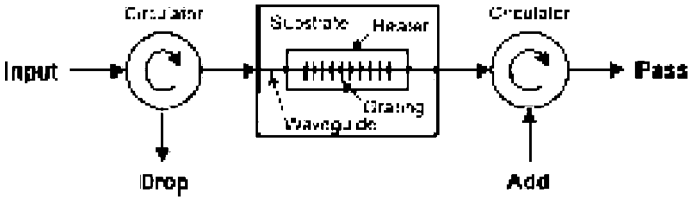

Figure B7.42. Optical add–drop filter using a thermo-optic tunable polymer Bragg grating and a pair of three port circulators [64]. The incoming signals will propagate through the left circulator into the Bragg grating, which reflects the drop wavelength back and passes the other channels through. In the same way, the add signals are reflected back and recombine with the through channels. Reproduced by permission of SPIE.

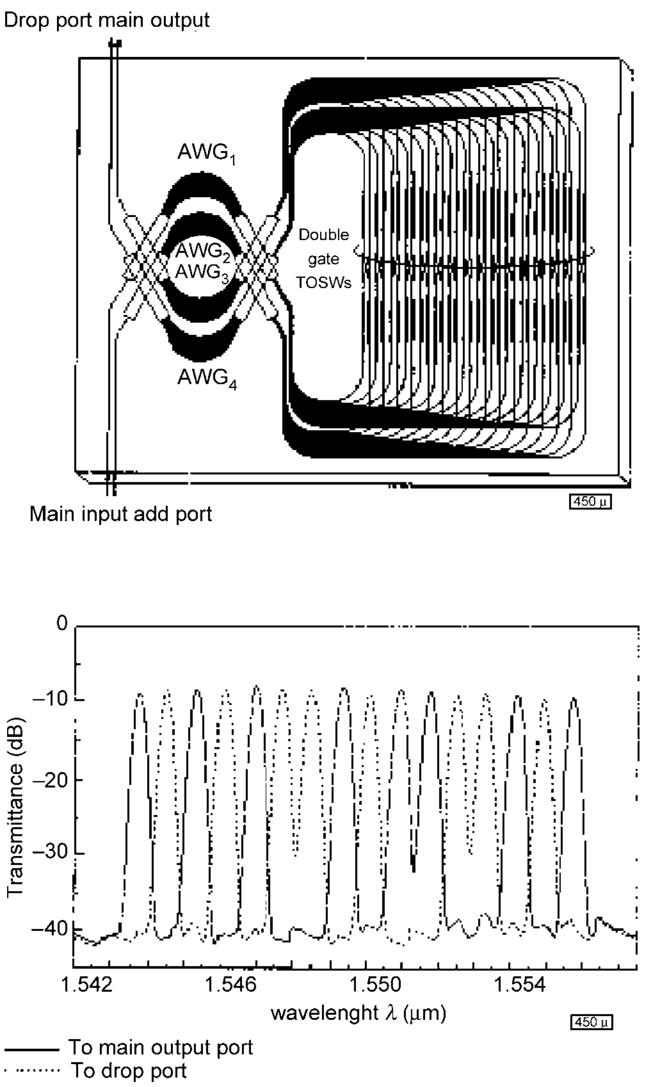

Figure B7.43. Integrated silica waveguide 2 × 2 optical crossconnect for 16 channels for each input/fibre [183]: layout with four AWGs and double stage TO switches, transmission spectrum for channels passing through (solid line) and dropped channels (dotted). Reproduced by permission of IEEE.

- Cross gain modulation (XGM)—an incoming photon will depopulate the conduction band, thus changing inversion and gain. One application of XGM is wavelength conversion, the concept of which is shown in figure B7.46: for an incoming '1' at the signal wavelength λ_{signal} the gain for the probe signal at wavelength λ_{probe} will drop, producing a '0'.
- Associated with the change in inversion is a variation in index and thus phase (cross phase modulation XPM), and this phase change is used in waveguide interferometers for signal processing:

Figure B7.44. Monolithic 2 × 2 crossconnect with two AWGs: design [184] and on-chip spectra of an InP device [177]. Reproduced by permission of IEEE.

- Time division demultiplexing: the monolithic InP MZI with SOAs in both arms depicted in figure B7.47 [187] (the architecture being the same as the GaAs all-optical passive switch in section B7.5.4/figure B7.39) represents a device for demultiplexing a 40 Gbit s^{-1} stream into 10 Gbit s^{-1} streams. Initially, the Mach–Zehnder is symmetric, but control pulse 1 will introduce a phase change in the upper SOA and will switch the signals from one output port to the other. As a result, the input data stream is demultiplexed. Control pulse 2 is introduced with an appropriate timing delay and resets the MZI to the initial state. The subsequent control pulses are needed for achieving switching speeds beyond the limit of the SOA carrier lifetimes (30–300 ps) [152].
- Wavelength conversion via XPM is explained schematically in figure B7.48(*a*): the switching signal $\lambda_{\mathrm{switch}}$ will introduce a de-phasing in the interferometer, thus impressing the data pattern on the continuous-wave probe wavelength $\lambda_{\mathrm{signal}}$. The result is one inverted and one noninverted signal as shown on the right hand side. The corresponding monolithic integrated InP device is shown in figure B7.48(*b*) together with the performance at 10 Gbit s^{-1} modulation [186], comparing the BER for the initial ('back-to-back') and wavelength converted signal. Besides monolithic solutions, hybrid integrated circuits had been published earlier [188].

XPM and XGM wavelength conversion are both suitable for single wavelengths, but not in WDM systems as—besides the signal λ_{switch}—all the other data channels also contribute to XGM and XPM. Despite the fact that XPM devices have a more complicated layout and are difficult to fabricate, they have significant advantages: higher extinction ratio for the wavelength converted signal, availability of both inverted and noninverted data outputs and regeneration of the signal (see section B7.5.8). Also, the direct amplitude modulation in XGM introduces chirp

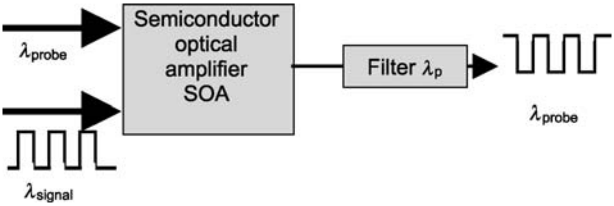

Figure B7.46. Wavelength conversion by cross-gain modulation (XGM) in a nonlinear semiconductor optical amplifier SOA. An incoming '1' on the signal wavelength will reduce the gain at the wavelength of the probe laser, producing an inverted signal.

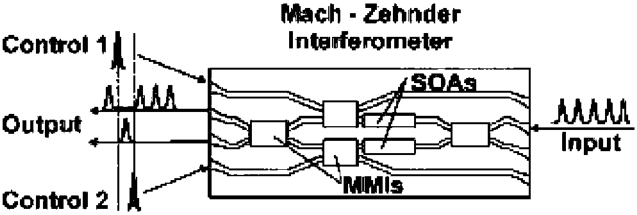

Figure B7.47. OTDM device [187]. The architecture is similar to the one in figure B7.39, but this time nonlinear InGaAsP SOAs in the 1.5 μm telecom window are used. Reproduced by permission of IEEE.

(i.e. the instantaneous phase of the signal is a function of the amplitude), but chirp can be controlled in XPM devices.

- Four wave mixing (FWM), which also arises in passive nonlinear transmission media such as fibre, causes three waves at frequencies ω_1, ω_2 and ω_3 to generate a fourth wave at frequency $\omega_1 + \omega_2 - \omega_3$. Pumping at wavelength $\omega_{pump} = \omega_1 = \omega_2$ and providing an idler at $\omega_{idler} = \omega_3$ results in a wavelength converted signal at $\omega_s = 2\omega_{pump} - \omega_{idler}$, as schematically shown in figure B7.49.

  In contrast to XPM and XGM, four wave mixing can convert several signals at once.

For an exhaustive treatment of all-optical time division multiplex system techniques, in particular using semiconductor and also fibre-based devices, see reference [63 chapter 9] and chapters A2.4, B.6 and C3.5.

For nonlinear optics, see chapters A2.4 and reference [8], and for SOAs in particular, see reference [7 chapter 11].

B7.5.8 All-optical regeneration

Degradation of the OSNR in a system arises from the accumulation of amplified spontaneous emission (ASE) from the line amplifiers, chromatic dispersion of the transmission fibre and components, PMD and third order nonlinearity of the fibre (self phase and cross phase modulation [189, 142]). This leads to a transparent reach of about 1500–2000 km, and the signal needs to be regenerated before further transmission. In [109], a re-circulating loop network with a reach of 69 000 km had been demonstrated using electronically driven modulators for reshaping the 20 Gbit s^{-1} signals for every 100 km.

All-optical regeneration could be an interesting alternative to electronic regeneration for different reasons: it is expected to be more cost effective through elimination of expensive O–E–O converters, moreover all-optical regeneration allows the processing of low as well as high bit rate signals rather than

being specifically designed for 10 or 40 Gbit s^{-1}. Also, 40 Gbit s^{-1} is believed to be the limitation for electronic regeneration but optical regeneration may perform at bit rates above this.

For regenerating a signal, three levels of manipulation are considered [107]:

- Optical re-amplification of the optical signal (1R regeneration).
- Amplification and re-shaping (2R).
- Amplification, re-shaping and retiming fully recovers the signal (3R). Retiming is necessary when accumulation of jitter, i.e. random signal delay through phase modulation in the fibre or in nonlinear devices (such as wavelength converters) is an issue.

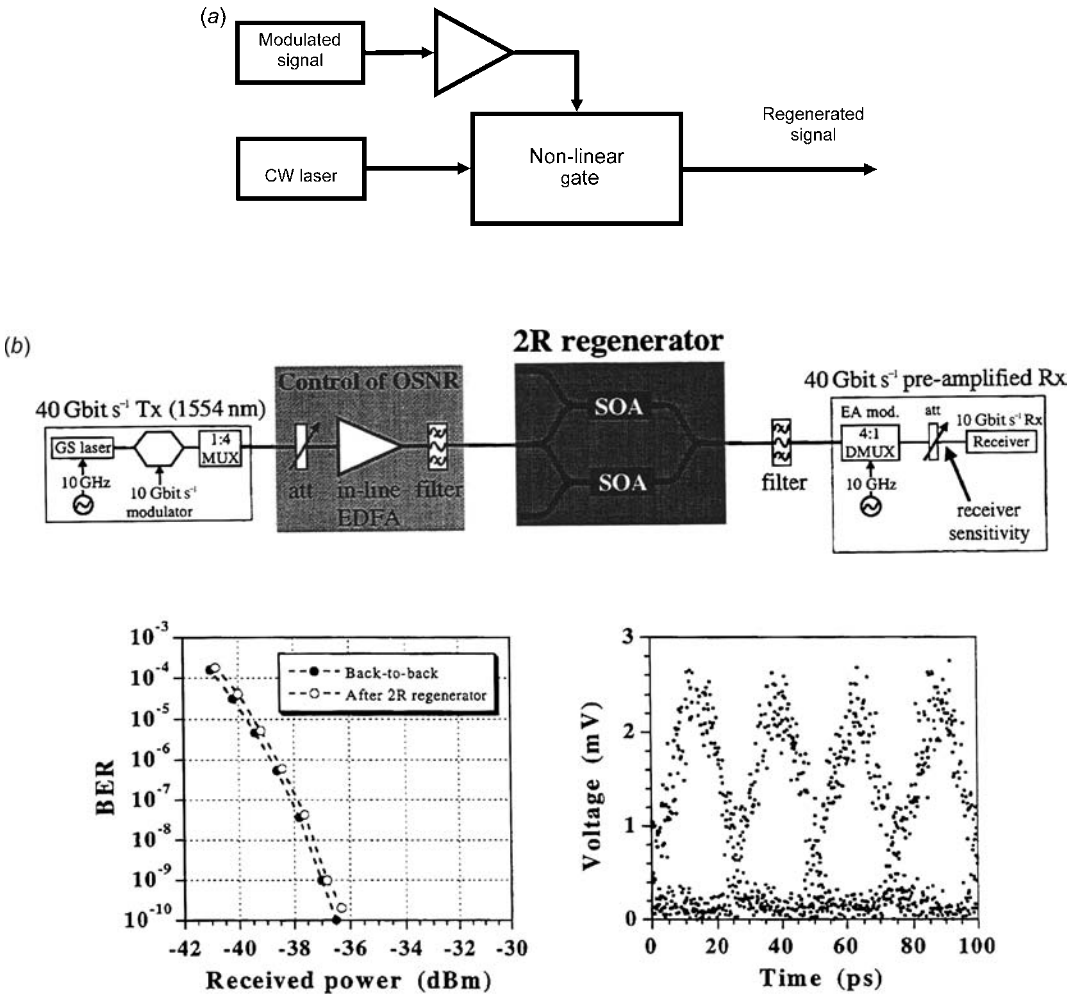
1R regeneration can be done all-optically in a linear amplifier (see chapters A1.6 and B5) or through OE-conversion followed by an electrical amplification and EO-conversion.

2R signal reshaping and amplification can be implemented with an amplifier and a nonlinear gate as sketched in figure B7.50(*a*): the nonlinear gate modulates a ‘clean’ CW signal having the same wavelength as the input data. Besides fibre based nonlinear devices, the SOA Mach–Zehnder interferometer previously used for XPM (section B7.5.7) provides a nonlinear amplitude response and can thus be used as a gate, as demonstrated in [190] for regeneration of 40 Gbit s^{-1} signals. In the SOA, the presence of the CW laser reduces the carrier lifetime through stimulated emission [152], thus enabling operation at high bit rates.

Figure B7.50(*b*) [190] shows the set-up for a 2R experiment at 40 Gbit s^{-1} as well as the BER results for a system with a 2R regenerator compared to the back-to-back operation of the Tx/Rx. The penalty is <0.2 dB, indicating that the 2R regenerator restores the signal almost to its initial quality.

3R regeneration (figure B7.51(*a*)) requires—besides 2R amplification and reshaping—the extraction of a jitter-free clock signal from the incoming data stream. The clock signals are then sent to the nonlinear optical gate, which is modulated by the initial data stream, and as a result a jitter-free signal is generated at the 3R output.

The main difficulty is the extraction of the clock signal, which can be done opto-electronically or all-optically via, for example, self-pulsating laser diodes (SP-LDs) [191, 192]. The SP-LD initially has a free-running repetition rate, and the basic principle (figure B7.51(*b*)) of clock extraction is that the SP-LD will change and lock its repetition rate to the data bit rate when optical data signals are injected into the



(a) (b)

Figure B7.50. (*a*) 2R regenerator. The nonlinear all-optical gate modulates a 'clean' CW signal having the same wavelength as the modulated input signal. (*b*) Set-up for 2*R* regeneration at 40 Gbit s^{-1} (top) [190] and system performance (bottom): bit error rate versus received power in a back-to-back configuration and after the 2R regenerator. The penalty of <0.2 dB indicates that the signals are regenerated almost with their initial signal-to-noise ratio. The bottom right figure is the oscilloscope trace of the received signal. Reproduced by permission of the Optical Society of America.

laser. The oscilloscope traces in figure B7.51(*c*) [193] show the incoming 5 Gbit s^{-1} data consisting of 1s and 0s (top) and the extracted clock signal constists of a train of '1' pulses.

In system experiments, 3R regeneration has been demonstrated for up to 40 Gbit s^{-1} bit rate using polarization rotation in a nonlinear fibre [194] and later on using a fibre based interferometer including an SOA as the nonlinear decision gate [195]. The latter set-up and experimental results are shown in figure B7.51(*d*): the inserts represent oscilloscope traces of the incoming and regenerated signals, and the BER diagrams show a PP of about 2.2 dB.

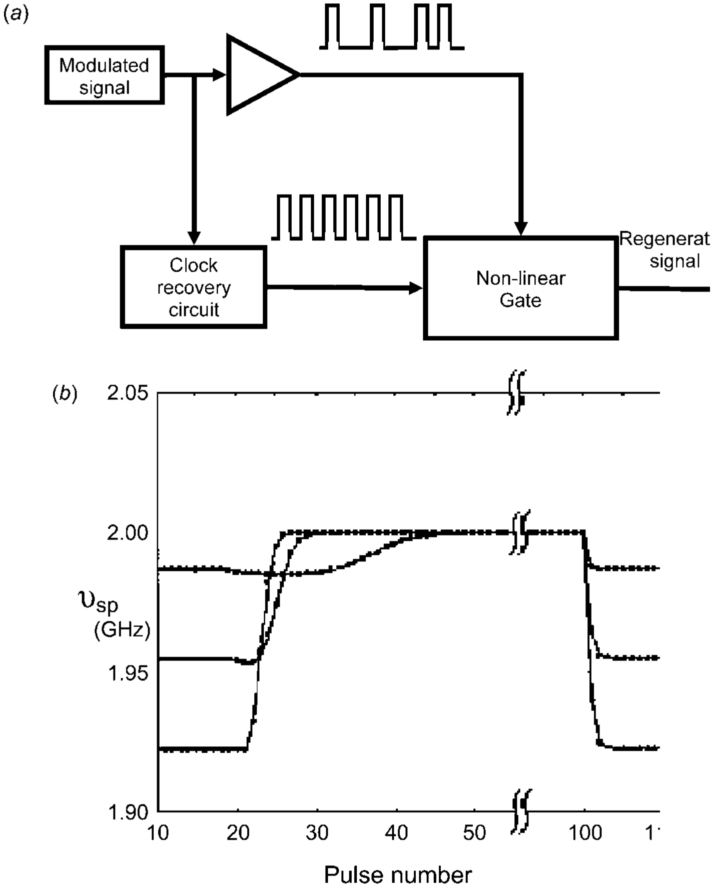


Figure B7.51. (*a*) Schematic 3R regenerator, consisting of a (noisy) input signal, from which the clock recovery circuit will extract a regular train of signals. The clock signals in turn will gate the all-optical nonlinear circuit, so that the data are not only re-amplified and re-shaped but also re-timed. (*b*) Self-pulsating laser diode [192] for clock recovery: the figure shows how laser diodes with different free-running frequencies will lock their repetition rate when synchronization pulses of precisely 2 GHz are injected. (*c*) Self-pulsating laser diode as a 5 Gbit s^{-1} clock recovery circuit: the clock signal (a train of '1' pulses) is extracted from an incoming signal consisting of '1's and '0's (top) [193]. (*d*) 3R regeneration (40 Gbit s^{-1}) [195]. In the experimental set-up (top), the nonlinear gate consists of a fiber-based Mach–Zehnder interferometer with a nonlinear SOA in one arm. BER (bottom) as a function of the received power, comparing the regenerated signals (open symbols) to a back-to-back experiment (full symbols). For a BER of 10^{-9}, the power penalty is about 2.2 dB. The insets are oscilloscope traces of the initial and regenerated signals. Reproduced by permission of IEEE.

B7.6 Conclusion

Integrated optics deals with compact single function devices, devices with integrated multiple functions (either on a single chip or in a single package) or devices with a functionality which cannot be achieved with common bulk or thin film optic devices. Besides these advantages in functionality or performance, the main driver for integrated optic devices is the desire for device footprint and reduced cost. The latter will be achieved through ongoing investments and standardization.

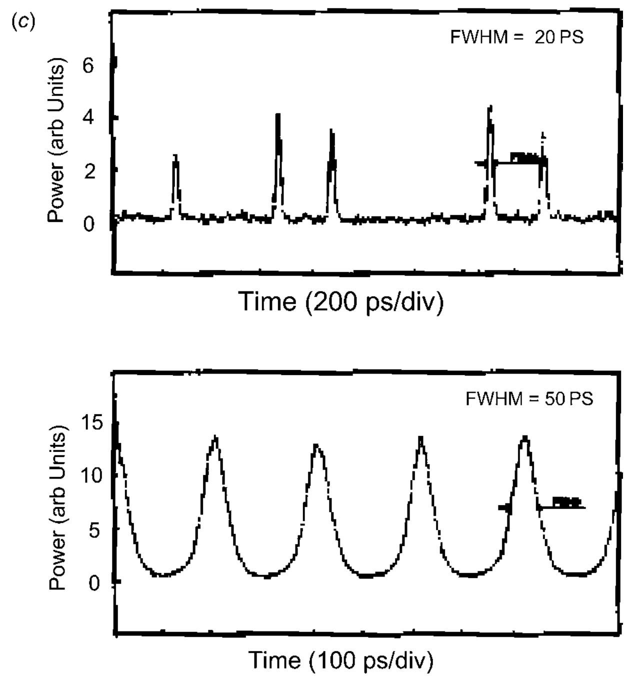

Figure B7.51. (Continued)

Tremendous work has been done over the last 20 years, but there are still a few words of caution:

- The technology is much less mature than electronics.
- As pointed out in section B7.3, there are multiple materials and technologies: that unlike in electronics where Si has an outstanding role, at present there is no material that is capable of addressing all needs in terms of device performance and cost simultaneously. InP may take the lead as it is suitable for the fabrication of both active and passive functions, but fundamental issues such as wafer size and materials compatibility will need to be addressed.
- Another difference with respect to electronics relates to the density of the optical circuits: the typical size of an optical chip is a few mm^2, which considerably limits the number of functions on a single substrate. The connection of the optical circuit to the outside world is done by aligning single mode fibre—the typical fibre diameter of 125 μm limits the number of I/O connections.
- Many current high speed devices (such as the switches in section B7.5.4, or the optical crossconnect in B7.5.5) use the electro-optic effect in SOAs, but all-optical devices (in analogy to the 'all-electronic' transistor) are still a subject of fundamental research, and thus are far from deployment.

Figure B7.51. (Continued)

However, there are key advantages of optical devices: the capability of achieving modulation speeds beyond 40 Gbit s^{-1}, the absence of electromagnetic interference, and finally optical devices may be used for sensing applications in environments in which electrical charges are prohibited.

Today, integrated optics is the technology of choice for a few functions such as filters, switches and gain equalizers. In future telecommunication applications, we will see an increasing deployment due to the advantages in device functionality, footprint, device cost and finally modulation speed resulting in higher transmission capacities.

Further reading

The textbooks in [80], [22], [20], [13] and [2] develop the theory of waveguides, couplers and splitters as well as electro-optic and magneto-optic control. For approximation methods in channel waveguides and numerical techniques see in particular references [1] and [2].

Material properties of nonlinear materials are found in [8], with details on nonlinear semiconductor devices in [7 chapter 11] and applications of nonlinear devices for TDM systems in [63 chapter 9].

Okamoto [2] and Madsen [22] treat authoritatively single mode planar waveguide building blocks and integrated devices, and [22] is the key reference for the design of optical filters. [20] and [2] have chapters on BPM, and [7 chapter 12] focuses on numeric design tools and their accuracy.

The recent books in [63] and [7] have specific chapters on hybrid and monolithic integration technique as well as lithium niobate components, rare-earth doped glass waveguides and integrated InP devices.

Packaging of opto-electronic devices is discussed in [79] in specific chapters on laser packaging, optical interconnection techniques and interconnection loss budgets.

Optical network components, propagation in fibre and network architectures are described from a practical perspective in [142], and detailed theoretical treatment of (single and multi-channel) signal propagation in fibre and noise in systems can be found in [189]. Finally, Agrawal [106] treats nonlinear effects in fibre and applications such as Raman amplification and nonlinear optic fibre devices.

B8
Infrared devices and techniques

Antoni Rogalski and Krzysztof Chrzanowski

B8.1 Introduction

Looking back over the past 1000 years, we notice that infrared (IR) radiation itself was unknown until 200 years ago when Herschel's experiment with a thermometer was first reported. He built a crude monochromator that used a thermometer as a detector so that he could measure the distribution of energy in sunlight [1]. Following the works of Kirchhoff, Stefan, Boltzmann, Wien and Rayleigh, Max Planck culminated the effort with the well-known Planck's law.

Traditionally, IR technologies are connected with controlling functions and night-vision problems with earlier applications connected simply with detection of IR radiation, and later by forming IR images from temperature and emissivity differences (systems for recognition and surveillance, tank sight systems, anti-tank missiles, air–air missiles). The years during World War II saw the origins of modern IR techniques. Recent success in applying IR technology to remote sensing problems has been made possible by the successful development of high-performance IR detectors over five decades. Most of the funding has been provided to fulfil military needs, but peaceful applications have increased continuously, especially in the last decade of the 20th century. These include medical, industry, earth resources and energy conservation applications. Medical applications include thermography in which IR scans of the body detect cancers or other traumas, which raise the body surface temperature. Earth resource determinations are done by using IR images from satellites in conjunction with field observation for calibration (in this manner, e.g. the area and content of fields and forests can be determined). In some cases, even the state of health of a crop be determined from space. Energy conservation in homes and industry has been aided by the use of IR scans to determine the points of maximum heat loss. Demands to use these technologies are quickly growing due to their effective applications, e.g. in global monitoring of environmental pollution and climate changes, long time prognoses of agriculture crop yield, chemical process monitoring, Fourier transform IR spectrometry, IR astronomy, car driving, IR imaging in medical diagnostics and others.

Nowadays, only about 10% of the market is commercial. After a decade, the commercial market can grow to over 70% in volume and 40% in value, largely connected with volume production of uncooled imagers for automobile driving [2]. In large volume production for automobile drivers, the cost of uncooled imaging systems will decrease to below $1000.

The infrared range covers all electromagnetic radiation longer than the visible, but shorter than millimetre waves. Many proposals of division of the IR range have been published. The division shown below (table B8.1) is used by the military community and is based on the limits of spectral bands of commonly used IR detectors. Wavelength of 1 μm is a sensitivity limit of popular Si detectors. Similarly, wavelength of 3 μm is a long wavelength sensitivity of PbS and InGaAs detectors; wavelength of 6 μm is a sensitivity limit of InSb, PbSe, PtSi detectors and HgCdTe detectors optimized for the 3–5 μm

Table B8.1. Division of infrared radiation.

Region (abbreviation)	Wavelength range (μm)
Near infrared (NIR)	0.78–1
Short wavelength IR (SWIR)	1–3
Medium wavelength IR (MWIR)	3–6
Long wavelength IR (LWIR)	6–15
Very long wavelength IR (VLWIR)	15–30
Far infrared (FIR)	30–100
Submillimetre (SubMM)	100–1000

atmospheric window; and finally wavelength of 15 μm is a long wavelength sensitivity limit of HgCdTe detectors optimized for the 8–14 μm atmospheric window.

B8.2 Infrared system fundamentals

B8.2.1 Thermal emission

All objects are composed of continually vibrating atoms, with higher energy atoms vibrating more frequently. The vibration of all charged particles, including these atoms, generates electromagnetic waves. The higher the temperature of an object, the faster the vibration, and thus the higher the spectral radiant energy. As a result, all objects are continually emitting radiation at a rate with a wavelength distribution that depends upon the temperature of the object and its spectral emissivity, $\varepsilon(\lambda)$.

Radiant emission is usually treated in terms of the concept of a blackbody [3]. A blackbody is an object that absorbs all incident radiation and conversely, according to the Kirchhoff law, is a perfect radiator. The energy emitted by a blackbody is the maximum theoretically possible for a given temperature. The radiative power (or number of photons emitted) and its wavelength distribution are given by the Planck radiation law:

$$W(\lambda, T) = \frac{2\pi hc^2}{\lambda^5}\left[\exp\left(\frac{hc}{\lambda kT}\right) - 1\right]^{-1} \quad \mathrm{W\,cm^{-2}\,\mu m^{-1}} \tag{B8.1}$$

$$P(\lambda, T) = \frac{2\pi c}{\lambda^4}\left[\exp\left(\frac{hc}{\lambda kT}\right) - 1\right]^{-1} \quad \mathrm{photons\,s^{-1}\,cm^{-2}\,\mu m^{-1}} \tag{B8.2}$$

where λ is the wavelength, T the temperature, h Planck's constant, c the velocity of light and k Boltzmann's constant.

Figure B8.1 shows a plot of these curves for a number of blackbody temperatures. As the temperature increases, the amount of energy emitted at any wavelength increases too, and the wavelength of peak emission decreases. The latter is given by the Wien displacement law:

$$\lambda_{\mathrm{mw}} T = 2898\ \mu\mathrm{m\,K} \quad \text{for maximum watts}$$
$$\lambda_{\mathrm{mp}} T = 3670\ \mu\mathrm{m\,K} \quad \text{for maximum photons}$$

The loci of these maxima are shown in figure B8.1. Note that for an object at an ambient temperature of 290 K, λ_{mw} and λ_{mp} occur at 10.0 and 12.7 μm, respectively. We need detectors operating

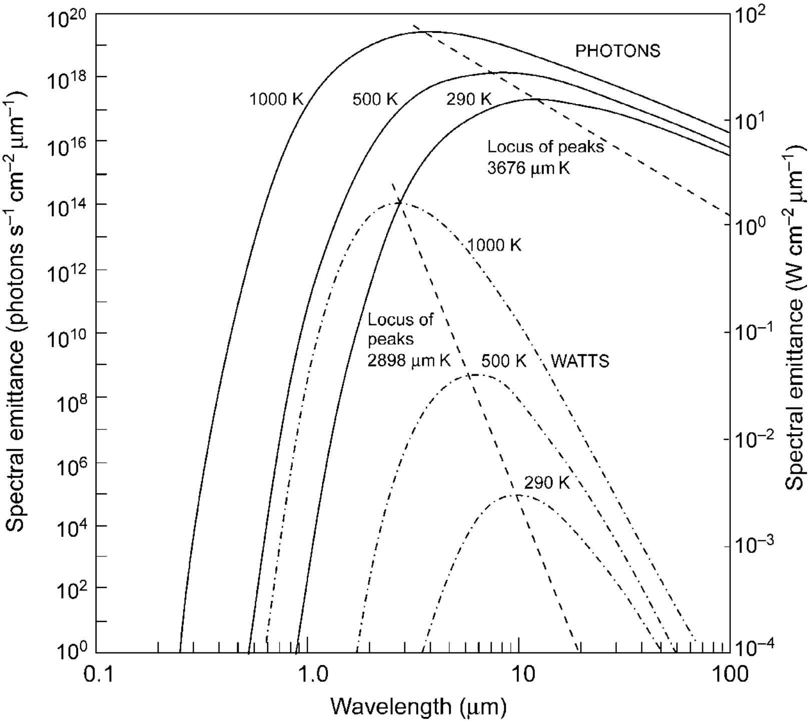

Figure B8.1. Planck's law for spectral emittance. Reproduced from [4].

near 10 μm if we expect to 'see' room temperature objects such as people, trees and trucks without the aid of reflected light. For hotter objects such as engines, maximum emission occurs at shorter wavelengths. Thus, the waveband 2–15 μm in infrared or thermal region of the electromagnetic spectrum contains the maximum radiative emission for thermal imaging purposes.

B8.2.2 Atmospheric transmission

Most of the above mentioned applications require transmission through air, but the radiation is attenuated by the processes of scattering and absorption. Scattering causes a change in the direction of a radiation beam; it is caused by absorption and subsequent reradiation of energy by suspended particles. For larger particles, scattering is independent of wavelength. However, for small particles, compared with the wavelength of the radiation, the process is known as Rayleigh scattering and exhibits a λ^{-4} dependence. Therefore, scattering by gas molecules is negligibly small for wavelengths longer than 2 μm. Also smoke and light mist particles are usually small with respect to IR wavelengths, and IR radiation can therefore penetrate further through smoke and mists than visible radiation. However, rain, fog particles and aerosols are larger and consequently scatter IR and visible radiation to a similar degree.

Figure B8.2 is a plot of the transmission through 6000 ft of air as a function of wavelength. Specific absorption bands of water, carbon dioxide and oxygen molecules are indicated that restrict atmospheric transmission to two windows at 3–5 and 8–14 μm. Ozone, nitrous oxide, carbon monoxide and methane are less important IR absorbing constituents of the atmosphere.

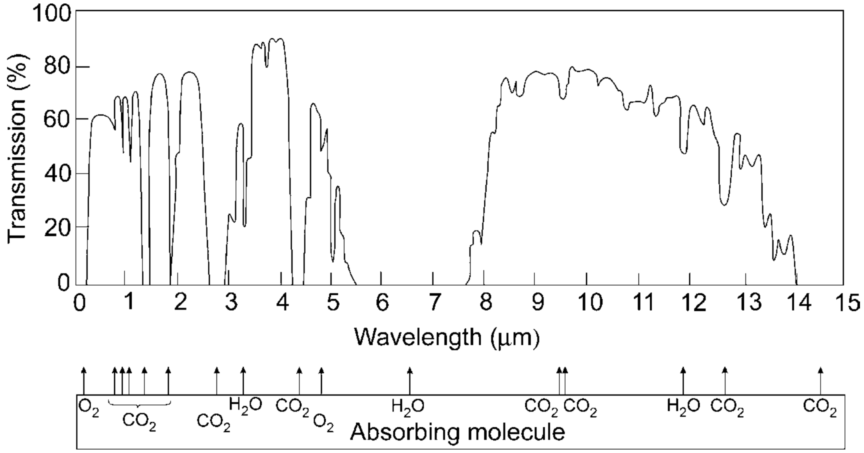

Figure B8.2. Transmission of the atmosphere for a 6000 ft horizontal path at sea level containing 17 mm of precipitate water. Reproduced from [5].

B8.2.3 Scene radiation and contrast

The total radiation received from any object is the sum of the emitted, reflected and transmitted radiation. Objects that are not blackbodies emit only the fraction $\varepsilon(\lambda)$ of blackbody radiation, and the remaining fraction, $1-\varepsilon(\lambda)$, is either transmitted or, for opaque objects, reflected. When the scene is composed of objects and backgrounds of similar temperatures, reflected radiation tends to reduce the available contrast. However, reflections of hotter or colder objects have a significant effect on the appearance of a thermal scene. The powers of 290 K blackbody emission and ground-level solar radiation in MWIR and LWIR bands are given in table B8.2. We can see that while reflected sunlight has a negligible effect on 8–13 μm imaging, it is important in the 3–5 μm band.

A thermal image arises from temperature variations or differences in emissivity within a scene. The thermal contrast is one of the important parameters for IR imaging devices. It is the ratio of the derivative of spectral photon incidence to the spectral photon incidence

$$C = \frac{\partial W/\partial T}{W}$$

The contrast in a thermal image is small when compared with visible image contrast due to differences in reflectivity. For a 291 K object in a 290 K scene, it is about 0.039 in the 3–5 μm band and 0.017 in

Table B8.2. Power available in each MWIR and LWIR imaging band.

IR region (μm)	Ground-level solar radiation (W m^{-2})	Emission from 290 K blackbody (W m^{-2})
3–5	24	4.1
8–13	1.5	127

Reproduced from [4].

the 8–13 μm band. Thus, while the LWIR band may have the higher sensitivity for ambient temperature objects, the MWIR band has the greater contrast.

B8.2.4 Choice of IR band

In general, the 8–14 μm band is preferred for high performance thermal imaging because of its higher sensitivity to ambient temperature objects and its better transmission through mist and smoke. However, the 3–5 μm band may be more appropriate for hotter objects, or if sensitivity is less important than contrast. Also additional differences occur, e.g. the advantage of the MWIR band is the smaller diameter of the optics required to obtain a certain resolution and that some detectors may operate at higher temperatures (thermoelectric cooling) than is usual in the LWIR band where cryogenic cooling is required (about 77 K).

Summarizing, MWIR and LWIR μm spectral bands differ substantially with respect to background flux, scene characteristics, temperature contrast and atmospheric transmission under diverse weather conditions. Factors that favour MWIR applications are: higher contrast, superior clear-weather performance (favourable weather conditions, e.g. in most countries of Asia and Africa), higher transmittivity in high humidity and higher resolution due to ~3 × smaller optical diffraction. Factors that favour LWIR applications are: better performance in fog and dust conditions, winter haze (typical weather conditions, e.g. in West Europe, North USA, Canada), higher immunity to atmospheric turbulence and reduced sensitivity to solar glints and fire flares. The possibility of achieving higher signal-to-noise (S/N) ratio due to greater radiance levels in LWIR spectral range is not persuasive because the background photon fluxes are higher to the same extent, and also because of readout limitation possibilities. Theoretically, in staring arrays charge can be integrated for the full frame time, but because of restrictions in the charge-handling capacity of the readout cells, it is much less compared to the frame time, especially for LWIR detectors for which background photon flux exceeds the useful signals by orders of magnitude.

B8.2.5 Detectors

The figure of merit used for detectors is detectivity. It has been found in many instances that this parameter varies inversely with the square root of both the detector's sensitive area, A, and the electrical bandwidth, Δf. In order to simplify the comparison of different detectors, the following definition has been introduced [6]

$$D^* = \frac{(A\Delta f)^{1/2}}{\Phi_e}(\mathrm{SNR}) \tag{B8.3}$$

where Φ_e is the spectral radiant incident power. D^* is defined as the rms signal-to-noise ratio (SNR) in a 1 Hz bandwidth per unit rms incident radiation power per square root of detector area. D^* is expressed in cm Hz$^{1/2}$ W^{-1}, which is recently called 'Jones'. Spectral detectivity curves for a number of commercially available IR detectors are shown in figure B8.3. Interest has centred mainly on the wavelengths of the two atmospheric windows 3–5 and 8–14 μm, though in recent years there has been increasing interest in longer wavelengths stimulated by space applications.

Progress in IR detector technology is connected mainly to semiconductor IR detectors, which are included in the class of photon detectors. In the class of photon detectors, the radiation is absorbed within the material by interaction with electrons. The observed electrical output signal results from the changed electronic energy distribution. The photon detectors show a selective wavelength dependence of the response per unit incident radiation power. They exhibit both perfect signal-to-noise performance and a very fast response. But to achieve this, the photon detectors require cryogenic cooling.

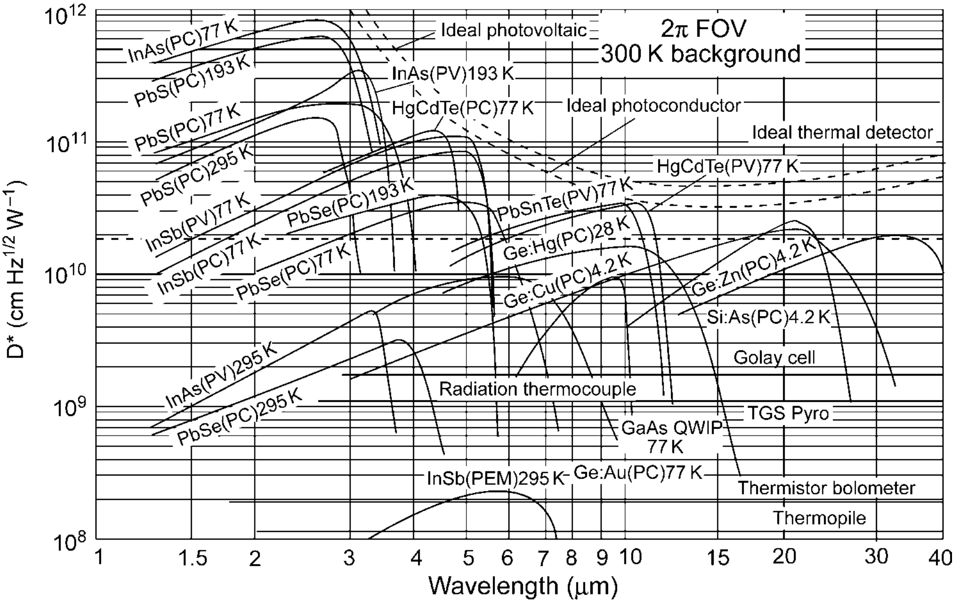

Figure B8.3. Comparison of the D^* of various commercially available infrared detectors when operated at the indicated temperature. The chopping frequency is 1000 Hz for all detectors except the thermopile (10 Hz), thermocouple (10 Hz), thermistor bolometer (10 Hz), Golay cell (10 Hz) and pyroelectric detector (10 Hz). Each detector is assumed to view a hemispherical surround at a temperature of 300 K. Theoretical curves for the background-limited D^* for ideal photovoltaic and photoconductive detectors and thermal detectors are also shown.

Cooling requirements are the main obstacle to the more widespread use of IR systems based on semiconductor photodetectors making them bulky, heavy, expensive and inconvenient to use. Depending on the nature of interaction, the class of photon detectors is further sub-divided into different types. The most important are: intrinsic detectors (HgCdTe, InGaAs, InSb, PbS, PbSe), extrinsic detectors (Si:As, Si:Ga), photoemissive (metal silicide Schottky barriers) detectors and quantum well detectors (GaAs/AlGaAs QWIPs).

The second class of IR detectors is composed of thermal detectors. In a thermal detector, the incident radiation is absorbed to change the temperature of material, and the resultant change in some physical properties is used to generate an electrical output. The detector element is suspended on lags, which are connected to the heat sink. Thermal effects are generally wavelength independent; the signal depends upon the radiant power (or its rate of change) but not upon its spectral content. In pyroelectric detectors, a change in the internal spontaneous polarization is measured, whereas in the case of bolometers a change in the electrical resistance is measured. In contrast to photon detectors, thermal detectors typically operate at room temperature. They are usually characterized by modest sensitivity and slow response but they are cheap and easy to use. The greatest utility in IR technology has been found by bolometers, pyroelectric detectors and thermopiles. Typical values of detectivities of thermal detectors at 10 Hz change in the range between 10^8 and 10^9 cm Hz$^{1/2}$ W^{-1}.

Up until the nineties of the 20th century, thermal detectors have been considerably less exploited in commercial and military systems in comparison with photon detectors. The reason for this disparity is that thermal detectors are popularly believed to be rather slow and insensitive in comparison with photon detectors. As a result, the worldwide effort to develop thermal detectors was extremely small relative to that of photon detectors. In the last decade, however, it has been shown that extremely good imagery can be obtained from large thermal detector arrays operating uncooled at TV frame rates. The speed of thermal detectors is quite adequate for nonscanned imagers with two-dimensional (2D) detectors. The moderate sensitivity of thermal detectors can be compensated by a large number of elements in 2D electronically scanned arrays. With large arrays of thermal detectors the best values of NEDT, below 0.1 K, could be reached because effective noise bandwidths less than 100 Hz can be achieved.

B8.2.6 Cooling

The signal output of a photon detector is so small that at ordinary temperatures it is swamped by the thermal noise due to random generation and recombination of carriers in the semiconductor. In order to reduce the thermal generation of carriers and minimize noise, photon detectors must be cooled and must therefore be encapsulated. The method of cooling varies according to the operating temperature and the system's logistical requirements. Most 8–14 μm detectors operate at about 77 K and can be cooled by liquid nitrogen. In the field, however, it is more convenient to use compressed air and a Joule–Thompson minicooler [7]. The operation of the Joule–Thompson cooler is based on the fact that as the high-pressure gas expands on leaving a throttle valve, it cools and liquefies. The gas used must be purified to remove water vapour and carbon dioxide which could freeze and block the throttle valve. Specially designed Joule–Thompson coolers using argon are suitable for ultra-fast cool-down.

The use of cooling engines, in particular those employing the Stirling cycle [8], has increased recently due to their efficiency, reliability and cost reduction. The Stirling engine requires several minutes cool-down time; the working fluid is helium. Both Joule–Thompson and engine-cooled detectors are housed in precision-bore Dewars into which the cooling device is inserted (see figure B8.4). Mounted in the vacuum space at the end of the inner wall of the Dewar, and surrounded by a cooled radiation shield compatible with the convergence angle of the optical system, the detector looks out through an IR window. In some Dewars, the electrical leads to detector elements are embedded in the inner wall of the dewar to protect them from damage due to vibration.

Many detectors in the 3–5 μm waveband are thermoelectrically cooled. In this case, detectors are usually mounted in a hermetic encapsulation with a base designed to make good contact with a heatsink.

B8.2.7 IR optics

The optical block in an IR system creates an image of observed objects in the plane of the detector (detectors). In the case of a scanning imager, the optical scanning system creates an image with the number of pixels much greater than the number of elements of the detector. In addition, optical elements like windows, domes and filters can be used to protect the system from the environment or to modify the detector spectral response.

There is no essential difference in design rules of optical objectives for visible and IR ranges. The designer of IR optics is only more limited because there are significantly fewer materials suitable for IR optical elements, in comparison with those for the visible range, particularly for wavelengths over 2.5 μm.

There are two types of IR optical element: reflective elements and refractive elements. As the names suggest, the role of reflective elements is to reflect incident radiation and the role of refractive elements is to refract and transmit incident radiation.

Mirrors used extensively inside IR systems (especially in scanners) are most often met as reflective elements that serve manifold functions in IR systems. Elsewhere they need a protective coating to prevent them from tarnishing. Spherical or aspherical mirrors are employed as imaging elements. Flat mirrors are widely used to fold optical paths, and reflective prisms are often used in scanning systems.

Figure B8.4. Three ways of cooling IR detectors: (*a*) four-stage thermoelectric cooler (Peltier effect), (*b*) Joule–Thompson cooler and (*c*) Stirling-cycle engine.

Four materials are most often used for mirror fabrication: optical crown glass, low-expansion borosilicate glass (LEBG), synthetic fused silica and Zerodur. Less popular in use are metallic substrates (beryllium, copper) and silicon carbide. Optical crown glass is typically applied in nonimaging systems. It has a relatively high thermal expansion coefficient and is employed when thermal stability is not a critical factor. LEBG, known by the Corning brand name Pyrex, is well suited for high quality front-surface mirrors designed for low optical deformation under thermal shock. Synthetic fused silica has a very low thermal expansion coefficient.

Metallic coatings are typically used as reflective coatings of IR mirrors. There are four types of most often used metallic coating: bare aluminium, protected aluminium, silver and gold. They offer high reflectivity, over about 95%, in the 3–15 μm spectral range. Bare aluminium has a very high reflectance value but oxidizes over time. Protected aluminium is a bare aluminium coating with a dielectric overcoat that arrests the oxidation process. Silver offers better reflectance in the near IR than aluminium and high reflectance across a broad spectrum. Gold is a widely used material and offers consistently very high reflectance (about 99%) in the 0.8–50 μm range. However, gold is soft (it cannot be touched to remove dust) and is most often used in the laboratory.

The most popular materials used in manufacturing refractive optics of IR systems are: germanium (Ge), silicon (Si), fused silica (SiO_2), glass BK-7, zinc selenide (ZnSe) and zinc sulfide (ZnS). The IR-transmitting materials potentially available for use as windows and lenses are gathered in table B8.3 and their IR transmission is shown in figure B8.5.

Germanium is a silvery metallic-appearing solid of very high refractive index (≈ 4) that enables design of high-resolution optical systems using a minimal number of germanium lenses. Its useful

Table B8.3. Principal characteristics of some infrared materials.

Material	Waveband (μm)	$n_{4\,\mu m}$, $n_{10\,\mu m}$	dn/dT ($10^{-6}\,K^{-1}$)	Density ($g\,cm^{-3}$)	Other characteristics
Ge	3–5, 8–12	4.025, 4.004	424 (4 μm), 404 (10 μm)	5.33	Brittle, semiconductor, can be diamond turned, visibly opaque, hard
Si	3–5	3.425	159 (5 μm)	2.33	Brittle, semiconductor, diamond turned with difficulty, visibly opaque, hard
GaAs	3–5, 8–12	3.304, 3.274	150	5.32	Brittle, semiconductor, visibly opaque, hard
ZnS	3–5, 8–12	2.252, 2.200	43 (4 μm), 41 (10 μm)	4.09	Yellowish, moderate hardness and strength, can be diamond turned, scatters short wavelengths
ZnSe	3–5, 8–12	2.433, 2.406	63 (4 μm), 60 (10 μm)	5.26	Yellow–orange, relatively soft and weak, can be diamond turned, very low internal absorption and scatter
CaF_2	3–5	1.410	−8.1 (3.39 μm)	3.18	Visibly clear, can be diamond turned, mildly hygroscopic
Sapphire	3–5	1.677 (n_o) 1.667 (n_e)	6 (o), 12 (e)	3.99	Very hard, difficult to polish due to crystal boundaries
AMTIR-1	3–5, 8–12	2.513, 2.497	72 (10 μm)	4.41	Amorphous IR glass, can be slumped to near-net shape
BK7 (glass)	0.35–2.3		3.4	2.51	Typical optical glass

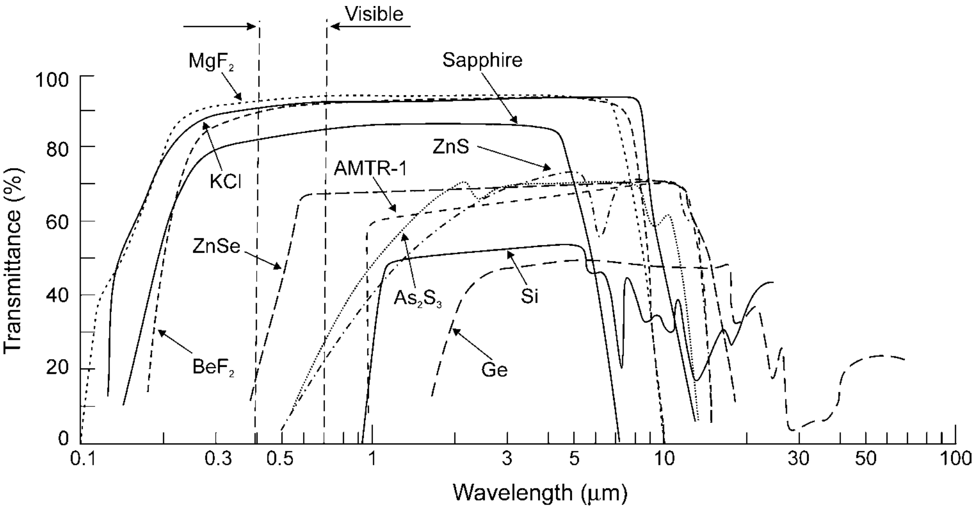

Figure B8.5. Transmission range of infrared materials. Reproduced from [9].

transmission range is from 2 to about 15 μm. It is quite brittle and difficult to cut but accepts a very good polish. Additionally, due to its very high refractive index, antireflection coatings are essential for any germanium transmitting optical system. Germanium has a low dispersion and is unlikely to need colour correcting except in the highest-resolution systems. In spite of high material price and cost of antireflection coatings, germanium lenses are particularly useful for the 8–12 μm band. A significant disadvantage of germanium is the serious dependence of its refractive index on temperature, so germanium telescopes and lenses may need to be athermalized.

Physical and chemical properties of silicon are very similar to properties of germanium. It has high refractive index (≈ 3.45), is brittle, does not cleave, takes an excellent polish and has large dn/dT. Similarly to germanium, silicon optics must have antireflection coatings. Silicon offers two transmission ranges: 1–7 and 25–300 μm. Only the first one is used in typical IR systems. The material is significantly cheaper than germanium. It is used mostly for IR systems operating in the 3–5 μm band.

Single-crystal material has generally higher transmission than polycrystalline material. Optical-grade germanium used for the highest optical transmission is n-type doped to receive a conductivity of 5–14 Ω cm. Silicon is used in its intrinsic state. At elevated temperatures, semiconducting materials become opaque. As a result, germanium is of little use above 100°C. In the 8–14 μm region, semi-insulating GaAs may be used at the temperatures up to 200°C.

Ordinary glass does not transmit radiation beyond 2.5 μm in the IR region. Fused silica is characterized by a very low thermal expansion coefficient that makes optical systems particularly useful in changing environmental conditions. It offers a transmission range from about 0.3 to 3 μm. Because of low reflection losses due to the low refractive index (≈ 1.45), antireflection coatings are not needed. However, an antireflection coating is recommended to avoid ghost images. Fused silica is more expensive than BK-7, but still significantly cheaper than Ge, ZnS and ZnSe, and is a popular material for lenses of IR systems with bands located below 3 μm. BK-7 glass characteristics are similar to fused silica; the difference is only a bit shorter transmission band up to 2.5 μm.

ZnSe is expensive material comparable to germanium; has a transmission range from 2 to about 20 μm, and a refractive index about 2.4. It is partially translucent in the visible and reddish in colour. Due to the relatively high refractive index, antireflection coatings are necessary. The chemical resistance of the material is excellent.

ZnS has excellent transmission in the range from 2 to 12 μm. It is usually a polycrystalline material that shows only a light yellow colour. Recently also colourless, low-scatter grades of ZnS have become available. Because of the relatively high refractive index of 2.25, antireflection coatings are needed to minimize flux reflection. The hardness and fracture strength are very good. ZnS is brittle, can operate at elevated temperatures and also can be used to colour correct high-performance germanium optics.

The alkali halides have excellent IR transmission; however, they are either soft or brittle and many of them are attacked by moisture, making them generally unsuitable for industrial applications. For more detailed discussion of the IR materials, see references [10, 11].

B8.2.8 Night-vision system concepts

Night-vision systems can be divided into two categories: those depending upon the reception and processing of radiation reflected by an object and those which operate with radiation internally generated by an object. The latter systems are described in the subsection below.

The human visual perception system is optimized to operate in daytime illumination conditions. The visual spectrum extends from about 420 to 700 nm and the region of greatest sensitivity is near the peak wavelength of sunlight at around 550 nm. However, at night fewer visible light photons are available and only large, high-contrast objects are visible. It appears that the photon rate in the region from 800 to 900 nm is five to seven times greater than in the visible region around 500 nm. Moreover, the reflectivity of various materials (e.g. green vegetation, because of its chlorophyll content) is higher between 800 and 900 nm than at 500 nm. It means that at night more light is available in the NIR than in the visual region and that against certain backgrounds more contrast is available.

A considerable improvement in night-vision capability can be achieved with night viewing equipment which consists of an objective lens, image intensifier and eyepiece (see figure B8.6). Improved visibility is obtained by gathering more light from the scene with an objective lens than the unaided eye; by use of a photocathode that has higher photosensitivity and broader spectral response than the eye; and by amplification of photo-events for visual sensation.

B8.2.9 Thermal imaging system concepts

Thermal imaging is a technique for converting a scene's thermal radiation pattern (invisible to the human eye) into a visible image. Its usefulness is due to the following aspects [4]:

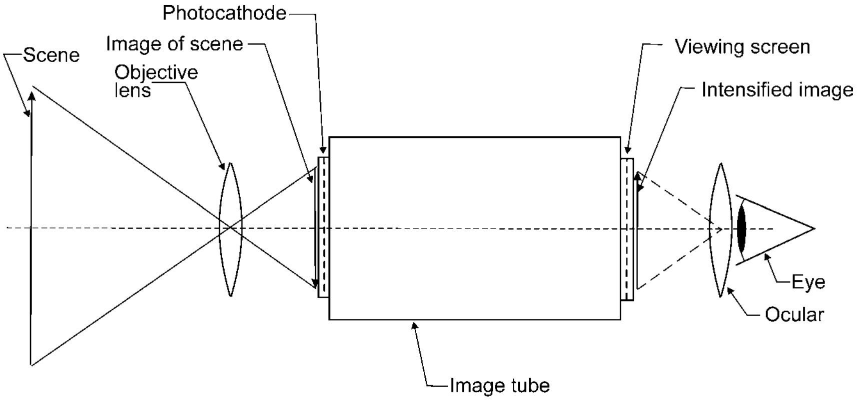

Figure B8.6. Diagram of an image intensifier.

- it is totally passive technique and allows day and night operation;
- it is ideal for detection of hot or cold spots, or areas of different emissivities, within a scene;
- thermal radiation can penetrate smoke and mist more readily than visible radiation;
- it is a real-time, remote sensing technique.

The thermal image is a pictorial representation of temperature difference. Displayed on a scanned raster, the image resembles a television picture of the scene and can be computer processed to colour-code temperature ranges. Originally developed (in the 1960s) to extend the scope of night-vision systems, thermal imagers at first provided an alternative to image intensifiers. As the technology has matured, its range of application has expanded and now extends into the fields that have little or nothing to do with night vision (e.g. stress analysis, medical diagnostics). In most present-day thermal imagers, an optically focused image is scanned (mechanically or electronically) across detectors (many elements or 2D array) the output of which is converted into a visual image. The optics, mode of scanning and signal processing electronics are closely interrelated. The number of picture points in the scene is governed by the nature of the detector (its performance) or the size of the detector array. The effective number of picture points or resolution elements in the scene may be increased by an optomechanical scanning device which images different parts of the scene on to the detector sequentially in time.

The performance of a thermal imager is usually specified in terms of temperature resolution. It can be shown that the temperature sensitivity of an imager, the so-called noise equivalent temperature (NETD), can be given by [12]:

$$\mathrm{NETD} = \frac{4f_{\#}^{2}(\Delta f)^{1/2}}{A^{1/2}t_{\mathrm{op}}M^{*}} \tag{B8.4}$$

where $f_{\#}$ is the f-number of the detector optics ($f_{\#} = f/D$, f is the focal length and D the diameter of the lens), t_{op} the transmission of the optics and M^{*} the figure of merit that includes not only the detector performance D^{*} but also the spectral dependence of the emitted radiation, $(\partial S/\partial T)_{\lambda}$, and the atmospheric transmission t_{at}. It is given by the following equation:

$$M^{*} = \int_{0}^{\infty}\left(\frac{\partial S}{\partial T}\right)_{\lambda} t_{\mathrm{at}\lambda}D_{\lambda}^{*}\,\mathrm{d}\lambda \tag{B8.5}$$

NETD is the difference of temperature of the object required to produce an electric signal equal to the rms noise at the input of the display [6]. Temperature resolution depends on the efficiency of the optical system, responsivity and noise of the detector, and SNR of the signal processing circuitry.

For high sensitivity, the NETD must be low. The sensitivity increases inversely as the square root of the electrical bandwidth. For a given size of IR scene, the electronic bandwidth is inversely proportional to the number of parallel detector elements, and so the thermal sensitivity increases as the square root of the total number of detector elements, irrespective of the parallel or serial content of the array.

B8.3 IR systems

This section briefly concentrates on selected IR systems and is arranged in order of increasing complexity: smart weapon seekers, FLIRs and space-based systems. A comprehensive compendium devoted to IR systems was copublished in 1993 by the Infrared Information Analysis Center (IRIA) and the International Society for Optical Engineering (SPIE) as *The Infrared and Electro-Optical Systems Handbook* (executive editors: Joseph S Accetta and David L Shumaker).

B8.3.1 Smart weapon seekers

The seeker is the primary homing instrument for smart weapons that include missiles, bombs, artillery projectiles and standoff cruise missiles. They can be categorized into three groups: passive nonimaging seekers, passive imaging seekers and active laser guided seekers.

Passive nonimaging seekers use a circular optical plate with adjacent transparent and nontransparent parts called the reticle that is fixed at the image plane of the imaging optics of the missile head (figure B8.7). A single IR detector, of size a bit larger than the reticle, is placed just behind it. The location of the point image of the target on the reticle plate changes, even when the target does not change its position, due to rotation of the reticle or rotation of the imaging optics. Therefore, radiation emitted by the target generates electrical pulses at the detector output. The pulse duration and phase of these pulses give information about the angular position of the target (figure B8.8).

The grandfather of passive IR seekers is the Sidewinder seeker developed in the 1950s: it employed vacuum tubes and a lead salt single-element detector. During the next decades it was found that, despite their simplicity, passive nonimaging seekers are very effective for guiding missiles when the target is on a uniform background. Therefore, at present, the majority of currently used short-range smart missiles use this type of seeker. However, the effectiveness of passive nonimaging seekers decreases significantly for

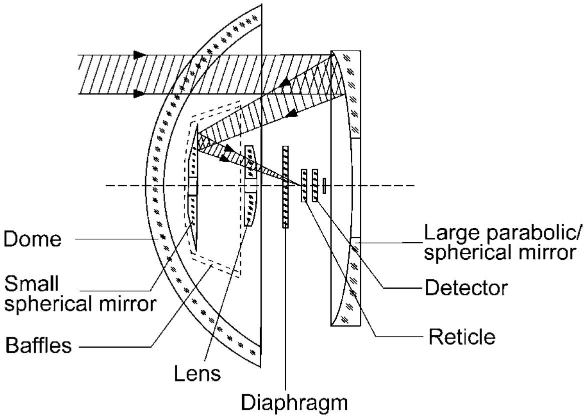

Figure B8.7. Optical diagram of a typical passive nonimaging seeker.

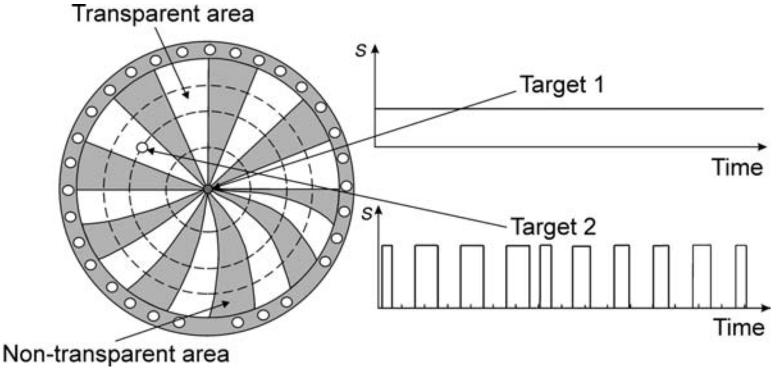

Figure B8.8. Exemplary reticle and the signal generated at the detector output by a few targets of different location.

targets on nonuniform background like typical ground military targets or in the presence of countermeasures. Therefore, the trend of future systems is towards passive imaging seekers.

Passive imaging seekers have a TV camera or a thermal camera in their optoelectronic head. The location of a target is determined from analysis of the image generated by a camera. Some of the air-to-ground missiles attack and destroy ground targets, particularly large nonmovable targets like bridges, bunkers, buildings, etc. However, significant technical limitations exist. First, the seekers using TV cameras can operate only in daylight conditions. Second, it is very difficult to design a thermal camera for high-speed missiles. Such a camera must be of small size, very fast operating, reliable, ready to withstand harsh environmental requirements and of low manufacturing cost. Therefore, the imaging missiles using thermal cameras in their optical heads are still at a development stage.

Active laser guided seekers can be divided into two subclasses: seekers homing on the irradiated target and seekers irradiated with a laser beam (see figure B8.9). Seekers homing on the irradiated target cooperate with a laser illuminator and use the laser radiation reflected by the target. These seekers enable very accurate location of small targets in a highly nonuniform background and are particularly well suited for air-to-ground missiles or bombs. However, it is an active method and employing warning systems or other countermeasures can significantly reduce its effectiveness.

Seekers irradiated with a laser beam are kept on their flight to the target within the beam emitted by the laser illuminator that irradiates the target. Laser radiation, which gives information on target location, comes directly from the illuminator to the sensors at the back of the missile, not after the reflection by the target as in the previous method. Therefore, low-power illuminators can be used here and the effectiveness of the warning systems is reduced.

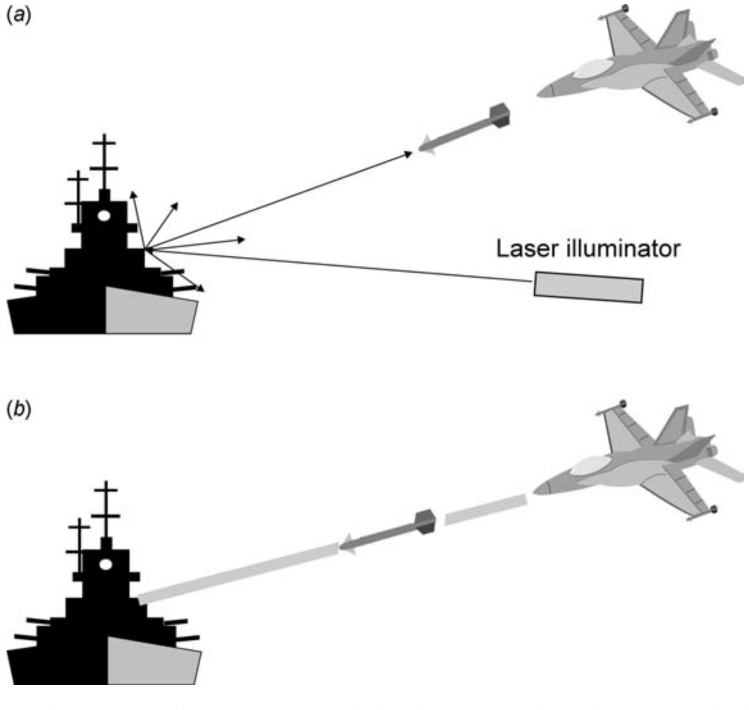

Figure B8.9. Principle of operation of active laser guided seekers: (*a*) seekers homing on the irradiated target and (*b*) seekers irradiated with a laser beam.

The new generation of standoff weapons relies on real-time target recognition, discrimination, tracking, navigation and night vision. It is predicted that the smart weapons will tend to replace the radar emphasis as stealth platforms are increasingly used for low-intensity conflicts. It is more difficult to perform IR missile warning than radar guided missile warning.

A representative architecture of a staring seeker is shown in figure B8.10. To keep seeker volume, weight and power requirements low, only the minimum hardware needed to sense the scene is included. We can note that the seeker's output is going to a missile-based processor, behind the FPA in the seeker, to perform tracking and aimpoint selection. The concept of the seeker's operation includes a standby turn-on, followed by a commit, which cools the FPA. At the beginning, the seeker is locked onto its target by an external sensor or a human. Next, the missile is launched and flies out locked onto its target, matching any target movement. Finally, when the target is close and imaged, the missile chooses an aimpoint and conducts final manoeuvres to get to the target or selects a point and time to fuse and explode.

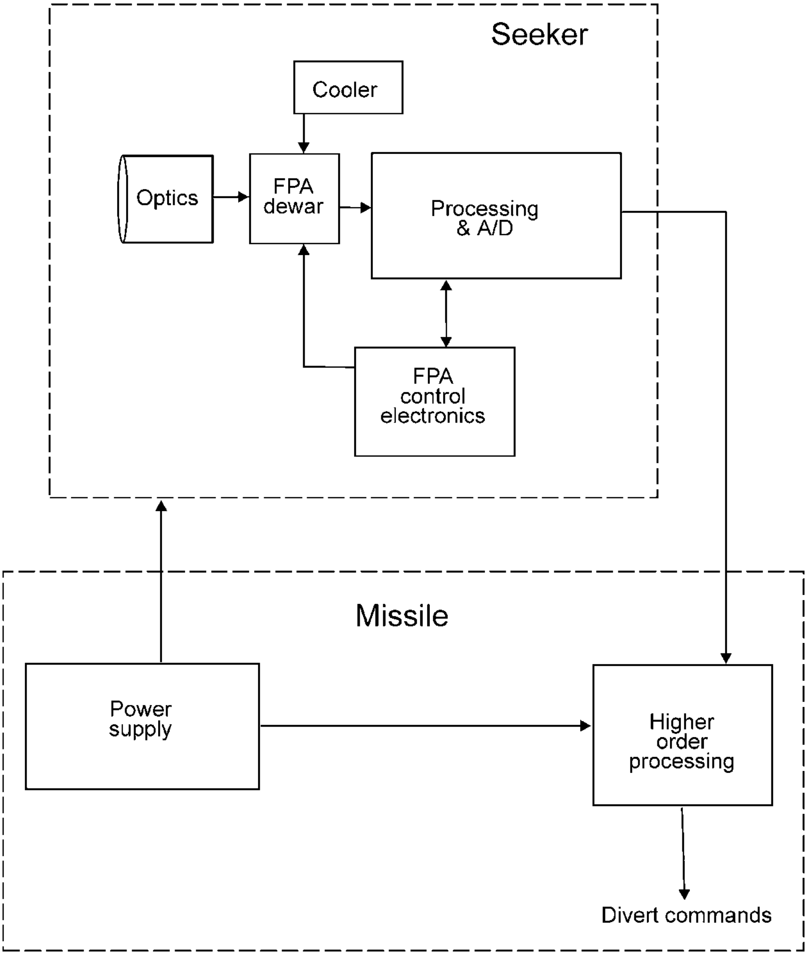

Figure B8.10. Representative imaging (staring) seeker architecture. Reproduced from [7].

B8.3.2 Image intensifier systems

The image intensifiers are classed by generation (Gen) numbers. Gen0 refers to the technology of World War II, employing fragile, vacuum-enveloped photon detectors with poor sensitivity and little gain. Gen1 represents the technology of the early Vietnam era, the 1960s. In this era, the first passive systems, able to amplify ambient starlight, were introduced. Though sensitive, these devices were large and heavy. Gen1 devices used tri-alkali photocathodes to achieve gain of about 1000. By the early 1970s, the microchannel-plate (MCP) amplifier was developed comprising more than two million microscopic conducting channels of hollow glass, each of about 10 μm in diameter, fused into a disc-shaped array. Coupling the MCP with multi-alkali photocathodes, capable of emitting more electrons per incident photon, produced GenII. GenII devices boasted amplifications of 20 000 and operational lives of 2500 h. Interim improvements in bias voltage and construction methods produced the GenII+ version. Substantial improvements in gain and bandwidth in the 1980s heralded the advent of GenIII. Gallium arsenide photocathodes and internal changes in the MCP design resulted in gains ranging from 30 000 to 50 000 and operating lives of 10 000 h.

Many candidate technologies could form the basis of a GenIV, ranging from enhanced current designs to completely different approaches. Among those are devices with a new photocathode that extend spectral response to 1.6 μm and the use of an amplifying mechanism other than MCPs. Other potentials include lightweight systems that fuse the outputs from image intensifiers and thermal imagers, and those that couple electron-bombarded CCD arrays—providing sensitivity in the NIR and MWIR regions—with miniature flat-panel displays. The first GenIV tubes demonstrated substantial increase in target detection range and resolution, particularly at extremely low light levels.

Figure B8.11 shows the response of a typical Gen3 image intensifier superimposed on the night sky radiation spectrum. This figure also shows the CIE photopic curve illustrating the spectral response of the human visual perception system, and the GenII response.

Various implementations of image intensifier tubes have been realized. Phosphor output image intensifiers were reviewed in depth by Csorba [14]. The image is focused onto a semitransparent photocathode and photoelectrons are emitted with a spatial intensity distribution which matches the focused image. In image intensifiers, the electrons are then accelerated towards a phosphor screen where they reproduce the original image with enhanced intensity. Three common forms of image tube are shown in figure B8.12.

In a ‘proximity-focused’ tube, a high electric field (typically 5 kV), and a short distance between the photocathode and the screen, limit spreading of electrons to preserve an image. This form of tube is compact, the image is free from distortion and only a simple power supply is required. However, the resolution of such a tube is limited by the field strength at the photocathode and the resolution is highest when the distance between cathode and screen is small.

An electrostatically focused tube is based upon a system of concentric spheres (cathode and anode, typical bias voltage of 15 kV). In practice, the electrodes depart radically from the simple spherical concept. Additional electrodes can be introduced to provide focusing control and reduce the image distortion, while fibre-optic windows at input and output can be used to improve image quality and provide a better matching to objective and coupling optics. Power suppliers are very simple and lightweight, so this type of tube is widely used in portable applications.

A magnetically focused system gives very high-resolution imagers with little or no distortion. The focusing coil, however, is usually heavy and power consuming. For the best picture quality, the power suppliers for both tube and coil must be stable. This type of tube is used in applications where resolution and low distortion are vital and weight and power consumption do not create unacceptable problems.

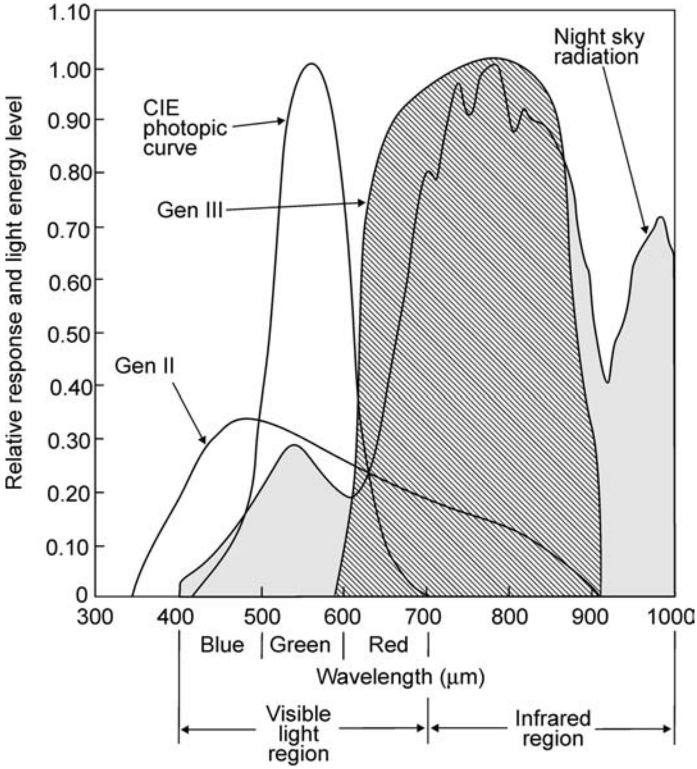

Figure B8.11. Image intensifier tube spectral response curves. Reproduced from [13].

Image intensifiers are widespread in many military applications [15]. The advent of night-vision devices and helmet-mounted displays places additional constraints on the helmet, which is now an important element of the cockpit display system, providing weapon aiming, and other information—such as aircraft attitude and status—to the pilot. For example, figure B8.13 illustrates Marconi Avionics' conventional product produced in large quantities.

B8.3.3 Thermal imaging systems

The basic concept of a modern thermal imager system is to form a real image of the IR scene, detect the variation in the imaged radiation, and, by suitable electronic processing, create a visible representation of this variation analogous to conventional television cameras.

Due to existing terminology confusion in the literature, we can find at least 11 different terms used as synonyms of the earlier defined thermal imaging systems: thermal imager, thermal camera, thermal imaging camera, FLIR (forward looking infrared), IR imaging system, thermograph, thermovision, thermal viewer, infrared viewer, infrared imaging radiometer, thermal viewer, thermal data viewer and thermal video system. The only real difference between the above-mentioned terms is that the designations 'thermograph', 'infrared imaging radiometer' and 'thermovision' usually refer to thermal cameras used for measurement applications, while the other terms refer to thermal cameras used in observation applications. For example, thermographic imagers supply quantitative temperature, while radiometers provide quantitative radiometric data on the scene (such as radiance or irradiance) or process these data to yield information about temperatures.

Thermal imagers have various applications, depending on the platform and user. Most of them are used in military applications. They often have multiple fields of view (FOV) that are user switchable during operation, which gives both a wide, general surveillance mode as well as a high magnification and narrow field for targeting, designating or detailed intelligence gathering. Many military thermal imagers are integrated with a TV camera and a laser range finder. A TV colour camera is used during daytime conditions due to its superior image quality. Nonmilitary uses include generic search and track, snow rescue, mountain rescue, illegal border crossing detection and pilot assistance at night or in bad weather, forest fire detection, fire fighting, inspection and discreet surveillance and evidence gathering. A small but increasing group of thermal imagers enables noncontact temperature measurement and these cameras are used in areas of industry, science and medicine.

The simplest scanning linear array used in thermal imaging systems, the so-called focal plane array (FPA), consists of a row of detectors (figure B8.14(*a*)). An image is generated by scanning the scene across the strip using, as a rule, a mechanical scanner. At standard video frame rates, at each pixel (detector) a short integration time has been applied and the total charge is accommodated. A staring array is a 2D array of detector pixels (figure B8.14(*b*)) scanned electronically.

The scanning system, which does not include multiplexing functions in the focal plane, belongs to the first-generation systems. A typical example of this kind of detector is a linear photoconductive array (PbS, PbSe, HgCdTe) in which an electrical contact for each element of a multielement array is brought off the cryogenically cooled focal plane to the outside, where one electronic channel is used at ambient

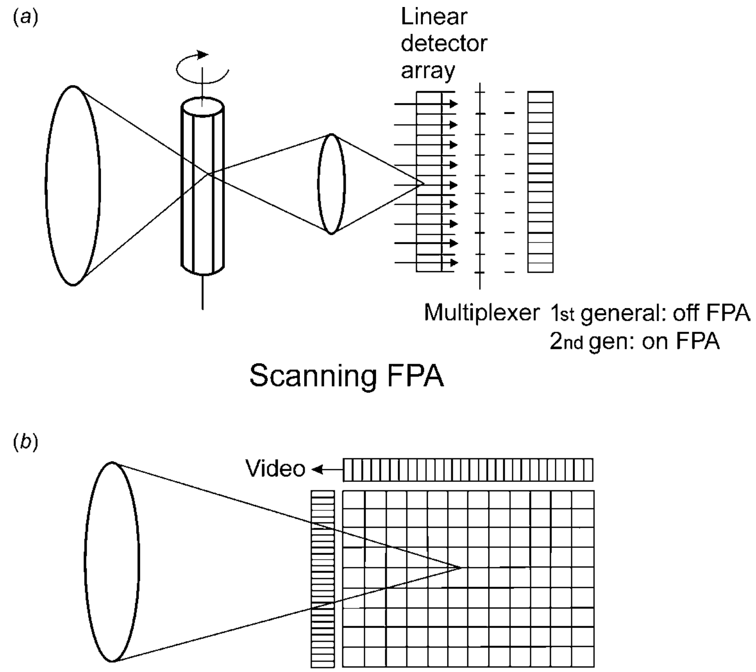

Figure B8.14. Scanning and staring focal plane arrays.

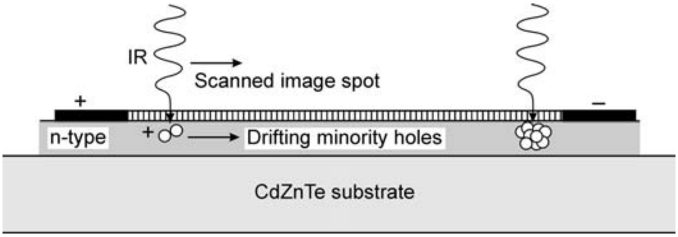

Figure B8.15. Cross-section of a SPRITE photoconductive detector.

temperature for each detector element. The US common module HgCdTe arrays employ 60, 120 or 180 photoconductive elements depending on the application.

A novel variation of the standard photoconductive device, the SPRITE detector, was invented in England [17]. A family of thermal imaging systems has utilized this device; however, now decline in its usage is observed. The SPRITE detector provides signal averaging of a scanned image spot which is accomplished by synchronization between the drift velocity of minority carriers along the length of a photoconductive bar of material and the scan velocity of the imaging system (see figure B8.15). Then the image signal builds up a bundle of minority charge which is collected at the end of the photoconductive bar, effectively integrating the signal for a significant length of time and thereby improving the signal-to-noise ratio.

The second-generation systems (full-framing systems), being developed at present, have at least three orders of magnitude more elements ($>10^6$) on the focal plane than first-generation systems and the detector elements are configured in a 2D array. These staring arrays are scanned electronically by circuits integrated with the arrays. These readout integrated circuits (ROICs) include, e.g. pixel deselecting, antiblooming on each pixel, subframe imaging, output preamplifiers and some other functions. The optics merely focuses the IR image onto the matrix of sensitive elements.

Intermediary systems are also fabricated with multiplexed scanned photodetector linear arrays in use and with, as a rule, time delay and integration (TDI) functions. Typical examples of these systems are HgCdTe multilinear 288×4 arrays fabricated by Sofradir, both for 3–5 and 8–10.5 μm bands with signal processing in the focal plane (photocurrent integration, skimming, partitioning, TDI function, output preamplification and some others).

A number of architectures are used in development of IR FPAs [18]. In general, they may be classified as hybrid and monolithic ones, but these distinctions are often not as important as proponents and critics state them to be. The central design questions involve performance advantages versus ultimate producibility. Each application may favour a different approach depending on the technical requirements, projected costs and schedule.

In the monolithic approach (see figure B8.16), some of the multiplexing is done in the detector material itself rather than in an external readout circuit. The basic element of a monolithic array is a metal–insulator–semiconductor (MIS) structure. An MIS capacitor detects and integrates the IR-generated photocurrent. Although efforts have been made to develop monolithic FPAs using narrow-gap semiconductors, silicon-based FPA technology with Schottky-barrier detectors is the only technology matured to a level of practical use.

Hybrid FPA detectors and multiplexers are fabricated on different substrates and mated with each other by flip-chip bonding (figure B8.17) or loophole interconnection. In this case, we can optimize the detector material and multiplexer independently. Other advantages of the hybrid FPAs are near 100% fill factor and increased signal-processing area on the multiplexer chip. In the flip-chip bonding, the detector array is typically connected by pressure contacts via indium bumps to the silicon multiplex

pads. The detector array can be illuminated from either the frontside or backside (with photons passing through the transparent detector array substrate). In general, the latter approach is most advantageous. When using opaque materials, substrates must be thinned to 10–20 μm in order to obtain sufficient quantum efficiencies and reduce the crosstalk.

Two types of silicon addressing circuit have been developed: CCDs and complementary metal–oxide–semiconductor (CMOS) switches. In CCD addressing circuits, the photogenerated carriers are first integrated in the well formed by a photogate and subsequently transferred to slow (vertical) and fast (horizontal) CCD shift registers [19].

An attractive alternative to the CCD readout is coordinative addressing with CMOS switches. The advantages of CMOS are the existing foundries. Design rules of 0.25 μm are in production with pre-production runs of the 0.13 μm design rules. At present, CMOS with a minimum feature ≤ 0.5 μm is also enabling monolithic visible CMOS imagers.

The minimum resolvable temperature difference (MRTD) is currently considered as the most important parameter of thermal imaging systems (see reference [20]). MRTD enables us to estimate the probability of detection, recognition and identification of military targets knowing the MRTD of

the evaluated thermal imager. Military standards determining testing of the thermal imaging systems usually specify that MRTD values for a set of spatial frequencies of the tested imager must be lower than certain values if the imager is to pass the test.

The MRTD is a subjective parameter that describes ability of the imager–human system for detection of low-contrast details of the tested object. It is measured as a minimum temperature difference between the bars of the standard four-bar target and the background required to resolve the thermal image of the bars by an observer versus spatial frequency of the target (see figure B8.18). The measurement results of typical military thermal imagers for airborne surveillance are shown in figure B8.19.

IR cameras versus FLIR systems

Historically, a 'camera' includes neither the storage medium nor the display, while the 'camera system' includes the complete package. At present, the manufacturers offer an optional recording medium (usually CD-ROM), display, and electronics for the display. For example, figure B8.20 is a photograph of the Inframetrics microbolometer IR camera ThermaCam 395.

'FLIR' is archaic 1960s jargon for forward-looking IR to distinguish these systems from IR line scanners, which look down rather than forward. Conversely, most sensors that do look forward are not considered to be FLIRs (e.g. cameras and astronomical instruments). The term

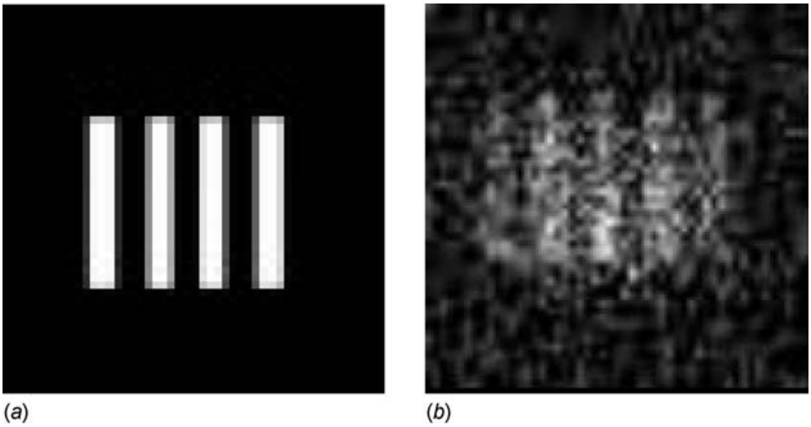

Figure B8.18. Image of standard four-bar target used during MRTD measurement: (*a*) high temperature difference between target and background and (*b*) low temperature difference between target and background.

'FLIR' should be eliminated from IR techno-speak, but is still used and is likely to remain in the jargon for a while.

It is difficult to explain the difference between camera and an FLIR system. In general, FLIRs are designed for specific applications and specific platforms, their optics is integrated into the package, and they are used mostly by people. Cameras usually rely on 'imaging' of a 'target' and they are designed for generic purposes, without much consideration for form and fit; they can be used with many different fore optics and are often used by computers and machines (not just people).

The term 'FLIR' usually implies military or paramilitary use, air-based units and scanners. The FLIR provides automatic search, acquisition, tracking, precision navigation and weapon delivery functions. A typical FLIR is comprised of four line replaceable units, such as an FLIR

optical assembly mounted on a gyro-stabilized platform, an electronics module containing all necessary electronics circuits and a cryogenically cooled detector array, a power supply unit, and a control and processing assembly.

Figure B8.19 shows representative camera architecture with three distinct hardware pieces: a camera head (which contains optics, including collecting, imaging, zoom, focusing and spectral filtering assemblies), an electronics/control processing box and the display. Electronics and motors to control and drive moving parts must be included. The control electronics usually consist of communication circuits, bias generators and clocks. Usually the camera's sensor (FPA) needs cooling and therefore some form of cooler is included, along with its closed-loop cooling control electronics. The signal from the FPA is of low voltage and amperage and requires analogue preprocessing (including amplification, control and correction), which is located physically near the FPA and included in the camera head. Often, the A/D is also included here. For user convenience, the camera head often contains the minimum hardware needed to keep volume, weight and power to a minimum.

Typical costs of cryogenically cooled imagers around \$50 000 restrict their installation to critical military applications allowing conducting of operations in complete darkness. Moving from cooled to uncooled operation (e.g. using silicon microbolometer or BST pyroelectric arrays) reduces the cost of an imager to below \$20 000. The cost of pyroelectric vidicons is usually a few thousand dollars; however, they have NEDT of 0.5°C (although some of them are now reported as low as 0.2°C) and typically poor image quality compared with full-frame staring arrays. They present a major departure from the camera architecture presented in figure B8.21.

Cameras usually produce high-quality imagers with NEDTs of 0.05–0.1°C. Details and resolution vary by optics and focal planes. A good camera produces an image akin to that of a black and white television.

In the 1960s the earliest FLIRs were linear scanners. In the 1970s first-generation common modules (including a Dewar containing 60, 120 or 180 discrete elements of photoconductive HgCdTe) were introduced. The next generation of FLIRs employed a dense linear array of photovoltaic HgCdTe,

usually 2(4) × 480 or 2(4) × 960 elements in TDI for each element. At present, these systems are replaced by full-framing FLIRs that employ a staring arrays (PtSi, HgCdTe, InSb and QWIP).

FLIRs are usually in several discrete packages referred to as line replaceable units (LRUs) such as: scanner head, power supply, image processor, recorder, display and controls. They have the form of boxes spread around the host platform. The controls and display must be mounted in the cockpit with the humans. A representative FLIR architecture with the video signal output (to support LRU for image and higher-order processing) is shown in figure B8.22. Many systems depart significantly from the architecture of figure B8.22.

FLIRs usually use telescopes in the sense that the lens system is focused at a distance very much larger than the focal length. Characteristics such as field of view (FOV), resolution, element size and

spatial frequency are expressed in angular units. By convention, FOV is expressed in degrees, resolution in milliradians, spatial frequency in cycles per milliradian and noise in units of temperatures.

Worldwide, there are over 100 different FLIR systems in operation. The most important of them are described in the literature [7, 21]. Several FLIRs integrate a laser ranger or target designator.

Figure B8.23 shows Falcon Eye, a representative conformal FLIR. This IR device receiver unit features a special gimbal set that allows the 5 in ball to rotate side to side and up and down. This head-steered FLIR adds an excellent degree of tactical flexibility and night situation awareness by allowing the pilot to look in any direction—including directly above the aircraft.

Recent outgrowths of military FLIRs are the infrared search and track (IRST) systems. They are a subset or class of passive systems whose objective is to reliably detect, locate and continuously track IR-emitting objects and targets in the presence of background radiation and other disturbances. They are used in a radar-like manner (usually with a radar-like display) to detect and track objects. Most of

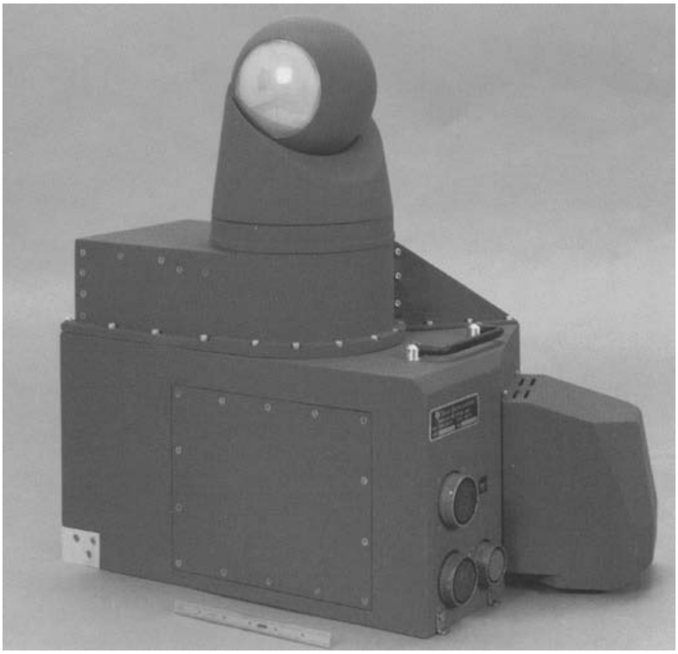

Figure B8.23. Falcon Eye, a representative conformal FLIR (photography courtesy of Texas Instruments).

the current research in IRST systems is concentrated in signal processing to extract target tracks from severe clutter.

Another group of outgrowths of military thermal imagers are airborne line scanners. These are one-dimensional scanning systems that enable creation of a two-dimensional thermal image of the observed scenery only when the system is moving. In contrast to typical thermal imagers with FOV not higher than about 40°, the airborne line scanners can provide FOV up to about 180°. Due to wide FOV airborne thermal scanners are widely used in military aerial reconnaissance.

B8.3.4 Space-based systems

The formation of NASA in 1958, and development of the early planetary exploration programme, was primarily responsible for the development of the modern optical remote sensing systems, as we know them today. During the 1960s optical mechanical scanner systems became available that made possible acquisition of image data outside the limited spectral region of the visible and NIR available with film. ‘Eye in The Sky’ was the first successfully flown long-wavelength sensor launched in 1967. A major milestone was the development of the Landsat Multispectral Scanner because it provided the first multispectral synoptic in digital form. The period followed the launch of Landsat-1 in 1972 stimulated the development of a new series of air- and spaceborne sensors. Since that time, hundreds of space-based sensors have been orbited.

The main advantages of space IR sensors are as follows [7]:

- the ability to tune the orbit to cover a ground swath in optimal spatial or temporal way;
- a lack of atmospheric effects on observation;

- global coverage;
- the ability to engage in legal clandestine operations.

Hitherto, anti-satellite weapons do not exist, so satellites are relatively safe from attack. The disadvantages of satellite systems are protracted and excessive costs of fabrication, launch and maintenance of satellites. Moreover, such operations as repair and upgrade are difficult, expensive and usually not possible.

The space-based systems installed on space platforms usually perform one of the following functions: military/intelligence gathering, astronomy, Earth environmental/resources sensing or weather monitoring. So these functions can be classified as forms of Earth remote sensing and astronomy.

Figure B8.24 shows representative space sensor architecture. It should be stressed, however, that many individual space sensors do not have this exact architecture.

Intelligence and military services from wealthy nations have long employed space-based sensors to acquire information. A satellite-borne IR warning receiver, designed to detect intercontinental ballistic missiles, is a strategic system that protect a large area, or nation. The US spends about $5 billion per year on space reconnaissance [7]. Although the cold war is over, the long-term strategic monitoring to access military and economic might is still important. Intelligence gathering of crop data and weather trends from space has also been used by hunger relief organizations to more effectively forecast droughts and famines. The military also has space-based surveillance for missile launches and additionally, space basing provides excellent viewing geometries for global events as nuclear explosions and environmental changes that the military is concerned about.

Imaging with IR FPAs provides increasingly detailed and quantitative information about relatively cool objects in the space of our galaxy and beyond. Dwarf stars, for example, or giant Jupiter-like planets in other distant solar systems, do not emit much visible and ultraviolet light, so they are extremely faint at these wavelengths. Also, the longer IR wavelengths can penetrate dusty and optically opaque nebulous molecular clouds in interstellar space where new stars and planetary systems are forming.

There are several unique reasons for conducting astronomy in space [7]:

- to eliminate the influence of absorption, emission and scattering of IR radiation;
- to answer basic cosmological and astronomical questions (e.g. formation of stars, protoplanetary discs, extra-solar planets, brown dwarfs, dust and interstellar media, protogalaxies, the cosmic distance scale and ultra-luminous galaxies);
- to observe the Earth's environment (detecting the subtle changes indicating environmental stresses and trends).

B8.4 Noncontact thermometers

Infrared thermometers always measure temperature indirectly in two stages:

- measurements of radiation power in one or more spectral bands;
- determination of an object temperature on the basis of the measured radiometric signals.

Even simple IR thermometers usually consist of five or more blocks (see figure B8.25). An optical objective is usually used to increase the amount of radiation emitted by the tested object and to limit thermometer FOV. The signal at the output of the detector is typically amplified, converted into a more convenient electronic form and finally digitized. A separate visualization block is typically used for presentation of the measurement results.

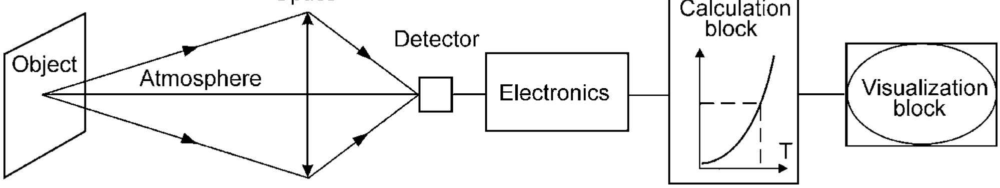

Figure B8.25. General diagram of a simple noncontact thermometer (after reference [22]).

The IR thermometers can be divided into a few groups according to different criteria: presence of an additional co-operating source, number of system spectral bands, number of measurement points, width of system spectral bands and transmission media.

In a passive system, the object temperature is measured knowing the radiation power emitted by the object in one or more spectral bands. With an active system we can get some information about the emissive properties of the tested object by using an additional co-operating source that emits radiation directed to the tested object and measuring the reflected radiation. They are active systems. Active thermometers are more sophisticated, more expensive and so far only in a few applications can they really offer better accuracy than passive systems. Therefore, nowadays, almost all practical noncontact thermometers are passive ones.

In the passive single-band systems, the object temperature is determined using a system calibration chart derived from radiometric calculation of the output signal as a function of blackbody temperature. The temperature of nonblackbody objects can be corrected if only their emissivity over the spectral band is known.

The ratio of the power emitted by a greybody at two different wavelengths does not depend on the object emissivity but only on the object temperature. In passive dual-band systems, the object temperature is usually determined using a calibration chart that represents a ratio of the emitted power in two bands as a function of the object temperature.

At present, at least 95% of systems available commercially on the market are passive single-band systems; passive dual-band systems are rather rarely used; passive multiband systems are still at a laboratory stage of development.

According to the number and location of measurement points, the infrared thermometers can be divided into pyrometers, line scanners and thermal cameras. Pyrometers enable temperature measurement of only a single point or rather of a single sector (usually a circle or a square) of the surface of the tested object. Line scanners enable temperature measurement of many points located along a line. Thermal cameras enable temperature measurement of thousands of points located within a rectangle, square or circle, and create a 2D image of temperature distribution on this area.

Most commercially available noncontact thermometers are pyrometers (see figure B8.26). They are small, light and low-cost systems that have found numerous applications in industry, science, etc. Line scanners are especially suitable for temperature measurement of moving objects and have found applications in the automotive industry, welding, robotics, etc. Thermal cameras offer the greatest capabilities of all discussed types of noncontact thermometer. In spite of their high price, they have found numerous applications such as control of electrical supply lines, heat supply lines, civil engineering, environmental protection, nondestructive testing and many others.

The fixed, inflexible configuration of a noncontact thermometer (like that presented in figure B8.26) is not a good solution in situations when direct sighting due to obstructions is impossible, significant interference is present and electronics must be placed at a safe distance, or very high temperatures exist. In such situations, it is better to use flexible fibre thermometers without the optics block.

B8.5 Radiometers

In general, the IR thermometers discussed in section B8.4 can be treated as a class of radiometers because they determine temperature on the basis of the signal generated by the radiant flux coming to the detector. However, the IR thermometers are designed to measure only temperature and it is usually not possible to use them to measure radiant flux. In our definition, a radiometer is an instrument designed to measure quantities of IR radiation, radiant properties of materials or IR detector parameters.

The IR radiometers can be divided into a few groups according to different criteria: measured quantity, number of spectral bands and number of measurement points. Radiometers enable

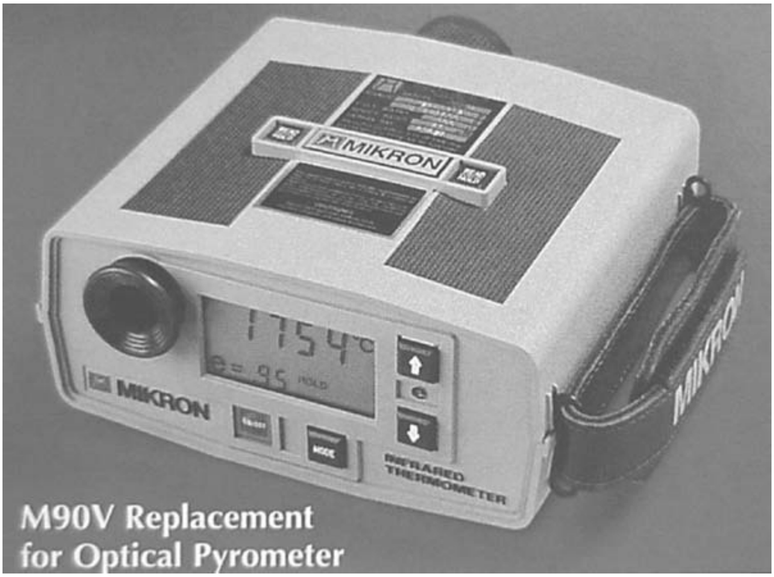

Figure B8.26. M90V pyrometer manufactured by Mikron Instrument Company, Inc. (photography courtesy of Mikron Inc.)

measurement of such quantities of IR radiation as radiant power, radiant energy, radiant intensity, radiance, irradiance, radiant exposure; radiant properties of materials (like emissivity, reflectance and transmittance); parameters of IR detectors (like responsivity and detectivity). However, all these features are possessed by only a small group of radiometers that are generally bulky, laboratory type and expensive systems. Their extreme versatility is usually achieved by a modular approach coupled with an extensive selection of accessories and powerful application software packages which enables the user to tailor a turn-key system to their exact requirements as well as insuring expandability in the future. On the other hand there are radiometers of design optimized for measurements of only a single quantity. Optical power meters are the prime example of radiometers from the latter group (see figure B8.27).

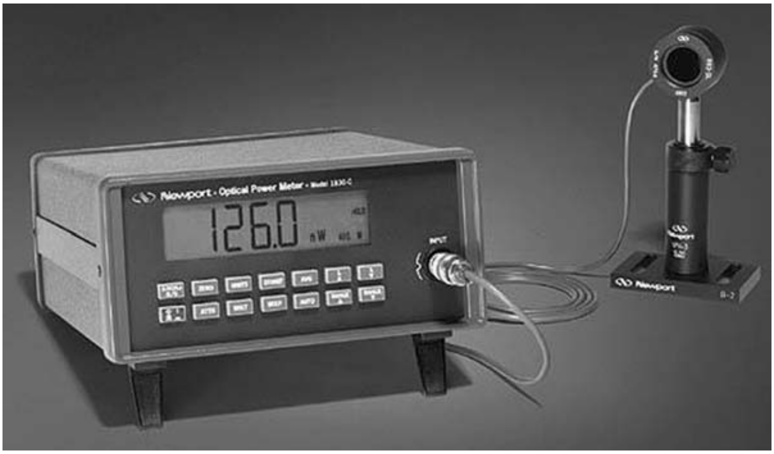

Figure B8.27. Optical power meter model 1830 (see www.newport.com) (with permission from Newport Inc.).

According to the criterion of number of spectral bands, the IR radiometers can be divided into the following groups: single-band radiometers, dual-band radiometers and multiband radiometers. Multiband radiometers enable measurements of one of the above-mentioned radiometric quantities in at least three separate spectral bands. When the spectral bands are narrow and their numbers are high enough, then the multiband radiometers are termed spectroradiometers. In contrast to the situation in noncontact thermometry where the single-band IR thermometers dominate on the market, the spectroradiometers have found a wide area of applications and are the most popular group of the radiometers.

The key component of any spectroradiometer is a module that can be termed the spectral band selector. Its task is to select the desired spectral band from the incoming radiation. This task is achieved by the use of three methods: variable filters, monochromators and Fourier transform (FT) interferometers.

The transmission wavelength of circular (linear) variable filters (VFs) changes continuously (discretely) with the position of the fraction of the filter. Simplicity of design is a great advantage of this type of spectroradiometer; it enables design of small-size, reliable, high-speed and mobile systems. However, using variable filters, it is not possible to achieve very good spectral resolution (typically about 2% of the wavelength). Next, because the system must measure output radiation selected by a variable filter of narrow spectral band and low transmission coefficient, it is necessary to use cooled IR detectors. Cooled sandwich InSb/HgCdTe enabling measurement in the spectral range 2.5–15 μm is a typical option for this type of spectroradiometer.

A monochromator is an optical instrument that uses a dispersing component (a grating or a prism) and transmits to the exit slit (optionally directly to the detector) only a selected fraction of the radiation incoming to the entrance slit. The centre wavelength of the transmitted spectral band can be changed within the instrument spectral region by rotation of the dispersing element. Dispersing prisms, or more often gratings, are used as the dispersing elements in monochromators.

The Michelson interferometer is the spectral band selector in FT spectroradiometers. The interferometer is usually built as an optical instrument consisting of a beam splitter and two flat mirrors arranged so as to recombine the two separated beams back on the same spot at the beamsplitter. One of the mirrors moves linearly in order to produce variable optical interference.

The Michelson interferometer can also be seen as a modulator. From a constant spectral radiation input, a temporal modulation occurs at the detector having a unique modulation frequency for each wavelength of radiation. The modulation frequency can be scaled via the velocity of the mirror movement. This modulated signal registered by the detector is called the interferogram. It is digitized at the rate of at least twice the maximum modulation frequency and a mathematical operation, the Fourier transform, is applied to retrieve the spectral distribution of the input radiation. A calibration with a known source is required in order to obtain quantitative radiometric results.

FT spectroradiometers are characterized by very good spectral resolution and very good sensitivity, better than offered by other types of spectroradiometer. Very good spectral resolution is the effect of use of the interferometer as a spectral selector. Very good sensitivity originates from the fact that the detector is irradiated not only by the radiation from a desired narrow spectral band but also by a full spectrum of radiation coming to the interferometer input. This feature enables design of high-speed, high-spectral-resolution FT spectroradiometers using noncooled or thermoelectrically cooled detectors (typically HgCdTe detectors) instead of bulky liquid-nitrogen-cooled detectors needed in the variable filter or dispersive spectroradiometers. However, the performance of the FT spectroradiometers can be severely reduced even by a very small nonalignment of the optical system which makes this type of spectroradiometer inherently sensitive to shocks and vibrations. Therefore, FT spectroradiometers were, for the last few decades, considered as rather laboratory type equipment that cannot be used in field applications. However, at present, this opinion is outdated as fully mobile FT spectroradiometers are on the market (see figure B8.28).

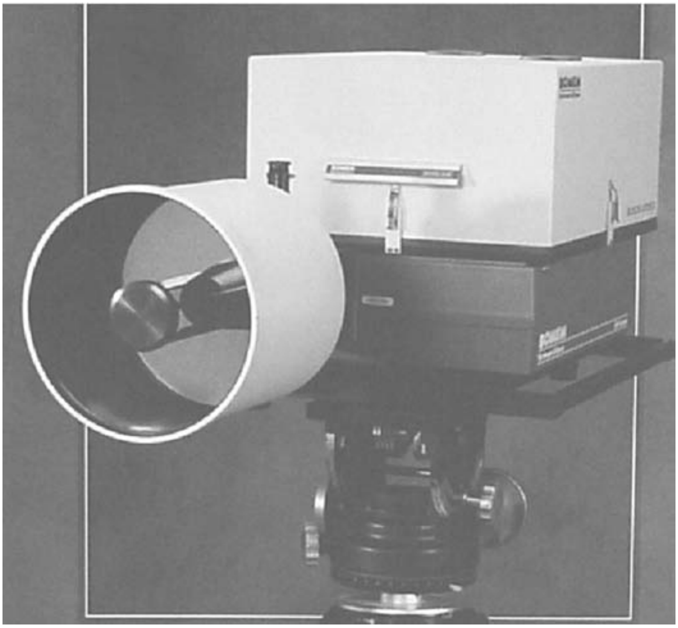

Figure B8.28. FT spectroradiometer (with permission from Bomem Inc.).

The great majority of commercially available spectroradiometers are systems enabling measurement of the spectral distribution of radiation emitted or reflected by a single spot and these systems can be termed the spot radiometers. There also exists another group termed the imaging spectroradiometers because these systems offer some imaging capabilities.

The optical system of any monochromator creates, at the output plane, a series of adjacent images of the input slit corresponding to wavelength. At one time only, one of these images fits to the exit slit and this radiation is measured by the detector located behind the stationary exit slit. Rotation of the dispersing element causes movement of these series images and the radiation from each of them can be measured. If we put an array detector at the output plane of the monochromator optical system, instead of the traditional configuration (an exit slit and a single detector behind), then this series of adjacent images of the input slit corresponding to wavelength will be focused on different parts of the array detector. Therefore, by use of an array detector, we could expect the possibility of simultaneous measurement of the radiation spectrum of different spots within the input slit. However, due to significant aberrations (curved output field, astigmatism) of the optical systems, this cannot be achieved in standard nonimaging spectroradiometers. The aberrations create a situation when only one image from the series—the image that fits the exit slit—is horizontally sharp. By use of a modified optical system with corrected curved output field and astigmatism, we can get sharp images of the input slit corresponding to wavelength focused on different parts of the array detector which enables simultaneous measurement of the spectrum.

The second class of imaging spectroradiometers is multiband (in the literature multispectral or hyperspectral) imaging systems generating simultaneously 2D images of the observed scenery in a number of spectral bands, where this number can vary from a few bands to over a hundred.

A high number of spectral bands being simultaneously recorded is typically achieved by use of a number of dichroic beam splitters, gratings, and linear detectors of different spectral sensitivity regions. The beam splitters separate the incoming parallel polychromatic beam into a few beams of separate

spectral bands, for example, see table B8.4. The grating separates the beams further and finally all these spectrally separated beams are focused by output optical objectives at different elements of the linear detectors.

The above-described system enables measurement of flux from a single spot in a number of spectral bands. However, because these systems employ a scanning system (typically the Kennedy-type reflective scanner) and are used in airborne applications, the imaging spectroradiometers generate a two-dimensional image of the land below the aircraft in different spectral bands (see figure B8.29).

B8.6 Light detection and ranging (LIDAR)

LIDAR is an acronym for light detection and ranging, a technique that uses laser light pulses to detect contaminations or aerosol in much the same way that sonar uses sound pulses, or radar uses radio waves. In radar, radio waves are transmitted into the atmosphere, which scatters some of the power back to the radar's receiver. A LIDAR also transmits and receives electromagnetic radiation, but at higher frequency. LIDARs operate in the ultraviolet, visible and IR region of the electromagnetic spectrum.

Different types of physical process in the atmosphere are related to different types of light scattering. Choosing different types of scattering process allows atmospheric composition, temperature and wind to be measured. The scattering is essentially caused by Rayleigh scattering on nitrogen and oxygen molecules, and Mie scattering on aerosols (dusts, water droplets, etc). At low attitudes, Mie scattering is predominant because of the higher cross-section and the high aerosol concentration.

In the LIDAR approach, a laser radiation is transmitted into the atmosphere and backscattered radiation is detected as a function of time by optical receiver. The return time of the reflected or scattered pulses provides range information. In a LIDAR arrangement, the backscattered light is collected by a telescope, usually placed coaxially with the laser emitter. The signal is then focused on a photodetector through a spectral filter, adapted to the laser wavelength. Different kinds of laser are used depending on the power and wavelength required. The lasers may be both cw or pulsed. LIDARs typically use extremely sensitive detectors, which convert the individual quanta of light first into electric currents and then into digital photocounts, which next can be stored and processed on a computer.

In general, a signal is produced by either direct absorption, fluorescence or Raman scattering. Absorption techniques are most straightforward and widely applied. In the atmosphere, for example, long-path absorption spectrometry is used in two wavelength bands—the infrared, where many molecules have characteristic fingerprints, and the ultraviolet (UV) to visible range.

In a typical case, the laser is alternatively tuned to a wavelength within the absorption band of interest (at λ_{on}) and then to a wavelength with negligible absorption (at λ_{off}), so that difference in the signal returned either from a surface or from air- or water-borne particles is recorded. By dividing the two LIDAR signals by each other, most troublesome and unknown parameters are eliminated and the gas concentration as a function of the range along the beam can be evaluated. Such applications require tunable lasers, either tunable diode lasers in the IR or Nd:YAG dye lasers in the UV to visible range.

The principle for different absorption LIDAR (DIAL) is schematically represented in figure B8.30. Let us now assume that wavelength couple (λ_{on}, λ_{off}) is sent simultaneously into the atmosphere. As λ_{on} and λ_{off} have been chosen close enough to exhibit the same scattering properties, the first chimney plume will cause an increase in the backscattering signal, because the concentration of aerosols is larger, but the same increase for both pulses. Conversely, the second chimney plume, which contains a certain quantity of the pollutant, will absorb the backscattered signal at the λ_{on}-wavelength much more strongly than at the λ_{off}-one. From this difference, and using the Beer–Lambert law, one can deduce the specific concentration of the pollutant under investigation versus range. For typical pollutants, such as sulfur dioxide, nitrous oxide, ozone and mercury, detection ranges for the part-per-billion detection level are between 0.5 and 5 km.

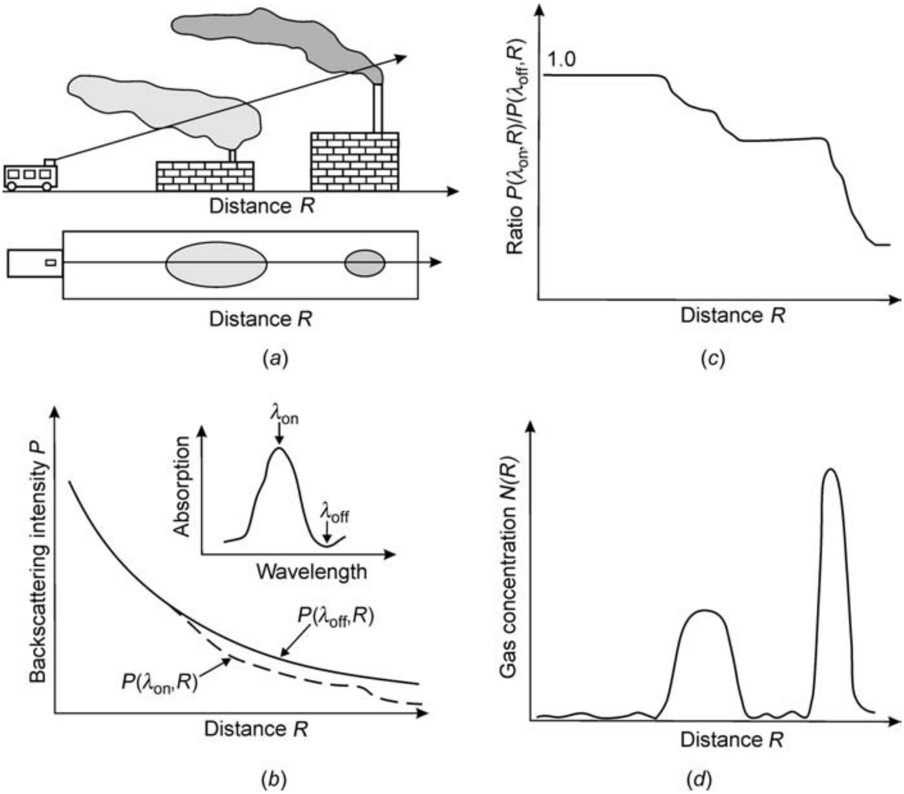

Figure B8.30. Illustration of the principle of different absorption LIDAR (DIAL): (*a*) pollution measurement situation, (*b*) back-scattered laser intensity for the on- and off-resonance wavelengths, (*c*) ratio (DIAL) curve and (*d*) evaluated gas concentration. Reproduced from [23].

The main alternative to direct-absorption spectrometry is Raman scattering. This occurs when photons are inelastically scattered from molecules, exciting them in the process and releasing some photon energy. Thus, Raman return signals are at a different, longer wavelength than the exciting wavelength. Raman cross-sections are much smaller than absorption cross-sections, so the Raman technique works well using high-power lasers only for higher concentrations (hundreds of parts per million) and distances of less than 1 km. Water vapour profiles can be obtained in vertical soundings up to several kilometres in height, and pressure profiles up to tens of kilometres are measurable using Raman signals from atmospheric N_2.

The other major technique, fluorescence spectrometry, has limited use in atmospheric measurement because the return signal is too weak. The technique is, however, an excellent way to monitor solid targets in the biosphere, such as oil, spills, algae bloom patches and forest area. The fluorescent signal from plants originates in the excitation of chlorophyll and other leaf pigments. Fluorescence LIDAR is also a powerful technique for measurements at mesospheric heights where the pressure is low and the fluorescence is not quenched by collisions. This technique has been used extensively to monitor layers of various alkali and alkaline earth atoms (Li, Na, K, Ca and Ca^+) at a height of about 100 km [23, 24].

In addition to monitoring pollutants, LIDAR is widely used to measure wind velocities via Doppler shifts. Recently, improved laser stability has expended LIDAR to more ambitious projects, including the study of winds in the stratosphere.

The main advantage of LIDAR is that it can map the location of chemicals over a wide region. Due to the rapid nature of laser pulses, the time resolution is critical (a few nanoseconds) to get good spatial resolution. Overall, DIAL systems can provide 2D or 3D information of air pollutants. However, most of the existing LIDAR systems have not met the pragmatic deployment requirements of users in industry or government. LIDAR systems are usually complex, large, expensive and require highly skilled personnel for their operation.

B8.7 IR gas sensors

IR gas detection is a well-developed measurement technology. In general, for toxic and combustible gas monitoring applications, IR instruments are among the most user friendly and require the least amount of maintenance.

There are a number of ways by which various IR components can be arranged to produce a gas analyser. The design may be relatively simple, or very complicated depending on the type of analyser for the applications. Figure B8.31 illustrates some of the basic features of an IR analyser.

The basic design is shown in figure B8.31(*a*), which consists of an IR source, bandpass filter and the interaction with the gas sample and detector. A detector is selectively sensitized to the absorption

wavelength of the gas whose presence is to be detected by the use of a narrow-bandpass optical filter. Clearly then, increased gas concentration in the optical path between source and filtered detector leads to a depression in signal level. The bandpass filter could be placed in front of the light source, instead of placing it in front of the detector.

In practice, in order to reduce false alarms and introduce a level of quantification, it is necessary to provide some calibration. Dependent on the application and instrument manufacturer, this may take the form of a reference chamber containing a known concentration of the gas, or measurement of a reference wavelength just slightly outside the absorption band and/or dual matched detectors.

Figure B8.31(*b*) shows another popular design with layout of two detectors. Modulated flashing IR sources are reflected back to the detectors. In this arrangement, the active detector has a filter for the target gas, while the reference detector has a filter with different wavelength. In such a way, the active detector is used to detect the target gas and the reference detector is used to ignore the target gas. In actual operation, the reference detector provides a base point value (or zero point) while the active detector is used to provide the signal. An advantage of this design is compensation of changes that occur in the detector's sensitivity with time (for example, change in the intensity of the light source).

The design illustrated in figure B8.31(*c*) uses two tubes or cells. One is a reference cell that is filled with a pure target or reference gas, while the other is a sampling cell in which the sample gas passes through. Additionally, a chopper in the form of disc with a number of slots in it is used. As the chopper rotates, it alternately allows the light beam to pass through the sample and reference cells. The detector gets it base reading from the reference cell.

There are many light sources available, ranging from a regular incandescent light bulb to specially designated heating filaments and electronically generated sources. The last sources are used to generate enough radiation at the wavelength of interest for the purpose of detecting the specific target gas. A heated wire filament, similar to that in a pen flashlight, is used in the 1–5 μm spectral range for the detection of most hydrocarbons, carbon dioxide and carbon monoxide. Alternatives include glowbars (rods of silicon carbide) or coils, typically of nichrome alloy resistance wire with high emissivity in the MWIR region.

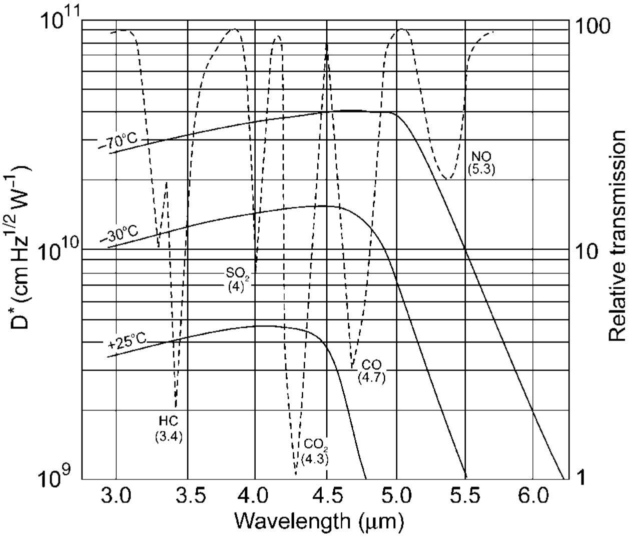

Figure B8.32. Detectivity of lead selenide detectors as a function of wavelength at operating temperatures of +25, −30 and −70°C, along with absorption spectra of some common air polluters.

Figure B8.32 shows the spectral response of lead selenide photoconductors superimposed over the absorption bands of the common air pollutants: HC, SO_2, CO, and NO. Such detectors are optimally matched to the 3–5 μm range. Beyond those wavelengths, the designer tends to be constrained to thermal detectors, the increased cost of the only suitable photon detector (HgCdTe) outweighing the performance benefits in most cases. Hence, the compromise is stated: lower performance over a very broad waveband or higher performance in a more limited one. For most specific applications, the more limited wavebands do contain sufficient structure and thus photon detectors are preferred. On the cost side, thermopiles are the cheapest option, and may be favoured when lower performance is acceptable. In most cases, however, the significant performance benefits of lead salt detectors more than compensate for their relatively small additional cost.

IR detection is applied to numerous applications. The most important are monitoring: in the transport industry (car and truck exhausts), petrochemical industry (gas leaks in refineries and oil rigs) and medicine (carbon dioxide exhalation and anaesthetic gases).

B9
Organic light emitting devices

Martin Grell

B9.1 Introduction and historic development

In many organic molecules, the absorption of a photon of given wavelength creates an excited state of the molecule (an ‘exciton’) which in turn is capable of re-emitting light of longer wavelength. This is known as fluorescence. The common feature of fluorescent dyes is the presence of alternating single- and double-bonds between carbon atoms (‘conjugated’ units), resulting in delocalized π-electron clouds. A wide range of fluorescent organic dyes, spanning the entire visible and near-IR spectrum, is now available, e.g. for dye laser applications.

Also, the semiconducting properties of a number of organic materials have long been known, and were studied first in crystalline phthalocyanine [1]. Since the 1970s, the amorphous polymeric organic photoconductor poly(vinyl carbazole) (PVK) has been widely studied and is now commonly used for electrophotography (generally, in the form of a charge transfer complex with the electron acceptor 2,5,7-trinitrofluorenone (TNF)). PVK is conceptually a ‘hybrid’ between low-molecular weight and polymeric organic semiconductors. The major difference between a mainchain conjugated polymer such as a polyene or a poly(*para*-phenylene vinylene) (PPV), and a sidechain conjugated polymer such as PVK is that in the mainchain polymer, the π-conjugation extends over more than one repeat unit, leading to a conjugated unit called the ‘effectively conjugated segment’ (ECS) longer than one repeat unit, and with rather different properties.

The capability of semiconducting organic materials to sustain and transport charge carriers (known as electron/hole polarons, or radical anions/cations) opens the possibility to generate excitons by the combination of an electron and a hole polaron rather than the absorption of a photon. The subsequent light emission from an electrically generated exciton is known as electroluminescence (EL). For semiconducting organic crystals, this was first reported by Pope, and Helfrich and Schneider, in the 1960s [2]. In 1983, Partridge reported for the first time on EL from a semiconducting polymer [3]; namely, PVK. Partridge used the common thin film device architecture as shown in figure B9.1. However, OLEDs based on PVK displayed poor brightness and efficiency. This was mainly due to the difficulty to inject electrons into PVK. Ideally, equal number of holes and electrons need to be injected for efficient EL. In 1987, a major breakthrough was reported by Tang and van Slyke of the Kodak group [4]. They introduced OLEDs with a multilayer organic semiconductor architecture. This allowed for better electron/hole balance and lead to devices with much improved brightness and efficiency.

Tang and van Slyke worked with highly fluorescent low-molecular weight organic molecules, and Partridge with a sidechain conjugated polymer. The mainchain conjugated semiconducting polymers that were studied in the 1970s and 1980s such as polyacetylene and polydiacetylene are not fluorescent, because in these polyenes, strong electron–electron interactions break parity alternation between subsequent excited states.

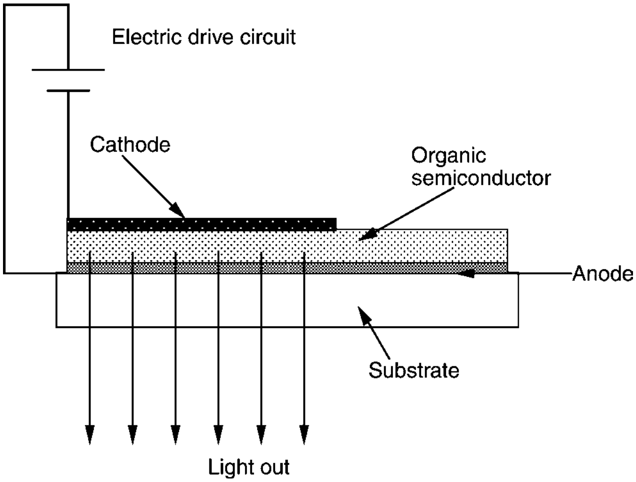

Figure B9.1. The basic OLED architecture. The thickness of the active organic semiconductor film is typically in the order of 100 nm. One of the electrodes (typically, the anode) needs to be transparent to allow for the coupling-out of light.

Thus, in polyenes, the first excited state has no dipole-allowed (fluorescent) transition to the groundstate. In the late 1980s, Friend, Burroughes, Bradley *et al* at Cambridge, experimented with poly(*para*-phenylene vinylene) (PPV), a conjugated polymer containing a phenyl ring in the mainchain. When they tried to establish the dielectric breakdown characteristics of PPV with a view towards its use as gate insulator in organic transistors, they were surprised to find electroluminescence (EL). They published their findings in 1990 [5]. With hindsight, it is surprising that EL from PPV was not discovered earlier, since PPV chemistry and its photoconducting and fluorescent properties had been established previously, much of it due to the work of Hörhold *et al* in Jena [6]. Similarly, another celebrated breakthrough in organic electronics, the discovery of 'synthetic metals' by Heeger, MacDiarmid, Shirakawa *et al* [7], was accidental due to the excessive addition of a catalyst.

The discovery of conjugated mainchain polymer EL has triggered a massive academic and industrial research effort, with the aim of developing and establishing a new flat panel display technology that in principle can replace both cathode ray tube and liquid crystal displays. In recent years, both the development of organic logic circuits based on organic field effect transistors (OFETs), and of organic photovoltaic devices has attracted increasing attention.

B9.2 Common OLED materials and their properties

B9.2.1 Common organic semiconductors

Before discussing OLEDs in detail, it is instructive to have a list of common organic semiconductors that have played an important role in the development of the field. Table B9.1 presents a compilation of a few examples that were selected from the wide variety reported in the literature. Commonly used acronyms are given and some basic properties of the materials are discussed.

(*a*) *Low-molecular weight materials*

TPD (*N*,*N*′-bis-(*m*-tolyl)-*N*,*N*′diphenyl-1,1-biphenyl-4,4′-diamine) is a hole transporting and weakly luminescent organic semiconductor. 6T (hexithiophene) is one representative of the thiophene family

of organic semiconductors which are known for their fast hole mobilities. PBD (2-(biphenyl-4-yl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole) is an electron conductor. Both TPD and PBD have been used as carrier injection layers in multilayer device architectures. Alq_3 (tris(8-quinolinolato)aluminum(III)) is an organometallic complex with efficient green electroluminescence and remarkable stability. $btp_2Ir(acac)$ (bis(2-(2′-benzothienyl)-pyridinato-*N*,C-3′)iridiumacetylacetonate) is the representative of a family of phosphorescent dyes that have been used successfully as triplet-harvesting emitters in efficient electrophosphorescent devices. ADS053 RE is the trade name for the red-emitting organolanthanide tris(dinapthoylmethane)mono(phenanthroline)-europium(III). Organolanthanides transfer both singlet- and triplet-excitons to an excited atomic state of the central lanthanide, resulting in very narrow emission lines, i.e. spectrally pure colours. NDSB Dendron (G2) is a nitrogen-cored distyryl benzene second-generation dendrimer. The core displays visible absorption and emission, the *meta*-linked dendronic sidegroups have a bandgap in the UV and for the purposes of charge injection, transport, and light emission can be considered as inert.

(*b*) *Polymeric materials*

PVK (poly(vinyl carbazole)) is a hole transporting and weakly emissive polymeric semiconductor that has been extensively used as photoconductor in photocopiers (in the form of a charge transfer complex with trinitrofluorenone). Conceptually, it is a hybrid between low-molecular weight organic semiconductors and conjugated polymers: The non-conjugated backbone gives it the film forming properties of a polymer, but the semiconducting units are isolated and retain the properties of low-molecular weight carbazole. PPV (poly(*para*-phenylene vinylene)) is a semiconducting, mainchain conjugated and highly emissive polymer. In the form shown in table B9.1, it is insoluble, and it is derived in situ via thermal conversion of a precursor. MEH–PPV (poly[2-methoxy-5-(2′-ethyl-hexyloxy)]-1,4-phenylene vinylene) is a soluble derivative of PPV with somewhat smaller bandgap due to the alkoxy substitution of the benzene ring. Both PPV and MEH–PPV are hole transporting polymers. CN–PPV (poly(2,5-hexyloxy *para*-phenylene) cyanovinylene) is an electron-transporting, low bandgap polymer due to the high electron affinity cyano substitution at the vinylene bond. PHT (poly(hexyl thiophene)) is weakly luminescent, but displays fast hole mobility, in particular, in its regioregular form. PPP (poly(*para*-phenylene)) is a blue emitter, but insoluble in the form shown in table B9.1. Substituting PPP with alkyl sidechains affects solubility, but also twists the rings away from coplanar arrangement. Methylated ladder-type PPP (MeLPPP) enforces coplanar ring arrangement by chemical bonds, and is a blue emitter showing homogeneous broadening only. Poly((9,9-dialkyl)2,7-fluorene)s (PFs) are efficient blue emitters with high carrier mobility. The related copolymer F8BT (poly(9,9-dioctylfluorene-*alt*-benzothiadiazole)) displays a lower bandgap (in the green) and electron transporting properties, as well as partial compatibility with PFs. Consequently, PF/F8BT blends have emerged as alternative to multilayer architectures. F8T2 (poly(9,9-dioctylfluorene-*alt*-dithiophene) is a hole-transporting fluorene copolymer with lower ionization potential than homo-PF.

B9.2.2 Comparing organic with inorganic semiconductors

The molecular nature of organic semiconductors leads to a number of significant physical differences between organic and inorganic semiconductors. The most important are summarized below.

(*a*) *Excitations are localized.* Wavefunction coherence in a conjugated polymer extends over a few (order 5) repeat units (the effectively conjugated segment (ECS) [6]), but not further. Consequently, excitations are localized on the rather short scale of the ECS. The wave vector k is not a good quantum number for a localized excitation. Charged excitations are generally more akin to the concept of the 'radical ion', as familiar from solution-based chemistry, than the concept of a 'polaron' in solid state physics (nevertheless, the term 'hole' is commonly used for radical cations). Neutral excitations or 'excitons' are best described as Frenkel, not Mott-Wannier, excitons.

Localization leads to a strong coupling between excitations and local molecular geometry. In the excited ECS, electron clouds and bond lengths are redistributed. In the case of charged excitations, these geometric relaxations can break the local symmetry, and thus activate vibronic bands in the infrared that are symmetry-forbidden (i.e. Raman- but not IR-active) in the ground state ('IRAVs'). In the case of neutral excitations (excitons), the fluorescence emitted on radiative decay to the ground state may display a relatively large Stokes shift and pronounced vibronic structure.

Typical exciton binding energies, E_b, are in the order 0.2–0.5 eV, and typical exchange energies, i.e. the energetic difference between singlet- and triplet-excitons, are 0.5–1 eV.

(*b*) *Excitations are one-dimensional.* Electronic transition moments are strong and highly directional, parallel to the chain or molecular axis. Some conjugated polymers display liquid crystalline self-organization at elevated temperatures, i.e. the spontaneous parallel alignment of an ensemble of chains [8]. Light polarized parallel to chain alignment then interacts very strongly with the polymer. Also, in aligned polymers, the mobility of charge carriers (radical ions) is enhanced when compared to the non-aligned polymer. Mobility is fastest parallel to the alignment direction, but even perpendicular to the alignment direction, the mobility is faster for an aligned than a non-aligned material [9, 10].

(*c*) *There are no 'dangling bonds'.* Even a very thin organic film always consists of complete molecules, with the chemical coordination at the film surface equal to that in the bulk. This is very different in vapour-deposited inorganic semiconductor films, where atoms at the surface usually are not chemically coordinated in the same way as in the bulk. These 'dangling bonds' distort the band structure at the film surface from its bulk properties. In contrast, surface- and bulk-ionization potentials, and electron affinities of organic semiconductors are generally equal.

B9.2.3 Controlling the bandgap

The relation between optical emission spectra and their perception as colours by human vision is essential for display technology. This shall not be discussed in detail here, a good review is in [11]. The basic facts are that colour perception changes in the order blue–green–yellow–orange–red as wavelength increases from 400 to >700 nm, and that colours are perceived pure when the emission band is narrow. It is therefore essential to control the bandgap of the emissive semiconductors in a display to reproduce the full colour gamut. It is one of the key assets of organic semiconductors that their bandgap can be controlled systematically via modification of their chemical structure. Chemical bandgap tuning can be classified roughly into three types: steric, electronic via sidechain variation and electronic via copolymerization. These are discussed in the following.

The steric control of bandgap

The degree of π-electron delocalization along a polymer backbone is governed by the conformation and configuration of the respective molecule. Conformation can be quantified, e.g. by a dihedral angle φ that describes the relative rotation of a stiff moiety with respect to a neighbouring stiff moiety around a flexible chemical bond connecting the two. The so-called rotational potential $E_{\text{rot}}(\varphi)$ describes the relative energy of the conformation as a function of dihedral angle. Generally, the π-overlap is optimized if successive units are coplanar ($\varphi = 0°$), but disappears if they are orthogonal ($\varphi = 90°$). Hence, in conjugated molecules, there is a contribution to the rotational potential that favours coplanar conformation. However, e.g. in coplanar biphenyl, there would be a clash between the H-atoms in the neighbouring rings for the coplanar arrangement that would be extremely costly in energy. The relative minimum for $E_{\text{rot}}(\varphi)$ is therefore not at $\varphi = 0°$; in the case of biphenyl, $\varphi_{\min} = 23°$ [12]. With the attachment of sidechains, these steric interactions increase, and the twist angle increases from 23° to 45° for *ortho*-dihexyl-substituted polyphenylene. This leads to a ‘blueshift’ (larger bandgap) due to reduced π-conjugation. A prominent example for steric bandgap tuning are the poly(alkyl thiophene)s (PATs), where bandgap tuning throughout the entire visible spectrum by steric effects alone was demonstrated. This is reviewed in [13]; however, PATs are rarely used in OLEDs as their PL quantum efficiencies are very low. Another prominent example for the control of bandgap by more or less bulky sidechains is the case of (non-emissive) poly(diacetylenes) (PDAs), as reviewed in [14].

A method to improve π-overlap, rather than disrupt it by sidechains, is to force rings into a coplanar arrangement by chemical bonds. Let us look at oligomers of *para*-phenylene (PPP), dioctyl fluorene (PFO), and ladder-type *para*-phenylene (MeLPPP), all of which have in common a backbone of *para*-linked benzene rings. In PPP, every ring can twist out-of-plane with respect to its neighbour. In PFO, rings are fused pairwise into a coplanar moiety, there is only one possible rotation per pair, i.e. per two rings. In MeLPPP, all rings are forced into a coplanar arrangement by chemical bonds, there is no degree of conformational freedom in the backbone. Table B9.2 shows the location of absorption maximum (as a measure of bandgap) in dependence of the number of benzene rings for different oligomers (unsubstituted oligo-*para*-phenylene/fluorene-endcapped dihexylfluorene/oligo-ladder-*para*-phenylene).

It is evident that for a given number of rings, the more the backbone is planarized, the smaller is the bandgap.

The electronic control of the bandgap

By introducing either electron-withdrawing or electron-donating chemical groups into a conjugated molecule, the electron affinity and ionization potential are affected, and hence the bondgap changes. Such groups can be introduced in two ways, namely as sidechains or in the mainchain. We discuss

Table B9.2. Absorption maxima for para-phenylene based oligomers versus number of benzene rings (data compiled from [15, 16]).

Number of benzene rings	Oligo-PP (eV)	Oligofluorene (eV)	Oligo-MeLPPP (eV)
3	4.44		3.70
4	4.25		
5	4.15		3.18
6	4.03	3.56	
7			3.00
8		3.43	
9			
10		3.35	

the following examples: Alkoxy-chains attached to PPV rings (MEH–PPV, sidechain modification), CN-groups attached to alkoxy-PPV vinylene bonds (CN–PPV, a case somewhat intermediate between sidechain and mainchain modification), and fluorene copolymers (mainchain modification).

MEH–PPV is an example for alkoxy-substituted PPVs. Its sidechains make MEH–PPV soluble in organic solvents such as THF or chloroform. Sidechains also somewhat isolate chain backbones from each other in the solid film which increases quantum yield over unsubstituted PPV. It was therefore a welcome step forward in the development of conjugated polymers. The alkoxy-linkage of its sidechains to the phenyl backbone ring also changes the electronic structure of the backbone. Alkoxy links have a tendency to donate electrons to the backbone which changes the shape and location of the HOMO. As a result, emission is redshifted compared to PPV, from green to orange.

The case of CN–PPV is somewhat intermediate between sidechain and mainchain modification. In addition to the alkoxy-sidechains in MEH–PPV, highly electron-withdrawing cyano groups are attached to the vinylene bonds. This leaves the conjugated backbone highly electron deficient, thus considerably increasing the electron affinity (by about 0.6 eV [13]). CN–PPVs emit in the red.

Another approach to bandgap control is copolymerization of different conjugated units into the polymer backbone. Copolymers between alkane- and alkoxy-substituted PPV-type polymers are discussed in [13]. Here, we focus on copolymers of fluorene. Polyfluorenes display a ‘blue’ bandgap that is almost indifferent to the type of sidechain attached. Note that sidechains are attached pairwise at the 9-position of the fluorene ring which itself is not part of the conjugated backbone. Consequently, there is little electronic impact of the sidechains on the backbone properties. However, strictly alternating copolymers of fluorenes with comonomers having different electronic properties were prepared, such as F8BT and F8T2. For both F8BT and F8T2, the resulting bandgap is reduced, and they both emit in the green–yellow region. The reduction in the size of bandgap has different reasons: In the case of F8BT, the benzothiadiazole comonomer has a higher electron affinity E_a than fluorene, thus leading to a polymer with higher E_a. In the case of F8T2, the two thiophene groups have a lower ionization potential I_p than fluorene, thus leading to a polymer with lower I_p. Thus, copolymerization not only allows control of bandgap, but also I_p and E_a in a predictable manner, and a large number of fluorene copolymers have been synthesized and studied. For a review, see [17]. Both the polymers have found interesting applications: some of the most efficient organic EL devices have been built from blends of a minority amount of F8BT as electron injecting/transporting material in PFO as hole injecting/transporting material. The miscibility (or at least, slow separation on the spincoating timescale) of PFO and F8BT is highly exceptional, and allows for the preparation of single layer devices with the properties of double layer devices. F8T2, on the other hand, is an excellent material for p-type OFET channels [9].

B9.3 Device preparation and characterization

Practical OLEDs conventionally use a film of indium tin oxide (ITO) on a glass substrate as anode. ITO is a highly doped semiconductor that exhibits almost metallic conductivity ($\sim 20\,\Omega/\square$), and is transparent to allow for the out-coupling of light. Onto the anode, one or several organic layers are prepared. Nowadays, ITO is usually coated with a PEDOT/PSS synthetic metal film, for reasons to be discussed in section B9.4.2. For a review of the remarkable properties of PEDOT/PSS, see [18]. Then, one or several organic semiconducting layers will be deposited; their functions are discussed in section B9.4.

Obviously, it is tempting to replace ITO completely by flexible sheets of PEDOT/PSS prepared on a plastic substrate which are now commercially available. For some small, low-resolution displays this is already possible. However, the most conductive PEDOT/PSS sheets to date still display a sheet resistance about one order of magnitude larger than ITO. This leads to a drop in the applied voltage across a large display and compromises the addressing of pixels far away from the voltage source.

The preparation of polymeric and low-molecular weight organic semiconductor layers is typically very different, and gives rise to two separate ‘cultures’ of organic semiconductor research. Polymers are typically processed from solution. Typical processes are spincasting, which is the conventional laboratory technique, or ink jet printing, which is of increasing interest for industrial production. Low-molecular weight molecules are typically processed by evaporation.

B9.3.1 Solution processing

A key asset of organic semiconducting polymers is that they can be molecularly engineered to be soluble. This allows for the preparation of good quality, uniform thin films over large areas by the spincoating (or spincasting) technique. Much of the interest and momentum in semiconducting polymer research results from this cheap and easy technique to make quality films of arbitrary size.

A typical spincasting solution has a concentration of 5–20 mg of polymer per millilitre of an organic solvent, such as toluene, xylene, tetrahydrofurane (THF), or chloroform. Before use, all solutions should be filtered through a microporous filter, with pore sizes in the range 0.2–0.45 μm.

The principle of a spincoater is shown in figure B9.2.

A drop of polymer solution is placed onto a substrate that is held down on a turntable by vacuum suction. As the turntable starts rotating, the solution spreads out into a thin film that wets the whole

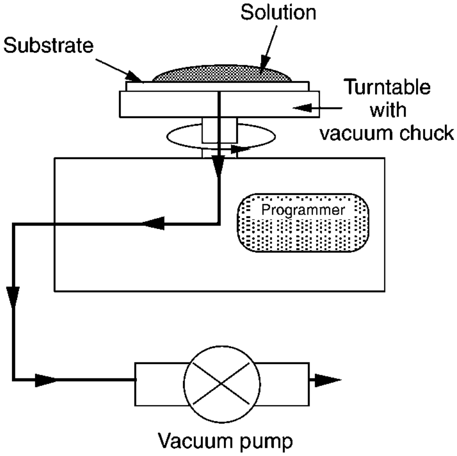

Figure B9.2. A spincoater.

substrate with uniform thickness. Typical 'spin speeds' are in the range 1000–4000 rpm, with spin times in the order of 1 min. Under rotation, the solvent evaporates and leaves behind a thin, uniform polymer film. In principle, there is no limit to the size of the film. In industry, films in the size of TV screens are spincoated routinely by automated systems. The thickness d of the resulting film is controlled by solution concentration c, viscosity η and spin speed ω according to equation (B9.1)

$$d \propto \frac{c\eta(c)}{\sqrt{\omega}}. \tag{B9.1}$$

The proportionality constant depends strongly on solvent, substrate, and other factors. Since η strongly depends on concentration, concentration has a much stronger impact on the thickness of the resulting film than spin speed. d typically will be in the order of 100 nm, with thickness control within a few nanometre via spin speed. Note that the thickness and quality of the resulting films depend on the solvent used. Sometimes, in particular when solvents of low volatility were used, it is advisable to dry films after spinning at moderatly elevated temperature (40–60°C) under vacuum.

Often, multilayer architectures of several layers with different organic semiconductors are required. To make these by spincasting, subsequent layers have to be spun from mutually exclusive solvents (so-called 'orthogonal' solvents), otherwise the first layer dissolves on spinning the second. This can be a challenge to material chemistry. The conjugated polymer community has recently started to use polymer blends deposited from a common solvent in one spin cycle, instead of multilayer architectures.

Drawbacks of the spincoating technique are the need for soluble materials, the sometimes limited options for deposition of multilayer devices, the waste of material that flies off the edge of the substrate on spinning, poor quality of films if the solvent evaporates very fast or does not wet the substrate well, and its limited use for low-molecular weight materials.

B9.3.2 Vapour deposition

For low-molecular weight materials, the method of choice for device fabrication is often vapour deposition instead of spincoating. The apparatus is shown in figure B9.3.

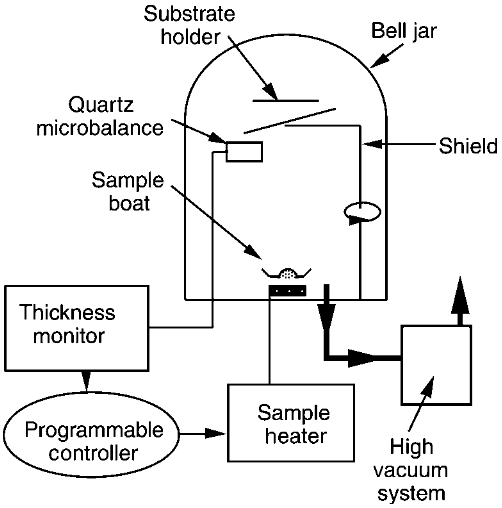

Figure B9.3. An evaporator system for the vapour deposition of small-molecule organic semiconductors, or metals.

In a vapour deposition chamber, high vacuum ($<10^{-6}$ bar) is required. This is usually established with a two-stage pumping system, comprising a rotary pump for a rough pre-vacuum, and an oil diffusion or turbopump for high vacuum. Material is placed into a metal 'boat' and is heated to evaporate and to condense on the substrate. This technique is applicable only to small molecules; polymers do not evaporate. A quartz microbalance is used to monitor the thickness and the deposition rate; this can be fed back via a controller to the sample heater to tune to a programmable deposition rate. Co-evaporation of different materials at the same time is an option, but to arrive at defined blend compositions, careful calibration of the heaters is required. Multilayer architectures, however, are easily made. Tang and van Slyke's first double-layer organic light emitting device was made by vapour deposition [4].

In some cases, exceptional control over the morphology of resulting films can be exercised by evaporation rate, and most importantly, type and temperature of the substrate. Higher temperature allows molecules to reorganize into more ordered structures immediately after deposition, but before a dense film is formed. The resulting films may have different crystal structures, and different orientation of the crystal axis with respect to the substrate; but these may be specific to certain substrates, which are not always useful for device fabrication. Control of morphology via evaporation conditions has been explored in much detail, e.g. for hexithiophenes [19].

Evaporators are also useful for the deposition of metal cathodes, which act as electrical contacts for devices, and can be applied to vapour deposited organic devices without breaking the vacuum. It is a drawback of the generally simpler and cheaper spincasting procedure that the subsequent evaporation of metal cathodes requires an additional high vacuum processing step. Recent polymer OLED research has therefore explored alternative metal deposition procedures that require no vacuum steps [20].

Device characterization

The electrical and optical properties of OLEDs are essential for their applications, and are characterized by a wide variety of methods. The most basic characterization of a conjugated material is by recording its absorption and photoluminescence (PL) spectra, and determining photoluminescence quantum yield (photons out per photons in). The relevant instrumentation and interpretation of such spectra has been discussed widely in the literature [21]. Instead, we discuss here the basic techniques specific to the use of such materials in OLEDs.

Electrical characterization

The current–voltage (C/V) characteristic of an OLED is determined simply by connecting the device electrodes to an electrical source-measure unit. Typically, voltage is ramped up continuously up to the order of 30 V or more, although for an OLED with low onset voltage, up to 10 V or less may be sufficient and higher voltages will lead to a damaging level of current. The typical range of current densities in an OLED under above voltage cycle will be 0.1 (or less) mA cm^{-2} at the light emission 'onset', up to the order of 100 mA cm^{-2} under the highest reasonable (i.e. non-destructive) drive voltages. Current sensitivity for a typical sample device, with typically a few square millimetre active area, should be at least 1 μA.

Often, while undergoing C/V characterization, the luminescent intensity emitted from an OLED is detected simultaneously by a photodiode. Luminescence/voltage characteristics is typically plotted into the same graph as current/voltage, resulting in current/voltage/luminescence ($C/V/L$) characteristics. However, the response of the photodiode is usually not calibrated, and luminescence results are presented in 'arbitrary units' (a.u.). Note that there is no physical current or luminescence 'onset' voltage for an OLED; practically, however, an 'onset' voltage is often reported. This only makes sense if a definition of 'onset' is given.

Quantifying 'brightness'

One of the most interesting properties of an OLED is how 'bright' it is, and how efficiently it converts electrical energy into light. The most straightforward quantity to characterize efficiency is the internal quantum efficiency η_{int}. η_{int} is the ratio of photons generated per two charge carriers injected (two because an exciton is formed from two carriers). To optimize η_{int}, we have to:

– *balance carrier injection.* An excess of one type of carriers means not all injected carriers can find a partner of opposite sign to form an exciton, and will exit the device at the opposite electrode as a 'blind' current. Unpaired carriers contribute to the number of carriers injected, but not the luminescence. Methods to optimize carrier balance are discussed in section B9.4.2.

– *emit as many as possible photons from each generated exciton.* Methods to maximize photon yield are discussed in section B9.5.

The 'external quantum efficiency' η_{ext} is defined as the number of photons coupled out from a device per two carriers injected. Remarkably, η_{ext} is often considerably smaller than η_{int}, often in the order $\eta_{\mathrm{ext}} \approx (1/8)\ \eta_{\mathrm{int}}$. Approaches to optimize η_{ext} are discussed in section B9.5.5.

Both internal and external quantum efficiencies are defined in terms of the fundamental electrical and photophysical properties of OLED operation. Their measurement, however, can be rather intricate. There is no direct approach to η_{int}. To measure η_{ext}, we have to count photons, e.g. in an 'integrating sphere' or with calibrated photometers.
